OFFICE OF EXPERIMENT STATIONS
A C TRUE, DIRECTOR

EXPERIMENT STATION RECORD

Volume XI, 1899-1900

WASHINGTON
GOVERNMENT PRINTING OFFICE
1900

U. S. DEPARTMENT OF AGRICULTURE.

Scientific Bureaus and Divisions.

Weather Bureau—Willis L. Moore, *Chief.*
Bureau of Animal Industry—D. E. Salmon, *Chief.*
Office of Plant Industry—B. T. Galloway, *Director.*
Affiliated Divisions:
Division of Vegetable Physiology and Pathology—A. F. Woods, *Chief.*
Division of Agrostology—F. Lamson-Scribner, *Agrostologist.*
Division of Pomology—G. B. Brackett, *Pomologist.*
Division of Statistics—J. Hyde, *Statistician.*
Division of Entomology—L. O. Howard, *Entomologist.*
Division of Chemistry—H. W. Wiley, *Chemist.*
Division of Botany—F. V. Coville, *Botanist.*
Division of Forestry—G. Pinchot, *Forester.*
Division of Biological Survey—C. Hart Merriam, *Chief.*
Division of Soils—M. Whitney, *Chief.*

Office of Experiment Stations—A. C. True, *Director.*

THE AGRICULTURAL EXPERIMENT STATIONS.

Alabama—*Auburn:* College Station; P. H. Mell.* *Uniontown:* Canebrake Station; H. Benton.†
Arizona—*Tucson:* R. H. Forbes.*
Arkansas—*Fayetteville:* R. L. Bennett.*
California—*Berkeley:* E. W. Hilgard.*
Colorado—*Fort Collins:* L. G. Carpenter.*
Connecticut—*New Haven:* State Station; E. H. Jenkins.* *Storrs:* Storrs Station; W. O. Atwater.*
Delaware—*Newark:* A. T. Neale.*
Florida—*Lake City:* W. F. Yocum.*
Georgia—*Experiment:* R. J. Redding.*
Idaho—*Moscow:* J. A. McLean.*
Illinois—*Urbana:* E. Davenport.*
Indiana—*Lafayette:* C. S. Plumb.*
Iowa—*Ames:* C. F. Curtiss.*
Kansas—*Manhattan:* J. T. Willard.*
Kentucky—*Lexington:* M. A. Scovell.*
Louisiana—*Audubon Park, New Orleans:* Sugar Station. *Baton Rouge:* State Station. *Calhoun:* North Louisiana Station. W. C. Stubbs.*
Maine—*Orono:* C. D. Woods.*
Maryland—*College Park:* H. J. Patterson.*
Massachusetts—*Amherst:* H. H. Goodell.*
Michigan—*Agricultural College:* C. D. Smith.*
Minnesota—*St. Anthony Park, St. Paul:* W. M. Liggett.*
Mississippi—*Agricultural College:* W. L. Hutchinson.*
Missouri—*Columbia:* H. J. Waters.*
Montana—*Bozeman:* S. Fortier.*
Nebraska—*Lincoln:* E. B. Andrews.*
Nevada—*Reno:* J. E. Stubbs.*
New Hampshire—*Durham:* C. S. Murkland.‡
New Jersey—*New Brunswick:* E. B. Voorhees.*
New Mexico—*Mesilla Park:* F. W. Sanders.*
New York—*Geneva:* State Station; W. H. Jordan.* *Ithaca:* Cornell University Station; I. P. Roberts.*
North Carolina—*Raleigh:* G. T. Winston.*
North Dakota—*Agricultural College:* J. H. Worst.*
Ohio—*Wooster:* C. E. Thorne.*
Oklahoma—*Stillwater:* J. Fields.*
Oregon—*Corvallis:* T. M. Gatch.*
Pennsylvania—*State College:* H. P. Armsb
Rhode Island—*Kingston:* A. A. Brigham.*
South Carolina—*Clemson College:* H. S. Hartz
South Dakota—*Brookings:* J. H. Shepard.*
Tennessee—*Knoxville:* ——— ———.
Texas—*College Station:* J. H. Connell.*
Utah—*Logan:* J. A. Widtsoe.*
Vermont—*Burlington:* J. L. Hills.*
Virginia—*Blacksburg:* J. M. McBryde.*
Washington—*Pullman:* E. A. Bryan.*
West Virginia—*Morgantown:* J. H. Stewart.*
Wisconsin—*Madison:* W. A. Henry.*
Wyoming—*Laramie:* E. E. Smiley.*

* Director. † Assistant director in charge. ‡ Acting director.

EXPERIMENT STATION RECORD.

Editor: E. W. ALLEN, PH. D., *Assistant Director.*

EDITORIAL DEPARTMENTS.

Chemistry, Dairy Farming, and Dairying—The EDITOR and H. W. LAWSON.
Meteorology, Fertilizers and Soils (including methods of analysis), and Agricultural Engineering—W. H. BEAL.
Botany and Diseases of Plants—WALTER H. EVANS, Ph. D.
Foods and Animal Production—C. F. LANGWORTHY, Ph. D.
Field Crops—J. I. SCHULTE.[1]
Entomology and Veterinary Science—E. V. WILCOX, Ph. D.
Horticulture—C. B. SMITH and V. A. CLARK.
With the cooperation of the scientific divisions of the Department and the Abstract Committee of the Association of Official Agricultural Chemists.

EDITORIAL NOTES.

Page.
Scientific aids, Department of Agriculture 1
Editorial management of the Record 2
The new Imperial Agricultural Department for the West Indies 101
The late Henry Lévêque de Vilmorin 201
Plant breeding and selection as a feature of experiment-station work 202
Veterinary work of the experiment stations 301
Two views of the functions of experiment stations 401
The development of the respiration calorimeter 501
Experiment-station exhibit for the Paris Exposition 601
Occurrence of leucocytes in normal milk 701
Causes of the changes in ripening cheese 702
Statistics of agricultural colleges and experiment stations for 1899 801
Comments on the work of the stations for 1899 803
Recent investigations on Texas fever 901
The services of President J. H. Smart and Prof. G. E. Morrow 1001

SPECIAL ARTICLES.

Selection and its effects on cultivated plants, Henry L. de Vilmorin 3
Convention of Association of Official Agricultural Chemists, 1899, E. W. Allen. 204
Thirteenth annual convention of the Association of American Agricultural Colleges and Experiment Stations, E. W. Allen 405
Artificial changes of physical properties of soils, Ewald Wollny 604
Adaptation of methods of cultivation and manuring to the physical properties of soils, Ewald Wollny 805

---

[1] Absent on leave.

LIST OF STATION PUBLICATIONS ABSTRACTED.

	Page.
ALABAMA CANEBRAKE STATION:	
Thirteenth Annual Report, 1898	240, 241, 251, 295
ALABAMA COLLEGE STATION:	
Bulletin 100, December, 1898	145, 154
101, January, 1899	139
102, February, 1899	139
103, March, 1899	292
104, April, 1889	232
105, August, 1899	921
106, November, 1899	1041
Index to Vol. VI, Bulletins 89–100, January–December, 1898	296
Eleventh Annual Report, 1898	697
ARIZONA STATION:	
Bulletin 30, January, 1899	236
Ninth Annual Report, 1898	213, 239, 240. 253, 295
Tenth Annual Report, 1899	812, 833, 842, 847, 850, 855, 858, 888, 897
ARKANSAS STATION:	
Bulletin 56, March, 1899	242
57, June, 1899	689
58, August, 1899	921, 923, 926, 927, 965
Eleventh Annual Report, 1898	295
CALIFORNIA STATION:	
Bulletin 122, January, 1899	64
123, January, 1899	46
124, May, 1899	534
125, May, 1899	636
Seed Bulletin, 1899–1900	1047
COLORADO STATION:	
Bulletin 50, December, 1898	245
51, March, 1899	337
52, April, 1899	378, 379
Eleventh Annual Report, 1898	314, 323, 339, 370, 394, 396
CONNECTICUT STATE STATION:	
Bulletin 128, April, 1899	279
129, May, 1899	270
Twenty-second Annual Report, 1898	705, 719, 722, 730, 742, 745, 748, 750, 754, 755, 757, 762, 769, 777, 799
CONNECTICUT STORRS STATION:	
Bulletin 19, February, 1899	189
Eleventh Annual Report, 1898	819, 835, 873, 877, 882, 886, 890, 897
DELAWARE STATION:	
Bulletin 43, 1899	141, 185, 189
44, March, 1899	141
45, October, 1899	815
Tenth Annual Report, 1898	421, 430, 434, 435, 468, 473, 485, 490, 493, 496
FLORIDA STATION:	
Bulletin 49, March, 1899	334, 376
50, May, 1899	739
GEORGIA STATION:	
Bulletin 41, October, 1898	30, 39
42, November, 1898	147, 167, 173
43, December, 1898	138
44, September, 1899	841

GEORGIA STATION—Continued. Page.

Bulletin 45, October, 1899 864
46, November, 1899 .... 1018, 1030
Eleventh Annual Report, 1898 396

IDAHO STATION:

Bulletin 16, 1899 173
17, 1899 351
18, 1899 340
19, 1899 .... 313, 327
20, 1899 1059

ILLINOIS STATION:

Bulletin 54, March, 1899 258
55, June, 1899 633
56, July, 1899 654
Circular 13, December, 1898 82
Eleventh Annual Report, 1898 396

INDIANA STATION:

Bulletin 75, January, 1899 236
76, March, 1899 277
77, March, 1899 .... 335, 340, 356
78. May, 1899 657
79, June, 1899 667
Circular 1, September, 1899 898
Eleventh Annual Report, 1898 396

IOWA STATION:

Bulletin 40, 1899 388
41, 1899 647
42, 1899 651
43, 1899 958

KANSAS STATION:

Bulletin 82, January, 1899 171
83, April, 1899 236
84, April, 1899 349
85, April, 1899 .... 333, 377
86, June, 1899 498
87, April, 1899 420
88, May, 1899 487
89, June, 1899 432
90, January, 1900 1037
Press Bulletin 25 182
Eleventh Annual Report, 1898 897

KENTUCKY STATION:

Bulletin 79, December, 1898 137
80, March, 1899 169
81, March, 1899 .... 260, 261
82, July, 1899 627
83, August, 1899 731
Tenth Annual Report, 1897 .... 314, 323, 396

LOUISIANA STATIONS:

Bulletin 53 (second series), 1898 28
54 (second series), 1898 .... 39, 67
55 (second series), 1899 230
56 (second series), 1899 588
Eleventh Annual Report, 1898 295

MAINE STATION: Page.

- Bulletin 49, February, 1899 ... 158
  - 50, March, 1899 ... 137
  - 51, April, 1899 ... 279
  - 52, May, 1899 ... 262
  - 53, September, 1899 ... 829
- Fourteenth Annual Report, 1898 ... 908, 909, 912, 913, 917, 928, 929, 931, 942, 956, 958, 959, 960, 964, 965, 969, 971, 974, 975, 983, 987, 998

MARYLAND STATION:

- Bulletin 59, January, 1899 ... 62
  - 60, March, 1899 ... 260

O

EXPERIMENT STATION RECORD.

VOL. XI. No. 1.

In accordance with the policy announced in the Report of the Secretary of Agriculture for 1898 graduate students will be given opportunities to avail themselves of the advantages for advanced study and research which are to be found in this Department and elsewhere in the national capital. An arrangement has recently been completed by which the Civil Service Commission will establish a register of "Scientific aids, Department of Agriculture." On this register will be enrolled graduates of the colleges which have received grants of land or money from the United States who may desire to enter the service of this Department at a salary not exceeding $40 a month. Besides furnishing a certificate of graduation the applicant is required to state what post-graduate courses, if any, he has pursued and in what special lines of science he has qualifications which would make his services useful to the Department. As a further evidence of his scientific ability he must submit a thesis on some subject of his own choice, or copies of original scientific articles published over his signature.

When openings for such candidates are presented by the work of any division of the Department, the Commission will be asked to certify the eligibles whose qualifications most closely conform to the requirements of the position to be filled. Once admitted to the Department the "scientific aid" will be expected to conform to the general regulations of the service, and to perform faithfully and regularly the duties assigned him by his superior officer. But he will be given opportunities to pursue some special line of study or research, and outside of office hours he will be able to take advantage of the many privileges which residence at the national capital affords, or in some instances he will be enabled to share in investigations which the Department is conducting outside of Washington. The term of service will depend very largely on the aptitude which the incumbent shows as an original scientific worker and the ability with which he discharges required duties, but in any case will be limited to two years. This limitation is made for the express purpose of putting the "scientific aids" on a temporary basis, with a view to encouraging their seeking outside positions suited to their attainments, or their fitting themselves to compete to advantage in the regular or special civil-service examinations which are held to supply eligibles for the permanent service of the Department. Such an arrangement is in a way comparable with that by which some colleges limit the term of service of their tutors or other junior instructors to two or three years, with a view to keeping them alert to fit themselves for higher posts in other institutions.

Under present conditions the number of scientific aids who can be admitted to the Department will be quite limited, so that only those who give evidence of superior qualifications for work along lines in which the Department is working may hope to be successful in their application for service. It is hoped, however, that when once the details of management of a corps of student assistants have been thoroughly adjusted by experience that the way may be opened for a larger force of this kind than can at present be maintained.

A large body of teachers and investigators are now being maintained throughout the Union at the expense of the nation and the States. To properly recruit the faculties of our State colleges, the staffs of our experiment stations and Government scientific departments, the graduates of our colleges need wider opportunities for graduate study. It is well that a part of their advanced study should be at the national capital and in connection with the scientific work which the National Government is carrying on. It is believed that it is a wise and economic plan to open the laboratories, libraries, and museums of the Government at Washington to the graduates of our colleges, and that the participation of an active and ambitious corps of the brightest and best of these graduates in the service of the Department will stimulate all the scientific workers in the service and promote the efficient pursuance of the practical ends for which all the scientific work of this Department is conducted.

It has been deemed proper to limit the register of "scientific aids" to the graduates of those institutions which are the beneficiaries of the national bounties, on the ground that this is simply carrying out the policy which Congress has established in making these colleges in a real sense national institutions.

With the present number active editorial management of the Record has been assigned to Dr. E. W. Allen, Assistant Director of this Office, and the duties of the Director will hereafter be confined to the more general supervision of this, as of other lines of work, in which the Office is engaged. This arrangement has come about through a gradual process of evolution and involves no change in the policy of the management of the Record. It is believed, however, that it will promote the greater thoroughness of our review of the literature of agricultural science, and, taken in connection with the recent strengthening of our editorial force, will enable us to make that review more complete and comprehensive than ever before.

SELECTION AND ITS EFFECTS ON CULTIVATED PLANTS.

HENRY L. DE VILMORIN.

The word *selection*, taken in its general sense, means *choice*. In natural history, when applied to plants or animals which man raises under domestication, it assumes a more restricted meaning and is applied only to the choice of individuals considered as agents of reproduction. It is in this sense alone that the word selection is used in this article.

The purpose of this paper is to indicate the reasons for making a certain choice, the results it may produce, the precautions that should accompany it, the practical methods of applying it, and the difficulties that may be met and may defeat the purposes in view.

Evidently the process is quite different from natural selection. The latter proceeds independently of man by the simple interplay of natural forces, while artificial selection is an act performed by man for the purpose of satisfying his needs and tastes. Nature modifies plants in *their* interest; man modifies them in *his;* but in the one case, as in the other, there is an acquirement of characters and a transmission of the characters acquired.

This article is not the proper place to discuss selection and its relation to evolution, of which the creation of varieties by selection is only one phase; nor is it the place to discuss the relative permanence of existing species. The task of the improver of cultivated plants is not to create new species but to establish and fix in known species well defined and constant races possessing distinct characters which may render them useful or agreeable to man.

The practice of selection is almost or quite as old as the practice of cultivation itself. It is certain that from the most remote beginnings of pastoral life primitive man has preferred the finest and best shaped animals for breeding purposes. In the same way when the culture of certain useful plants had succeeded to a more primitive form of pastoral agriculture or had become associated with it, the domesticated races of plants were gradually ameliorated by the diligence of some men who were more observant and interested than others; and the improved races were disseminated from place to place.

THE EFFECTS OF CULTIVATION ON PLANTS.

Much has been said of cultivation as a means of improving plants. The writer believes, however, that the selection of the individual intended to reproduce a sort has done infinitely more in this direction than cultivation, properly so called. Without doubt, the larger amounts of plant food, air, and room that are provided for the plant under careful cultivation, as compared with wild conditions, are the means by which some given plants attain to a greater individual development, but cultivation in general advances improvement principally because it gives to man an opportunity to observe the plant closely, to notice even the slightest variations in the characters of the different individuals, to note at the time of their occurrence all the variations which appear useful to him, and to fix them by sowing the seed from all the individuals that have shown these variations.

Superabundance of food supply undoubtedly favors the appearance in cultivated plants of variations which consist of multiplication of parts of a plant or the excessive development of certain parts among them, but heredity interferes to fix these characters, so that they are seen to persist in individuals escaped from cultivation and are perpetuated for a long time, even after the causes that brought them into existence have ceased to act.

SELECTION IN THE EARLIER AGES.

We possess few records bearing on the history of the improvement by selection of the various useful or ornamental plants in ancient times; yet the figures which have been left to us in paintings, mosaics, and sculptures indicate a notable improvement of the species cultivated by the Egyptians, the ancient Greeks, and the Romans, over the wild types of the same plants found in those regions at the present day. The leeks of Egypt, to the fame of which the sacred writings bear witness, are represented on the bas reliefs and paintings of Egyptian tombs as of a size far superior to that of the wild leeks of the mountains of central Asia, which, without doubt, represent the primitive type of the species. The Romans cultivated several varieties of *Brassica oleracea* that represented an immense advance over the wild type found on the coast regions of Europe. The flowers and fruits, figures of which are found frequently in Roman works of art, resemble more the varieties of the present day than the primitive types from which they were developed.

In passing it may be remarked, in reference to those fruits and flowers that are propagated by grafts and not by seeds, that selection is not entirely unconcerned in their culture, but even in such cases is found to exert its influence in several ways. A new variety generally originates from a seed which may have been accidentally planted, the resulting plant being reproduced and multiplied by grafting, or from seed planted by man, the various young plants being carefully observed from day to day and compared with each other, and meritorious novelties, if such appear, selected and propagated. In grafting, two things must be taken into consideration: In the first place, only those stocks should be used that are healthy, vigorous, as free as possible from defects and diseases, and well-provided with roots; and in the second place, the grafts should be taken from the youngest and healthiest shoots of the plant that is to be propagated and always from those that represent most faithfully the characters it is desired to reproduce. Sometimes variations are produced in plants by dimorphism, as by variation in the form or color of the foliage or in the shape or hue of the flowers, as often occurs in the chrysanthemum. There is then opportunity for the selection of the modified branch which is propagated by cuttings or any other method. The question of the permanence or running out of varieties of fruit trees, which is so often and so contradictorily discussed in the horticultural press of all countries, is intimately connected with this question of selection. There is no reason why a given type should run out if only proper stocks and healthy grafts are used in propagation, but the variety will certainly disappear if it is attacked by parasites to the extent that it is no longer possible to find a graft that does not carry with it its enemy.

To return to the history of selection of cultivated vegetables and flowers propagated by seeds. Italy, Provence, Flanders, and the neighborhood of Paris were, at about the beginning of modern times, the principal centers of the improvement of common plants. Seeds grown in these places bore a high reputation throughout Europe, and the popularity that they enjoyed shows that the characteristics developed in the various varieties of plants by these skillful and careful gardeners were well fixed, else they could not have reproduced themselves faithfully when cultivated under very different conditions of soil and climate. Vegetable gardeners have been for the most part the creators of European varieties of vegetables (and at the same time of many varieties of flowers, for the two occupations of vegetable gardener and florist were very often followed by the same individual as is frequently the case at the present day), and the uniformity, the constancy, and the cooking qualities of the varieties of vegetables originating in Naples, Milan, Lyons, Paris, and the Low Countries, bore witness to the skill, fine observation, and judgment in the application of selection which our predecessors possessed.

It is only since the latter half of the seventeenth century that the seed business has begun to be separated little by little from that of general gardening, and as division of labor always results in an improved product, the establishments that have devoted themselves exclusively to the growing of seed have come to do it better and more economically than the common gardeners whose time and effort were divided among various lines of production. In one respect, however, the competition of the market gardeners as well as that of the florists, properly so called, is still very useful to the careful seedsman in that it helps to keep him always in the front line of progress. To a less extent than the market gardener and florist the seedsman is brought in immediate contact with the consumer whose needs are the source of progress and new acquisitions. The former sometimes supply these needs, but often they turn to the seedsman and point out to him the prospect of increased profits as the reward for the creation of new and desirable varieties.

At the present day species that have been cultivated for many years have become, so to say, like wax in the hands of special growers, who mold them and fashion them to their taste, obtaining the various modifications of shape, size, flavor, etc., demanded by the preferences of their patrons and the caprices of fashion.

EXAMPLES OF SELECTION.

It would be difficult to select a more striking example of the variations that selection can develop and fix than the cultivated forms of *Brassica oleracea*. As already stated, this plant is a native of the coasts of western Europe, and is found on the shores of the Mediterranean, as well as on those of the Atlantic Ocean. The wild plant grows principally on the calcareous cliffs on the border of the sea. It is a semi-herbaceous, semi-ligneous vegetable, flowering from the second year onward, much branched and making each year both flowering branches and vegetative branches which are to flower the year following. The leaves are thick and fleshy, as are the flowering branches, while the stem and the crown of the root are also to a certain extent swollen and thickened. All of these characters will be found exaggerated greatly in the cultivated varieties of *B. oleracea*, but not all of them in any one race. Ordinarily one of the organs of the plant is selected with a view to obtaining one of the 20 or 30 forms of vegetables which, identical or nearly so with the others in their essential characteristics of flower and fruit, present most divergent forms as far as the organs of vegetation are concerned.

Cabbages, which form the most important group of cultivated *B. oleracea*, represent the plant reduced to its most simple form, that is, to a single erect stem bearing at its upper extremity numerous large, thickened leaves, more or less closely crowded together, which, according to their shape and the manner in which they are laid over each other, form heads that are oval (as in York Sugar Loaf), conical (Early Etampes, Pomeranian), spherical (Joanet, Holland Short Stem), or flattened (St. Denis, Brunswick). The same forms are found again in the Savoys, which differ from the ordinary cabbages in the form of development of the parenchyma between the little nerves of the leaves, giving the upper surface a blistered appearance: Oval (Long Headed Savoy), conical (St. Jean Savoy), spherical (Victoria Savoy), and flattened (Roblet Savoy).

Again, the same variety of forms is found among the red cabbages, where the entire leaf is colored a deep red: Conical (Red Conical), spherical (Red Dwarf Erfurt), flattened (Red Pologne).

All these forms without exception are the result of a patient and prolonged selection which has given to them almost complete permanence.

But these are not the only modifications of this plant, nor even of the leaves alone. There are the various headless cabbages or kale, which differ widely in respect to size, shape, and color. One of them, the collard (Rosette Colewort), has round, spoonshaped leaves, imbricated but not crowded together to such an extent as to deprive those in the middle of air and light and thus blanch them, as is the case with the inner leaves of the head cabbage. There are numerous varieties of kales with the leaves green or red, entire or laciniate, flat or curled; Portugal cabbage, cow cabbage, branched kales (*B. oleracea ramosa*), palm borecole, and many besides, among which Brussels sprouts is not the least strange. On a simple, straight stem are ranged petiolate, flattened, spoonshaped leaves. At the axil of each leaf is developed a little branch, the leaves of which fold over each other and are closely imbricated, forming a little hard head. Selection has solved the problem, apparently so difficult, of inducing the formation of heads on the branches of a stem without such formation at its top.

The stem of *B. oleracea*, as I have said, is in the wild type very large and capable of becoming thickened. Taking advantage of this tendency, selection has established a form the entire stem of which becomes large and fleshy and yields a product that can be used as a vegetable when it is young and tender, and is valuable as a food for cattle in winter when it has reached its full development.

If, instead of affecting the entire stem, the swelling is localized a little distance above the ground, the kohl-rabi is formed, the varieties of which are numerous, large or small, early or late, white or violet.

The capability of becoming thickened and fleshy is not limited to the stem. The tap root possesses it also, and plants which showed a marked tendency to vary in this way having been noticed and reproduced, have yielded, under the influence of long-continued selection, the turnip-rooted cabbage (*B. caulo-rapa*) and ruta-baga, the former of which has white flesh, the latter yellow. They are round, oblong, or flattened, and may weigh as much as 8 or 10 kg. Selection has produced these numerous forms from a root that weighs scarcely 1 or 2 ozs. in the wild state.

A still more remarkable modification was developed, as follows: The floral branch of *B. oleracea* is very thick and especially at the early period of its growth very tender and agreeable to the taste when cooked. Certain Italian gardeners noticed that the inflorescences of certain individuals had the sprouts larger and more thickened than others. Collecting the seed from these and selecting among the descendants of the second generation those plants which yielded the largest and shortest floral shoots, they have succeeded in creating the very characteristic modification known as the cauliflower. Here the pedicels of the flower have become very much thickened and flattened at the expense of the flowers themselves, which on the principal shoots have become atrophied and appear in small numbers only on the shoots of the third or fourth rank, which develop slowly on those heads which have not been cut at the time when they were good to eat. With the principal result once obtained, selection has produced varieties of cauliflower, early or late, of varying size, white, yellow, rose, or violet in color and of various degrees of hardiness.

Here, then, is a plant the different races of which have come down in culture under such different forms that an unusual keenness of insight or the aid of botanical science is necessary to explain that they truly belong to one wild type in which, in one case the leaves, in another the inflorescences, in still another the stem or the root, have been literally modified by the power of selection to such an extent that from infinitely slight variations at the beginning the differences between the various races have become greater than are often found in nature between different species of the same genus; and all of this has been accomplished by almost imperceptible steps under the influence of continued selection in a single direction.

Doubtless selection may be defined, but nothing can explain it so well as its results. For this reason I shall mention a few more examples taken from among the most common plants.

Take, for instance, celery. This is an aquatic perennial plant native in almost the entire basin of the Mediterranean, having its stem and petioles relatively large, tender, hollow, and of a pronounced aromatic odor. It was early observed in ditches and swamps, and introduced into cultivation. In the time of the Romans it was planted in gardens, more perhaps as an ornamental plant for use in domestic religious ceremonies than as a vegetable properly so called. When it came to be appreciated as a plant for the kitchen garden, it became an object of the gardener's attention. At first the size of the petioles was increased, then the plants with hollow petioles were eliminated as inferior to those in which the entire stalk was filled with tender, crisp flesh. Plants throwing up suckers were weeded out because growth force is always more economically utilized when it concenters about a single plant axis than when it is divided among several. The useful part of the celery being the stalk or petiole of the leaf, efforts were and are still directed toward the development of this organ by reducing others to the smallest size compatible with the good growth of the plant. The variety Pascal is very near to the present ideal of a green celery. The self-blanching celery was found in the neighborhood of Paris perhaps a dozen years ago by a very successful market gardener, Chemin. The original plant yielded seed from which was raised a good proportion of the new variety, but also some green plants. By persistent selection the proportion of green plants has been considerably reduced, but they have not yet entirely disappeared. By way of compensation this race has yielded a pretty variation with rose-colored ribs, which is becoming fixed. White Plume and Boston Market are two good American varieties. The latter throws up many suckers, which is considered a defect according to European standards. But attention has not always been concentrated upon the petioles of the celery. Connoisseurs have not failed to observe that the fleshy roots on which the leaves are inserted possessed an especial flavor and were sweeter, although not of as clear a color as the stalks. By selection certain plants have been obtained in which the root has been modified into a large, well-shaped, and very regular, rounded enlargement, as in the Erfurt and Prague turnip-rooted celeries.

It should be noted in comparing the various races of *B. oleracea* that but one organ is enlarged. If this organ is the root, the leaves and the petioles are proportionately diminished in size and serve only as auxiliary organs to the root. It is very difficult in general to develop two organs at the same time to any great degree in the same plant. In support of this assertion the beet may be mentioned, as the history of its cultural evolution presents many analogies to that of the celery. I shall devote only enough time to it to point out certain differences between these two vegetables. In the first place, in the case of the beet it is the kind of root developed that is of greatest importance. In this case the leaves are only the organs of assimilation and of transformation of the food absorbed. The form having the leaves, or rather the petioles and ribs of the leaves very much enlarged and the root small, branched, and fibrous, is known as the Swiss chard. Whenever there occurs an enlargement of the stalk or petioles properly so called, one may be certain that a decrease in the size of the root has already occurred or will occur immediately.

The deep red color of garden beets is of very great importance. But in sugar beets, the absence of color—that is, the perfect whiteness of the flesh of the root—is a condition of perfection. Selection has produced this very remarkable specialization. There is no necessary or absolute correlation between the color of the root and that of the foliage. In garden beets a thick, tender, sweet, and richly colored flesh is much desired. Now, a variety may have these qualities without its foliage showing, at least for the greater part of the growing period, any particularly deep coloration. In England it was the fashion to produce varieties of garden beets with large and deeply colored foliage (as in Dell's Dark Leaf beet). Some men of independence and good judgment have not hesitated to say that this is putting color to a bad use; that it is better to concentrate it in the root. As a matter of fact, the dark red Egyptian and Cheltenham Green beets and among the American varieties Edmand Early Turnip are living proofs that a variety may have finely colored roots and at the same time preserve in its leaves a noticeable proportion of green surface. A third class might be made of those having very deeply colored reddish brown foliage, which are used for decorative purposes only, as for instance, the Dracaena beet. But in agreement with the rule already laid down, this race has a small root of no culinary value.

I can not conclude this list of plants which have been modified by artificial selection in such divergent directions and which so plainly bear the impress of man's activity, without mentioning a few ornamental plants as well as garden vegetables.

Take for instance the amaranth. This is an annual plant from India of rapid growth with large alternate oval leaves and inconspicuous flowers in large bracteate clustered spikes. It has become, under the influence of selection, in one case a vegetable esteemed for its large and thickened leaves; in another case an ornamental, valued also for its leaves, which in this instance are variously colored and variegated; and in a third case it is valued for its inflorescence, which is so curiously modified that one would hardly recognize at first sight the original type in the strange variations that have been developed from it.

Let us consider only the extremes, the cockscomb and the feathered celosia. The former is a low-growing stocky plant with its flowering head enormously developed. An accidental fasciation of the stem has been fixed by selection and augmented to such an incredible degree that the size of the stem at its top must be measured by dissecting all the reduplications which form the part of the plant called the comb. This colored velvety mass, so ornamental in its bizarre effects, is the simple modification of an ordinary straight cylindrical stem into the comb.

From the same original type has been produced another entirely different plant. This is the feathered celosia, which is as graceful and light as the other is massive and stocky. Whereas all the stems were united into one in the cockscomb, they are here distinct, erect, and divided into ascending branches, each one of which ends in a plume having a varying number of filaments furnished with bright colored, silky bracts, and vary from golden yellow, through flame color and crimson to deep violet. In spite of such great differences in appearance between the two plants, it is not possible to observe the botanical characters and fail to recognize that both are modifications of the same original species.

From the same root are produced still other formations in which the ornamental part is not the inflorescence but the leaf, which is zoned or flagellated or bordered, sometimes with brown on a green ground work, or sometimes with bright red on yellow or brown or even simply on a brighter shade of red. All these pretty variations are the result of selection acting on the various forms found in nature or on modifications induced and patiently accentuated by man.

If it were not for the danger of making the list too long, many other examples of profound modifications brought about by the action of selection on the natural characters of wild plants could be mentioned. A single example that has been produced entirely within recent times will be instanced. The canna was introduced into garden culture about 1820 as a foliage plant; seeds were sown to obtain variations of form and color of foliage, and the success of M. Année in this respect is well known. More recently M. Crozy, of Lyons, and other growers have directed their efforts to increasing the size of the flower, as a result of which we have the large flowered varieties that to-day rival the gladiolus for garden decoration in summer. At the same time the color of the flowers has increased in brilliancy. It may be said indeed that hybridization has not been entirely unconcerned in this increase of size, but it is none the less selection that has taken advantage of the tendency thus introduced into the plant as a result of crossing, and that produces for us each year better varieties, the series of which is still far from being exhausted.

APPLICATION OF SELECTION.

If plants did not vary there could be no selection. The object of selection is to establish, fix, and sometimes to develop in plants certain qualities or new peculiarities which a plant has shown and some one has noticed.

It is not difficult to select plants. Anyone can do it, but it is not so easy to do it profitably. In order to succeed, one must be not only patient, attentive to the work in hand, but must also exercise judgment and common sense.

Every modification that a plant shows is not necessarily worth fixing. Experience alone can tell whether it is worth perpetuating. The Chinese primrose is one of those plants that within a short space of time, that is, within fifty or sixty years, has produced a very great number of good varieties under the influence of selection. It seems that any new character that appears in these plants is easily established. Several times I have found in cultivation, both at Paris and in the Riviera, certain bordered flowers, that is, flowers having a lighter colored border around a deeper colored disk, but all of my efforts to fix this pretty variation have thus far been in vain.

When a variation in a cultivated form is noticed, one should ask himself first whether it is worth fixing; for it is very evident that it would be time and labor lost if anyone should devote himself to the fixation of a character having neither interest nor usefulness. Several years ago a gardener brought to the writer a plant of a new celery that he had happened to find in a seed plat. He had transplanted it, saved the seeds from it, and sowed them, with the result that the type was reproduced very faithfully. It was a celery in which the pedicel or leaf stalk was shortened almost to the point of disappearance. The many crowded leaves spread over the ground in a compact rosette, but the plant had practically lost the very part that made it useful as a vegetable, that is, the stalks. I told him so and did not conceal from him the fact that his novelty appeared to me to mark a step backward and not forward, somewhat as if one had discovered a potato without tubers. I could not convince him that his novelty was not a fine thing, and I believe he actually found a house that introduced it into trade among their novelties. If horticultural novelties were a rarity, one could realize that anything new would be received with eagerness, but, as a matter of fact, novelties superabound, and one is tempted to say that the greatest virtue of a plant breeder is to be severe toward his own creations and not easily to become enthusiastic over their real or supposed merits. Hence, good judgment and experience are necessary in order to decide, when a variation appears, whether it is worth propagating or not with a view to establishing a new variety in the course of time.

If, as is most often the case, there is but one plant that shows the modification, the only thing to do is to collect the seeds from it to be planted again. But even here there are certain precautions to be taken. If the plant is one of those in which cross fertilization takes place easily, it is advisable to remove the possibility of pollination by plants of the same kind which might be in the vicinity. There are two ways of doing this: One is to destroy all plants of the same kind except the one to be propagated. The other is to cover the flowers of this plant so that they are protected from the pollen of other plants. It is advisable, if the flowers have already begun to open when the variation is noticed, to destroy all those that might have been fertilized by the pollen of any other plant, as this would introduce an unknown parentage into the race.

For the sake of simplicity I shall first consider the commonest case, that of a plant capable of self-fertilization, or one in which the different flowers of the same plant can fertilize each other, and do not require the aid of another plant of the same species. Seeds will then be collected only from those flowers which open after the plant has been covered. Suppose now that we have before us the seeds gathered from a plant that has shown the variation which we wish to propagate. The first thing to do is to sow these seeds in order to obtain a considerable number of young plants. The chances of finding something satisfactory among them naturally increases with the number of individuals among which we can choose. In this connection two important points are to be observed: (1) The inequality which is found in different cases in the proportion of plants conforming to the desired type in the first generation after the beginning of the selection. Sometimes, as has already been said, a single one is not obtained. Certainly this result is not encouraging; nevertheless this is not always an unqualified reason for abandoning the task to which one has set himself. Occasionally it happens that by gathering the seed from the plants of the second generation, the characteristics of the plant originally selected may reappear in the following generation.

Sometimes, on the contrary, the observed variation may reproduce itself completely and entirely in the first generation. This case is rare, but nevertheless it does occur. One day I noticed in a lot of double violet clarkias a plant with pure white double flowers. When gathered and sown by themselves, the seeds of this plant yielded only pure white flowers which have never varied. The race was established in a single generation. Generally, however, the result is intermediate—that is, certain individuals show the desired characters, while others revert to the earlier form. We shall consider in due season the proper method of procedure in a case like this. Meanwhile, I must take up the second point to which I have already referred, which is: (2) The necessity of sowing the seed under normal conditions. By these, I mean conditions which are not such as will influence artificially the characters of the plant produced by these seeds. In other words, structural or other peculiarities which the plants show should be the result of their natural tendencies and not the artificial result of cultivation. In a word, the plants under observation must have the opportunity to show their defects as well as good qualities. It goes without saying that a selection can not be useful and valuable unless so made. One must be in a position to decide that a plant behaves in a certain manner because it has an innate tendency to do so, and that it has not been constrained to a certain form artificially. An illustration will make my point better understood than many explanations. In selecting sugar beets those roots are sought for that are straight, long, and free from lateral branches This is right, for those that are branched are more difficult, and hence more expensive, to gather. Now, certain growers of beet seed in the north of France once formed the idea—thinking, no doubt, in this way to improve their varieties—of growing the plants which were to be used as seed stocks in very rich deeply worked soil, where they were very much crowded together; so much so that 16 to 20, or even more, grew on one square meter of ground. The result was that the beet assumed the form, and later the length of a thick whipstock. They were not branched because the roots were very closely crowded together. Their sugar content was abnormally high as a result of their growing so close together, and the conclusions drawn from the form of the roots and their sugar content, as determined in the laboratory, were tainted with error because they did not represent qualities truly acquired, but modifications accidentally imposed by external conditions. Thus these beets which were declared to be of good shape and composition in the laboratory yielded seed which, when sown in the open field, produced branched roots of only moderate sugar content, because the descendants had reassumed their true characters when they were released from the restraint which had been artificially imposed on the parent plants. Those beets, alone, may be considered unbranched that are free from roots when they are cultivated under conditions that would permit them to become branched if they had such a tendency. In order to obtain seed that will produce unbranched roots, the plants from which the selection is to be made must be grown under conditions as nearly as possible like those under which the same kind of plants are commonly grown that are intended for common domestic or industrial uses.

Let us return to a consideration of the successive operations of selection. Suppose that we have before us a lot of plants grown from seed of the plant which forms the point of departure in the establishment of a new variety. Of these plants some are *true to type*—that is, they reproduce faithfully the characters which we desire. Others have reverted to the older type and we destroy them. We also destroy those which correspond only imperfectly to the ideal which we have set before ourselves. Let us suppose that the tenth part of these plants are true to type and that we have twenty satisfactory plants before us. There are then open to us two methods of procedure. There is the method by individual selection of single plants and that of individual selection by group lots. The former is much the more exact, more simple, more direct, and less liable to error. But it has the disadvantage of being slow of operation, for at the end of three or four generations the grower still has only the seed produced by a single plant, and 2 or 3 years are still required to produce a large enough stock to introduce it into trade.

The method by group lots operates more rapidly and at the same time affords a considerable probability of establishing the variety. It consists in selecting not a single plant, but as large a number of perfectly satisfactory plants as can be found by individual examination of all the plants in the lot. These plants are grown together, the seeds are collected in one lot, and are planted the following year (if the plant is an annual) in order to obtain a larger number of plants, from which a larger number of individuals may be selected than in the preceding year, thus providing a good quantity of the seed of the improved race in a short time. The weak point in this method is that one does not know in what manner each individual plant has reproduced itself, so that in selecting a good plant one does not know that it was not derived from a parent that produced only 5 or 10 per cent of seed of the improved variety, the other nine-tenths reverting to the earlier type. This may happen and, of course, hinder the complete differentiation and establishment of the race.

There is a method that may be said to be intermediate between the two already described, which embraces, to a great extent, the advantages of both without their disadvantage. It is the method of seeding by single plants. This method requires somewhat more labor and attention. It is as follows: In the first generation from the original plant, instead of selecting only one individual as in the first method, several are chosen, all of them perfectly satisfactory in appearance, but instead of sowing them together and collecting the seed in a mixture, as in the second method, each is grown sufficiently far away from the others to avoid cross fertilization and the seed from each plant is collected separately. Each lot is again sown separately the next year and when the time comes to make a selection, the first step is to note to what extent each of the lots thus obtained has faithfully reproduced the characters of the plant from which it is sprung. (For the sake of clearness and convenience each plant selected receives a number or letter by which it is designated and its pedigree may be followed). A great difference is generally noticed in the behavior of the different plants in respect to the transmission of their characters. Those that do not reproduce the desired characters are entirely rejected. If any are found, as often happens, that reproduce entirely those of the parent plant, such plant or plants only are preserved, and their descendants may be used immediately for the multiplication of the new variety, which is thus established with a constancy that the best horticultural varieties do not always possess.

This process of seeding by individual plants is one of the most powerful means which the plant breeder possesses to establish with certainty and relative quickness new varieties of cultivated plants. About 20 years ago I applied this method to the improvement of sugar beets, a work that was begun by my father in 1850 and that I have made one of my principal lines of business for 25 years. In the laboratory of Verrières, as everywhere else at the present time, the roots of the sugar beet are submitted individually first to a physical selection as to size, form, color, etc., then to an examination by the polariscope for their sugar content. After this the most perfect roots are replanted and the seed from each one is collected and kept separate, but still before using this seed for the multiplication of the variety on a large scale, those plants must be determined which, beside their own characters, are endowed with that special quality which consists of faithfully transmitting those characters to their descendants. A small sample of the seed from each root, enough to produce about 50 plants, is sown the next year. The roots produced are examined physically and chemically at the laboratory in the usual manner. If the result of the test is unfavorable, the rest of the seed is thrown away; but if the test is favorable—that is, if the roots from which the seed was produced have demonstrated that they reproduce and transmit faithfully to their descendants the qualities for which they were chosen—the rest of the seed is sown with suitable care so as to obtain as great an increase of the variety as possible. Now, it is a fact of observation that individual plants or animals are very unequally endowed in this respect. I have already referred to this fact when I mentioned the case in which a new variety is established in a single generation. In an article on heredity, written in 1856, my father has so well presented this matter of the varying ability of individuals to transmit their own characters that I can do no better than quote the entire passage:

"An example drawn from the animal world will make this idea clearer. Suppose two stallions, eminently remarkable for eight characteristics, the same for both. Let the first of these characteristics be that of a fine head and shoulders, with the head shapely and well poised. We will not mention the other characteristics, which are of no importance to our argument, and pass directly to the eighth. Let this eighth characteristic be that of being a good stallion, and, since we are only making a supposition, we will define this by saying that it consists in the ability to transmit to descendants seven-eighths of his own characteristics. Now let us advance one generation and consider two male offspring of these animals. The first has transmitted seven of these characteristics, but he has not transmitted the first; hence this colt will have a head that is too large, badly poised, and he will not carry it well; but, as he has received the quality of being a good stallion, he will transmit with tenacity to his descendants his unshapely head, compensated, however, by his other good qualities. Let the offspring of the second stallion, on the other hand, possess all the visible characteristics of his father and be, to all appearances, a fine horse. But he has not received the eighth quality. In the second generation he will show his great defect. His offspring will have no common family resemblance and all the fine qualities which he received from his sire will thus be lost to the further improvement of the race. This ability to impress a very pronounced character on their offspring, which certain stallions possess to a much higher degree than others, is a fact well known to those who devote themselves to the improvement of domestic animals; but it is not generally known that in the plant world this fact is even more pronounced, so much so that certain plants endow their descendants with such prepotency that a race, equivalent almost to a species group, is formed at a single leap, while at other times thousands of individuals may be raised from a plant showing some noticeable peculiarity without a single one of them reproducing the distinctive trait of the parent. But as this ability to transmit a specific character is not indicated by any external characteristic and the result alone reveals its existence, it becomes necessary to be able to eliminate from the second generation all of the descendants of a plant imperfectly endowed in this respect; and for this reason I have been led to make it an absolute rule to keep the seed from different plants separate and not to mix the seed of two plants intended to be used in improving a race, no matter how perfect and how much alike these plants may appear."

When, after two or three generations, it is seen that the new variety is not becoming constant, that at each generation the reversions to the old type or variations in all directions are still found, it is better to abandon the selection entirely, or rather, cease to apply it to this lot, which is possibly lacking in the ability to transmit acquired characters, and to seek another point of departure in another individual better endowed in this respect.

DIRECTION OF SELECTION.

The characters that have determined the selection of a certain plant have just been spoken of. It is understood that anyone engaged in the selection of plants or animals is selecting for the purpose of improvement. Man's efforts to modify a plant by means of selection, however, may be more or less skillfully directed. Besides, the result obtained, though expressing exactly the breeder's ideal, may be very differently estimated according to the circumstances and the country. The ideal of a fruit, vegetable, or flower varies greatly according to the tastes of different persons, and the influence of these different tastes must make itself felt in one way or another in the direction given to selection.

There are certain considerations of common sense that must be observed under all circumstances, which, if forgotten or disregarded, will lead to unfavorable results that will everywhere be recognized as such. It would be useless to attempt to unite in one and the same plant two characters which antagonize or interfere with the utility of each other. For instance, certain very dwarf beans are often widely advertised as producing pods of wonderful length. If the description is exact, and there is no reason to doubt that it is, the pods being longer than the stem that bears them, they would touch the ground and very often rot from contact with the damp soil. Common sense would show that very long pods should be borne by pole beans and that very dwarf varieties should bear short but numerous pods.

For several years very large flowers have been the fashion and pansies and begonias are shown in which the flower is as large as the open hand. It has never been demonstrated that this is progress in a right direction. These flowers that are so large and abundant have not always the substance and stiffness necessary to hold them upright. The result is that they bend under the slightest unfavorable atmospheric changes or often even under their own weight and frequently become much less beautiful than smaller but more substantial and numerous flowers. There is another instance of improvement, so called, which I am not alone in considering quite the opposite. There is a very pretty species of helianthus (*H. cucumerifolius*) which is much esteemed in America and in Europe as a cut flower in summer. Its flowers, 3 or 4 in. in diameter, are of a pretty shape and superb golden color relieved by a black center. They are much sought after for sheaves and large bouquets. A florist has selected a variety called Stella which produces a much smaller number of flowers, 6 in. or more in diameter, like those of small varieties of *H. annuus*. With the loss of its abundance of flowers this plant has also lost the grace and lightness which constituted its especial merit.

The above example brings out a point that must be taken into consideration in selection. It is that there exist in nature certain laws of equilibrium or of compensation that must be taken into account; as, for instance, the law that the size of the organs in any given variety of plant varies inversely as their number. The same variety does not produce both very large and very numerous flowers. This fact is especially noticeable in the cultivated cineraria (*Senecio cruentus*). The flowers, which in the wild plant are scarcely as large as the flowers of the true daisy (*Bellis perennis*), are usually bred to resemble those of the ox-eye daisy (*Chrysanthemum leucanthemum*). This is not a wise application of selection. When of this size, the flowers that a well cultivated plant bears are no more than 50 or 60 in number. They cover the plant less completely than when they are a little smaller, but are 100 or 150 in number. The effect in the latter case is the more satisfactory. The details are lost in the mass of color, and abortive or accidentally injured specimens do not break the solidity of the mass as when the flowers are individually of such size that the removal of one of them necessarily leaves a gap.

Neither can a plant be expected to be at once very productive and very early. Time is an element of considerable importance in the growth of plants. The plant that grows under favorable conditions of temperature and light for a month longer than another will necessarily produce a considerably greater weight of organic matter, but there are many cases in which great earliness is an absolute condition of production. It is understood that under such conditions earliness is sought before anything else. It is a local necessity that must be taken into account. The problem of selection is almost always complicated with particular local requirements, and this explains the extreme multiplicity of cultivated varieties which certain people condemn without considering the reason for their existence.

The rôle of selection has been of the greatest importance in the past, as can be seen by the examples already cited. It will continue to be of immense importance in the future, for it is certain that mankind, in proportion as it increases in number and takes possession more and more completely of the surface of the earth, will be obliged to obtain from it more and more of food and other useful products. To accomplish this, man must improve animals and plants, which are the instruments of organic production, just as he improves the implements and machines which are the instruments of industrial transformations. Moreover, mankind will be compelled to apply selection not only to species already known, but also to those which are yet to be discovered.

Up to the present time selection has been applied particularly to annuals or biennials, plants in which generations follow each other rapidly. Under the management of corporate bodies, such as associations and local governments, it could be applied, for example, to forest trees, in which the difference between the best and poorest specimens, as is well known, is extremely great. Since a well established race of sugar beets has been obtained, why should not also a cork oak be bred, the cork of which will be of rapid development and faultless texture? The value of such a cork would be double or treble that of the ordinary article.

HOW SHOULD SEED BE COLLECTED FROM PLANTS?

In concluding these notes on selection, it appears advisable to touch upon a point to which certain people attach great importance, but on which my opinion does not agree with that usually held. I refer to the custom of collecting seeds from some certain part of a plant in preference to another. There is no idea more prevalent in gardening than that of the superiority of seeds collected from the base of the central stem over those of the top of the same stem, and especially over those of the lateral branches. I have made and had made experiments on this subject, and I have invariably found no difference among the seeds collected from various parts of the same plant with respect to the proportion of single and double plants obtained. I have repeated these experiments many times on ornamental plants with respect to the doubling of flowers, on vegetables with respect to the size and quality of the roots, and on cereals with respect to the yield in weight and the appearance of the seed, and I have always found that while individual plants may differ from each other in respect to the transmission of characters, yet from the same plant there was great uniformity of results obtained. The larger seeds produce slightly more vigorous plants in the earlier periods of growth, but do not give any guaranty of ability to transmit superior qualities. When a plant is known to be thoroughbred, and its ability to transmit its own characters has been established, I should always prefer the smallest seed that came from it, although collected from the part of the plant which is considered the least favorable in the common opinion, to the largest seed taken from the part believed to be most favorable, of a plant whose pedigree is less certain.

CONCLUSIONS.

Selection is the surest and most powerful instrument that man possesses for the modification of living organisms.

Variations are easily induced by change of environment and cultivation. The latter is an addition of especial importance, because it permits variations which are spontaneously produced to be easily observed and selected.

These modifications may affect the external characters of form, shape, and color, or the internal qualities of flavor, perfume, chemical composition, etc.

Selection may modify organisms in any direction not incompatible with the preservation of life, but there are certain characters that are mutually antagonistic: Individual size and number of parts, great productiveness and extreme earliness, relatively large size of a part, and very intense coloration. In order to be effective, selection must be continued in one and the same direction.

The value of the results obtained depends on the ability and judgment of the breeder. Varieties may degenerate as well as improve under selection.

The unit of selection is the individual. The superiority of one seed over others from the same individual, with respect to the transmission of characters, can not be foretold.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

The inverting power of tartaric, citric, and oxalic acids upon sucrose, H. GILLOTT (*Bul. Assoc. Belge Chim., 13* (*1899*), *Nos. 2, pp. 80–94; 3, pp. 119–130*).—A critical study of the influences of time, quantity, and kind of acid, and concentration of the solution upon the inversion of sucrose. Numerous tables are given, from which the following conclusions are drawn: (1) Tartaric acid possesses greater inverting power than citric acid; (2) oxalic acid manifests a greater inverting power than either tartaric or citric acid; (3) for each of the three acids named the amount of sugar inverted increases considerably with the temperature, amount of acid, concentration of the solution, etc.; and, (4) the temperature, the quantity of acid, and the quantity of sugar remaining constant, the amount of sugar inverted increases with the duration of action.—H. SNYDER.

Notes on the hydrolysis of cellulose by acids, G. W. ROLFE and W. H. BARLOW (*Tech. Quart., 12* (*1899*), *No. 1, pp. 51–61*).—This is a preliminary study of the products of the hydrolysis of cotton cellulose by means of decinormal sulphuric acid under pressures varying from 1 to 8 atmospheres. The specific rotary and cupric reducing powers of the soluble products formed at different stages of hydrolysis were determined and the results platted. The authors believe they have succeeded in considerably diminishing the experimental error of other investigators. By the method of hydrolysis employed less than 10 per cent of the cotton was hydrolyzed into soluble products. These products are believed to be in the main dextrose and xylose. Intermediate conversion products which are practically insoluble are formed during the process.

Observations on the determination of nitrogen by the Kjeldahl method, L. MAQUENNE and E. ROUX (*Ann. Agron., 25* (*1899*), *No. 2, pp. 76–82; Bul. Soc. Chim. Paris, 3. ser., 21* (*1899*), *No. 6, pp. 312–314; Rev. Chim. Analyt. et Appl., 1* (*1899*), *No. 5, pp. 145–119*).—An account is given of an investigation of the various sources of error in this method, such as incomplete digestion and the evolution of acid fumes when sodium sulphid and sodium hydroxid containing carbonate are used.

To avoid the error due to the evolution of carbon dioxid when carbonated soda solution is used, the authors recommend that a small basket containing pumice stone be suspended in the neck of a distillation flask before the soda is added. To do away with the error due to volatile sulphur compounds, sodium hypophosphite is substituted for sodium sulphid as a precipitant for the mercury. About 1 gm. of the hypophosphite is required for the precipitation. After adding the hypophosphite the solution is heated for a few minutes at 70 to 80° C. and cooled before the soda is added and the distillation commenced.

In tests made on colza cake, ground horn, and dried blood, the decomposition was complete only when digestion was continued for from ½ to 1 hour after the solutions had become colorless. It was found that all of the ammonia was carried over in the first 45 cc. of the distillate.

The iodometric method of determining the ammonia is not considered to possess any advantages over the ordinary acidimetric method.

The estimation of nitrites and nitrates, A. W. BLYTH (*Chem. News, 79 (1899), No. 2049, p. 102*).—The author has devised an apparatus in which nitrites and nitrates, either singly or together, can be determined as nitric oxid by means of ferrous chlorid.

> "The essential feature of the apparatus is a mercury valve which is made by connecting one end of a long delivery tube with the side tube of a flask and causing the other to dip below the surface of mercury in the mercurial trough, the bend of the delivery tube being 770 mm. above this level. The air from the flask is expelled by boiling, and a special feature is made of the ease with which successive vacua can be obtained in such a flask. The author has found that nitric oxid is evolved from nitrites at once, whereas there is an appreciable interval of from one to two minutes before any nitric oxid is formed from nitrates. Nitrates yield the whole of the nitric oxid only when the flask is evacuated several times. The results obtained with the apparatus are accurate."

Methods for the quantitative determination of fat in organs, W. KNOPFELMACHER (*Oesterr. Chem. Ztg., 2 (1899), No. 5, pp. 122–124*).—The author reviews the different methods which have been used for fat determination in meat, etc., showing the ineffectiveness of the old methods of extraction. He concludes that the choice lies between Dormeyer's method of digesting the material with pepsin and hydrochloric acid previous to extraction (E. S. R., 7, p. 919) and Frank's method of treatment with alcohol for 24 hours before extraction. The latter is simpler, although it does not secure quite as much fat as Dormeyer's method. Only investigation can decide which of these two methods is best adapted to the purpose.

Note upon the detection of horseflesh in sausage, F. JEAN (*Ann. Chim. Analyt. et Appl., 4 (1899), No. 3, pp. 81, 82*).—Glycogen is determined as follows: The suspected material, in a fine state of division, is macerated in water for an hour at 60 to 70°. To the liquid obtained by pressure a few drops of acetic acid are added. The soluble albuminoids are removed by coagulation and filtration, and the liquid reduced by evaporation to 20 cc. When cool, 100 cc. of 95 per cent alcohol is added to precipitate glycogen, which is collected on a filter, washed with alcohol and then with ether. The glycogen is finally dried and weighed. The iodin reaction of Brautigam and Edelmann for the detection of glycogen is described. No analyses are given or standard proposed.—H. SNYDER.

The variation in the composition of Paris green, with a scheme for its analysis, T. B. STILLMAN (*Stevens Indicator, 15, pp. 233–240; abs. in Tech. Quart., 12 (1899), No. 1, Rev. Chem., p. 15*).—The composition of pure Paris green, aceto-arsenite of copper, is given as CuO, 31.29 per cent; As_2O_3, 58.65 per cent; and $C_2H_4O_2$, 10.06 per cent. "Adulteration as such is said to be rare in this country, although many samples show an excessive amount of arsenious acid, and the commercial material does not give uniform results when used as an insecticide. Foreign samples are frequently adulterated with barium sulphate, calcium carbonate, lead chromate, or gypsum; but these may be added to alter the shade when the mixture is designed for use as a pigment. A simple scheme for the analysis of Paris green for the above impurities is given."

Choice of a substance for use as a basis for standardizing solutions in acidimetry and alkalimetry, S. P. L. JÖRENSEN (*Rev. Chim. Ind. 9, No. 107, p. 304; abs. in Jour. Soc. Chem. Ind., 18 (1899), No. 1, p. 74*).—Sodium oxalate is recommended, its advantages for the purpose being pointed out. A weighed portion is ignited in a platinum crucible, and the resulting carbonate is used for standardizing normal acid by titration.

Baumé's hydrometer—American standard, S. S. EMERY (*Jour. Amer. Chem. Soc., 21 (1899), Nos 2, pp. 118–132; 4, p. 388*).—A calculation of the degrees Baumé corresponding to specific gravities of liquids lighter and heavier than water.

The quantitative determination of glucose in pure solutions and in blood, A. BICKEL (*Arch. Physiol. [Pflüger], 75 (1899), No. 3–5, pp. 248–264*).—The outcome of the study was that in the quantitative analysis of dextrose, whether in aqueous solutions or aqueous extracts of animal tissue, an alkaline solution containing glucose should never be heated to a high temperature on account of the danger of losing a part of the dextrose by the decomposition due to the alkaline salts in the solution. An acid reaction prevents this decomposition.

The quantitative determination of glycogen, J. WEIDENBAUM (*Arch. Physiol. [Pflüger], 75 (1899), No. 3–5, pp. 113–119*).

The determination of glycogen according to Brücke and Külz, E. PFLÜGER (*Arch. Physiol. [Pflüger], 75 (1899), No. 3–5, pp. 120–247*).—It was found that the method involved an error of from 16 to 20 per cent. An attempt to make the method more exact was unsuccessful.

Determination of mustard oil in rape-seed cakes, V. STEIN (*Tidsskr. Landökon., 17 (1898), No. 7–8, pp. 503–510*).

Estimation of nicotin in tobacco, R. HEFELMANN (*Pharm. Centralhalle, 19 (1898), pp. 523, 524; abs. in Chem. Centbl., 1898, II, pp. 562, 563; Jour. Chem. Soc. [London], 76 (1899), No. 437, II, p. 261*).

Estimation of the bitter principles in hops, C. J. LINTNER (*Ztschr. Gesam. Brauw., 21 (1898), pp. 407, 410; abs. in Chem. Centbl., 1898, II, pp. 684, 685; Jour. Chem. Soc. [London], 76 (1899), No. 437, II, p. 264*).

Analysis of sumac, M. SPICA (*Leipzig Färber u. Zeugdr. Ztg., 47 (1898), p. 526; abs. in Bul. Assoc. Belge Chim., 13 (1899), No. 3, p. 154*).

The sumac of Sicily and its adulterants, F. ANDREASCH (*Gerber, 24 (1898), pp. 139, 151, 164, 176, 190, 201, 215; abs. in Bul. Assoc. Belge Chim., 13 (1899), No. 3, p. 158*).

A new method of quantitatively or qualitatively examining albuminoids, diastases, alkaloids, leucomains, or toxins, particularly those in urine, P. CHIBRET (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 7, pp. 431–433*).

A method for distinguishing between cotton-seed, sesame, peanut, and olive oils, M. TORTELLI and R. RUGGERI (*Staz. Sper. Agr. Ital., 31 (1898), No. 3, pp. 249–269*).

Notes on the arachidic and lignoceric acids of earthnut oil, and their estimation, L. ARCHBUTT (*Jour. Soc. Chem. Ind., 17 (1898), No. 12, pp. 1124–1127*).—The results obtained are applied in the detection of peanut oil in olive oil.

Colorimetric determination of iron in water, A. SEYDA-STETTIN (*Chem. Ztg., 22 (1898), No. 104, p. 1086*).

A needed modification of the determination of calcium carbonate in marls and soils, A. MAYER (*Landw. Vers. Stat., 51 (1899), No. 4–5, pp. 339, 340*).—The substitution of acetic acid (1 part of glacial acetic acid to 2 parts of water) for the hydrochloric acid usually employed is recommended. Acetic acid gives very accurate results with pure calcium carbonate in the Scheibler apparatus and possesses the advantage over hydrochloric acid of attacking but slightly iron carbonate, which is sometimes found in considerable amounts in marls and soils and which is of no value as an amendment.

Some notes on the content of volatile acids in wine, G. MORPURGO (*Oesterrr. Chem. Ztg., 2 (1899) No. 8, pp. 209–211*).

On the formation of sugar from the albumen of eggs, F. BLUMENTHAL (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 2, pp. 117–120*).—Recent work on this subject is briefly reviewed, and experiments by the author reported. The author believes that 8 to 12 gm. of sugar may be formed from 100 gm. of albumen (from white of egg).

A simple apparatus for the determination of nitrogen by the Kjeldahl method (*Ztschr. Analyt. Chem., 38 (1899), No. 3, p. 166; abs. in Chem. Centbl., 1899, I, p. 948, fig. 1*).

Apparatus for rapid analysis of milk, G. D. MACDOUGALD (*Jour. Soc. Chem. Ind., 18 (1899), No. 3, pp. 235–238, figs. 15*).

A new attachment for the Soxhlet extractor, S. ROBERTSON (*Arch. Hyg., 30 (1897), p. 318; abs. in Ztschr. Analyt. Chem., 38 (1899), No. 1, p. 45, fig. 1*).—The substance is contained in a glass cylinder with perforated bottom, over which a filter paper can be tied. Caps fitting over the top and bottom of the cylinder are provided for use during drying and weighing.

Report of agricultural-chemical examinations for 1898, V. STEIN (*Tidsskr. Landökon., 17 (1898), No. 7–8, pp. 500–523*).—Results of analytical work done for the Royal Danish Agricultural Society in examinations of feeding stuffs, dairy products, fertilizers, etc.—F. W. WOLL.

BOTANY.

Varieties of corn, E. L. STURTEVANT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 57, pp. 108, figs. 14*).—In this monograph about 800 varieties or synonyms are treated, and an attempt is made to place the nomenclature upon a sound scientific basis. The system of classification adopted brings closely related forms together and in this way a very considerable duplication of varieties is shown. The main divisions which the author follows are those described by him in the Bulletin of the Torrey Botanical Club for August, 1894 (E. S. R., 6, p. 274).

Poa fendleriana and its allies, T. A. WILLIAMS (*U. S. Dept. Agr., Division of Agrostology Circ. 10, pp. 6, fig. 1*).—The author has attempted to remove the cause of much confusion in herbaria by presenting a study of this species of grass and the numerous forms which have been confused with it. The species and varieties recognized are: *Poa longiligula*, *P. longiligula wyomingensis* var. nov., *P. longipedunculata*, *P. longipedunculata viridescens* var. nov., *P. scabriuscula* sp. nov., *P. brevipaniculata*, *P. brevipaniculata subpallida* var. nov., *P. fendleriana*, *P. fendleriana arizonica* var. nov., and *P. eatoni*.

Copper in plants, D. T. MACDOUGAL (*Bot. Gaz., 27 (1899), No. 1, pp. 68, 69, fig. 1*).—The wide distribution of copper in plants seems to be determined by the presence of the metal in the soil rather than by any selective power in the plants. It is stated that plants grown in ordinary soils may contain 30 mg. of copper to each kilogram of dry matter, while, according to Lehmann,[1] plants growing in soils rich in copper may contain as much as 560 mg. of copper per kilogram of dry matter. The author states that a specimen from a dead tree of *Quercus macrocarpa* recently examined at the University of Minnesota was found to contain slightly less than 500 mg. of copper per kilogram of dry matter. Examination of the wood showed the copper to be present in the form of finely divided reddish brown particles in the tracheides, vessels, and medullary parenchyma. It is presumed that it gained entrance to the tissues before the death of the tree, and had therefore passed through the conducting elements and been absorbed by the living cells of the medullary rays. The large amount of the substance present, the author states, supports Lehmann's conclusions that copper does not exert a marked injurious influence upon plants.

On the poisonous properties of sodium chlorid and sea water toward plants, H. COUPIN (*Rev. Gén. Bot., 10 (1898), No. 113, pp. 177–190, figs. 3*).—A series of experiments is reported in which the toxic effect of sodium chlorid and sea water toward the germination and growth of wheat, peas, vetches, lupines, maize, and *Beta maritima*, *Atriplex hastata maritima*, and *Cakile maritima* is shown. Different strengths of solution from 0.125 to 5 per cent were tested. It was found that the toxic strength of sodium chlorid solution for wheat was 1.8 per cent, peas 1.2 per cent, vetch 1.1 per cent, lupine 2.2 per cent, and maize 1.4 per cent. For plants not growing naturally near the seashore the average toxic strength of sodium chlorid solution is about 1½ per cent; for plants which naturally grow near the seashore their toleration of this salt is much higher. *Beta maritima* and *Cakile maritima* were killed by a 4 per cent solution and the *Atriplex hastata maritima* by a 5 per cent solution. These plants are able to withstand amounts of this salt in about the proportion in which it usually exists in sea water.

The effect of other solutions on these maritime plants was tested, and the toxic strength of magnesium sulphate was found to be about 3 per cent and of magnesium chlorid about 2½ per cent. These quantities are considerably in excess of the amount ordinarily found in sea water.

---

[1] Arch. Hyg., 27 (1896), p 1.

Influence of electricity upon plants, G. E. STONE (*Bot. Gaz., 27 (1899), No. 2, pp. 123, 124*).—The results of experiments based upon measurements of about 20,000 plants are briefly outlined. The more important factors indicate that electricity exerts an appreciable influence upon plants, and the application of certain strength of currents for one minute or less is sufficient to act as a stimulus. Germination and growth are both accelerated by electrical action. Plants do not respond immediately to electrical stimuli, but possess a latent period of about 25 minutes, that is, about the same as that for heliotropic and geotropic stimuli. Reaction to electrical stimuli is limited to a narrow range in the intensity of the current and is manifest either in the acceleration or retardation of metabolic activity according to the nature and strength of the current employed. There was found a minimum, optimum, cessation, and maximum stimulus, and the excitation produced by alternating currents was more marked than that produced by direct currents. The increase of stimulus necessary to produce an equally noticeable difference of perception bears a constant ratio to the total stimulus intensity which may be expressed by the ratio of 1:3.

Root tubercles upon spring and autumn grown legumes, B. D. HALSTED (*Bot. Gaz., 27 (1899), No. 2, p. 120*).—In an abstract of a paper presented before the Society for Plant Morphology and Physiology, it was shown that the ninth successive crop of wax beans upon the same plat, grown in spring, consisted of plants whose roots were abundantly supplied with nearly spherical tubercles, while the plants of the succeeding crop grown during the summer were almost without tubercles. As an explanation of this difference the author states that there was doubtless less available nitrogen in the comparatively cool earth of May than in the warmer ground of August. The denitrifying germs, being more active in midsummer, had provided a greater supply of combined nitrogen for the young plants. The spring crop, not having this abundant supply, was nitrogen hungry, and this furnished the proper condition for the abundant development of tubercles. The widely varying results which are secured in inoculation experiments, either with soil extracts or pure cultures, can probably find an explanation in this way.

Nitragin and the nodules of leguminous plants, MARIA DAWSON (*Proc. Roy. Soc. [London], 64 (1899), No. 406, pp. 167, 168*).—This paper consists of an abstract communicated to the Royal Society, in which the author states that a study of the tubercles found upon the roots of leguminous plants has led to the confirmation of the claim of the parasitic nature of both filaments and bacteroids contained in these organs. The filaments were not found to have any constant relation with the nucleus of the cells, as was represented by Beyerinck in 1888. By plasmolysis of the root hairs the infection tube is shown to have grown into the hair and does not correspond with the primordial utricle of the hair, showing that Frank was in error in regarding the tube as formed from the contents of the hair mingled with the fungus protoplasm. By staining with aniline blue and orseillin, these tubes and filaments appear to consist of strands of straight rodlets lying parallel to the longer axis of the filaments and embedded in a colorless matrix. This matrix, it is stated, does not consist of cellulose, chitin, or any form of slime. The swellings upon the filaments occur at places where the rodlets have become heaped up, and eventually burst liberating the rodlets. After liberation from the filaments they become transformed into X, V, and Y shaped bacteroids. This variety of shape does not occur when the organisms are cultivated outside of the plant on solid media, but are readily produced in a few days in liquid pea extract. By cultivating these organisms in drop cultures they seem to multiply by division into equal or sometimes slightly unequal halves. This method of division leads to the conclusion that the organisms belong to the Schizomycetes, but whether they are true bacteria or not is still undecided. The X, V, and Y shaped bacteroids when once formed appear incapable of further growth. These organisms are aerobic, and their power of fixing atmospheric nitrogen is to be further tested.

Commercial Nitragin is said to consist of minute micrococcus like bodies, straight and immovable. They multiply rapidly on gelatine media and in pea extract become converted into bacteroids. It is stated that Nitragin consists of the tubercle organism and as a result of inoculation of either seeds or soil, tubercle formation takes place. Crossing of kinds supplied for different genera and species are found quite successful within the tribe Vicieæ. Seedling peas grown in sterile tubes showed that direct infection of the young radicles and also of older roots is tolerably certain, providing the conditions under which germination occurred are maintained after infection. It is not necessary that the organism should pass through the soil in order to secure infection, and an accumulation of carbon dioxid around the roots is not a cause of failure in infection. The addition of Nitragin to soils rich in nitrates is said to be inadvisable, but a supply of it to soils poor in nitrates may result in increased yields, although better results would probably be obtained if instead of Nitragin, nitrates should be added to the soil.

Experiments with Nitragin and Alinit, A. SEMPOLOWSKI (*Deut. Landw. Presse, 26 (1899), No. 2, pp. 13, 14*).—Inoculation experiments are reported with Nitragin on lupines, serradella, horse beans, vetches, and peas; and with Alinit on oats and barley. The soil on which the experiments were conducted was a wet loam. The germination of the legumes which had received the inoculating material was hastened somewhat, while the Alinit seemed without effect in this regard. At the end of the season the plants were removed from the plats and the amounts of straw and grain and the percentage of nitrogen in the roots determined. The plats of small-leaved lupine, fodder vetch, and serradella showed considerable increases where inoculation was resorted to, while the uninoculated plats of peas, horse beans, and hairy lupine gave the best showing.

The plat of oats which had received the Alinit culture gave the best result, while with barley the uninoculated plat made the best showing.

Disordinate variations in hybrids, C. NAUDIN (*Rev. Hort.*, *70* (*1898*), *No. 21*, *pp. 509*, *510*).—The author gives the conclusions which he has arrived at after a long experience with hybrids between a considerable number of species of plants. The conclusions are in part as follows:

The more nearly congeneric species resemble each other, the more certain and easy is their hybridization. The resemblances, however, are physiological and do not always appear in external characters. Certain plants which are very different in general appearance cross very readily and produce fertile hybrids. This is the case with *Linaria vulgaris*, a plant having large yellow flowers, and *L. purpurea*, which has small dark-purple flowers. This is also true of *Nicotiana tabacum* and *N. glauca;* the first an annual with large leaves and pink flowers and the second a small tree with comparatively small leaves and small yellow flowers. That external resemblances are not a sure indication of physiological affinities is well shown in the case of squashes. *Cucurbita maxima*, *C. pepo*, and *C. moschata*, in spite of their great resemblances in habit, foliage, and flowers, do not hybridize, while *C. melanosperma*, though very different from the other species of the genus, is influenced by their pollen and produces fruits which, however, contain seeds with imperfect embryos.

Either from imperfections of the ovules, or more frequently of the pollen, or of both these, hybrids are often sterile, but as a compensation for this inferiority they are often larger and apparently more vigorous than the parent species.

The sterility of hybrids is far from general. A considerable number of them are in some degree fertile to their own pollen and more certainly so to the pollen of one or other of the parent species. Moreover, some are as fertile with themselves as are the parent species. External resemblances of the species do not warrant a conjecture as to the degree of fertility of their hybrids.

There is some truth in statements commonly made that hybrids soon revert to the specific types from which they came, or become extinct on account of the increasing imperfection of their reproductive organs, but the exceptions are numerous. In experiments in hybridization the successive generations were watched for many years. In the first generation, that which results directly from hybridization, the product is in general very uniform, the dissimilarity of the individuals not being very marked. The majority are intermediate beween the two parent species, some inclining more than others toward one of the two species. In the second generation the case is wholly different, the rule being dissimilarity. Among 100 individuals, possibly a dozen approach more or less to the parent species without reverting entirely.

The remainder are an aggregation of anomalous forms, no two of which are alike. This capriciousness resulting from hybridization the author terms disordinate variation (*variation désordonnée*).

Report on botanical survey in Alaska in 1898, W. H. EVANS (*U. S. Dept. Agr., Office of Experiment Stations Bul. 62, pp. 48–50*).—Brief popular notes are given on a collecting tour in the Cook Inlet region during the summer of 1898, and statements are made relative to various plants of economic value.

Grasses, clovers, forage, and economic crops, W. R. DODSON and W. C. STUBBS (*Louisiana Stas. Bul. 53, 2. ser., pp. 55, figs. 12*).—Notes are given treating of grasses, leguminous forage crops, hay and forage crops other than grasses and legumes, and economic plants other than hay and forage crops. Popular descriptions are given of these different plants and suggestions given as to their relative value in the State.

New species of North American grasses (*U. S. Dept. Agr., Division of Agrostology Circ. 9, pp. 7*).—This circular consists of a description of a number of new species of grasses of which Scribner and Williams describe *Poa capillarifolia, P. saxatilis, P. brevipaniculata, P. longiligula, P. planifolia, P. limosa, P. incurva, P. invaginata*; Scribner and Smith, *Elymus arenicolus*; Scribner, *Poa leckenbyi, P. acutiglumis, P. tenerrima, P. epilis*, and *Eragrostis lutescens.*

Oogenesis in Pinus laricio, C. J. CHAMBERLAIN (*Bot. Gaz., 27 (1899), No. 4, pp. 268–280, pls. 3*).—Studies on fertilization and embryology.

Comparative anatomy of hypocotyl and epicotyl in woody plants, F. RAMALEY (*Minnesota Bot. Studies, 2. ser., 1899, pt. 2, pp. 87–136, pls. 4, figs. 23*).—The author finds these two parts of the plant essentially dissimilar, although secondary changes may cause resemblances.

Seedlings of certain woody plants, F. RAMALEY (*Minnesota Bot. Studies, 2. ser., 1899, pt. 2, pp. 69–86, pls. 4*).—A number of seedlings were studied, from which it appears that generalizations relative to the form of cotyledons can not be safely made without a great mass of data.

A contribution to the life history of Rumex, B. FINK (*Minnesota Bot. Studies, 2. ser., 1899, pt. 2, pp. 137–153, pls. 4*).—Studies are given on the life history of *Rumex salicifolius* and *R. verticillatus.*

Contribution to the biology of winter wheat, S. TOPORKOV (*Selsk. Khoz. i Lyesov., 192 (1899), Jan., pp. 1–44*).

On the biology of Agaricus velutipes, R. H. BIFFIN (*Jour. Linn. Soc. Bot. [London], 34 (1899), No. 236, pp. 147–162, pls. 3*).

Influence of the medium on the growth of roots, J. WACKER (*Jahrb. Wiss. Bot. [Pringsheim], 32 (1898), No. 1, pp. 71–116; abs. in Bot. Centbl., 75 (1898), No. 10, pp. 308–310*).

Aerial roots of the grape, V. VANNUCCINI and G. E. RASETTI (*Staz. Sper. Agr. Ital., 31 (1898), No. 4, pp. 353–359, pl. 1*).

Seed dissemination and distribution of Razoumofskya robusta, D. T. MACDOUGAL (*Minnesota Bot. Studies, 2. ser., 1899, pt. 2, pp. 169–174, pls. 2*).—The fruit of this interesting parasite of *Pinus ponderosa* is said to be explosive, and is scattered by that means. The distribution of the plant is said to be determined to a large extent by air currents rising from the bottom of canyons, the parasite being found most abundantly near the rim of the canyon.

Some appliances for the elementary study of plant physiology, W. F. GANONG (*Bot. Gaz., 27 (1899), No. 4, pp. 255–267, figs. 7*).

Variations in the starch reserve in trees at different times of the year, E. MER (*Bul. Soc. Bot. France, 3. ser., 5 (1898), No. 5, pp. 299–309*).

Investigations made on the gum flow of trees during 1898, F. LUDWIG (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 10–11*).—A summary is given of some of the more important contributions published during 1898 on the gum flow of trees and its causes.

On the respiration of germinating wheat, G. BURLAKOW (*Arb. Naturf. K. Univ. Charkow, 31 (1897), Beilage, pp. I-XV; abs. in Bot. Centbl., 74 (1898), No. 11, pp. 323, 324*).

Coloring matter of flowers, P. A. KEEGAN (*Nat. Sci., 12 (1898), pp. 194-199; 14 (1899), pp. 143-149*).

Scientific and practical studies of Nitragin and Alinit with special reference to the latter, H. LAUCK (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), Nos. 1, pp. 20-23; 2, pp. 54-62; 3, pp. 87-90*).

On Alinit (*Centbl. Agr. Chem., 28 (1899), No. 3, pp. 156-165*).—A brief review of investigations on this subject.

The nitrogen problem, G. W. FIELD (*Rhode Island Sta. Bul. 50, pp. 57-62*).—This is a popular bulletin which treats of the primary chemical elements and simple nitrogenous compounds, the acquisition of nitrogen by bacteria, and the denitrifying organism.

Methods in plant histology, I, C. J. CHAMBERLAIN (*Jour. Appl. Micros., 2 (1899), No. 3, pp. 296-300, figs. 5*).

METEOROLOGY—CLIMATOLOGY.

Annual summary of meteorological observations in the United States, 1898 (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 26 (1898), No. 13, pp. 593-605, charts 5*).—This is a summary of observations on atmospheric pressure, temperature, precipitation, wind movement, cloudiness, and other meteorological phenomena "based essentially upon data received from about 140 regular Weather Bureau stations and 28 regular Canadian stations. The data are given in tables and charts and summarized in the text."

"The year opened with high temperature for the season east of the Rocky Mountains and cold weather in the Plateau region and on the middle and south Pacific coasts. The mild temperatures east of the Rocky Mountains continued throughout February and March, the winter being unusually mild, especially in North Dakota, the Lake region, and the Missouri and upper Mississippi valleys.

"Interlake navigation opened much earlier than usual. The Straits of Mackinac were free from ice on March 28, the earliest date but one during the 63 years that records have been kept. While navigation opened much earlier than usual, its close was marked by one of the greatest ice blockades at the west end of Lake Erie in the history of lake navigation. . . .

"There were several periods of very warm weather during July and August, the temperatures registered at a few stations east of the Appalachians being higher than ever before known. During the latter part of July and at intervals during August, periods of high temperatures, conjoined with high relative humidity, prevailed in the central and eastern portions of the country and much bodily discomfort was experienced.

"Temperature continued above normal generally until October, when a reversal of the prevailing conditions took place, such reversal being first observed in the Rocky Mountain and Plateau regions, where the temperature averaged from 1 to 4° below normal. The temperature was also below normal in October quite generally throughout the Northwest and also in the Gulf States, but remained above normal in the Lake region, the Ohio Valley, and Tennessee.

"The reversal noted as beginning in October was almost completely established during November, when the only districts showing plus departures were the Florida peninsula and the upper Lake region. In December temperature was below normal in practically all districts, the departures averaging from 1 to 8° below normal.

"The precipitation of the year just ended was below normal over by far the greater part of the United States. Fortunately, however, there was an abundance of rain generally throughout the middle portion of the central valleys and the Middle and New England States. Precipitation was below normal west of the Rocky Mountains, in the upper Mississippi and upper Missouri valleys, and from New Mexico eastward to the Atlantic. The normal precipitation over much the greater part of the last-named area, however, is more than sufficient for the needs of agricultural interests; the conditions as regards those interests were, therefore, not so unfavorable as they might otherwise have been.

"The drought which began in California in the fall of 1897 continued until May, 1898. In the latter month, which practically closes the rainy season on the Pacific coast, heavy rains fell in California and the Plateau region. The rainy season of 1898-99 in California began auspiciously, the September rains being above the average. The fall during October, November, and December, however, was below the average and at the close of the year grave apprehensions were entertained of a second season of diminished rains.

"In the Gulf and South Atlantic States the fall was below the average, although the deficiency was not so great as in former years. The precipitation of this region has been below normal with unimportant exceptions since 1890. It would be exceedingly interesting to discover the cause of the continued diminution."

Report of the Chief of the Weather Bureau, 1897-98 (*U. S. Dept. Agr., Weather Bureau Rpt. 1897-98, pp. 338, charts 38, dgms. 9*).—This report is divided into 7 parts. Part I, an administrative report, has already been noted (E. S. R., 10, p. 827). Part II gives a list of observing stations and changes therein during 1897, and hourly averages of atmospheric pressure, temperature, and wind from the records of automatic instruments at 28 stations. Part III contains monthly and annual meteorological summaries for 145 Weather Bureau stations. Part IV gives monthly and annual mean temperature and annual extremes of temperature, together with the dates of the first and last killing frost, 1897. Part V reports the monthly and annual precipitation for all stations, 1897. Part VI gives miscellaneous meteorological tables and reports, including general characteristics of the weather of 1897, temperature, precipitation, relative humidity, sunshine and cloudiness, severe local storms, loss of life by tornado and lightning, etc. Part VII contains the following articles: Climate of Cuba, Weather of Manila, and Temperature, rainfall, and humidity of San Juan, Porto Rico, by W. F. R. Phillips; Meteorological waves, and The distribution of moisture in the United States, by H. A. Hazen.

Meteorological observations, R. J. REDDING (*Georgia Sta. Bul. 41, pp. 183-185*).—A record is given of rainfall at Experiment, Georgia, during 1898, as well as of the mean temperature and rainfall at the same place for May-August, 1890-1898. The most remarkable feature of the weather during the year 1898 "was the excess of above 10 in. of rainfall over the average of the past 9 years. The total for the year was 57.24 in., and the average for 9 years was 47.05 in."

Meteorological observations at the Michigan Agricultural Experiment Station for the year 1896, R. C. KEDZIE (*Michigan Sta. Rpt. 1897, pp. 133-157*).—Daily and monthly summaries of observations during 1896 on temperature, pressure, precipitation, humidity, cloudiness, and wind movement, and a record of thunderstorms during the year.

A résumé of meteorological observations made at Châteaudun, France, during 1897, E. ROGER (*Rap. Champs D'Expériences et Démon.* [*Sta. Agron. Chartres*], *1896–97, pp. 155–161, fig. 1*).

Note of the storm in Eure-et-Loir, France, June 28, 1897, E. ROGER (*Rap. Champs D'Expériences et Démon.* [*Sta. Agron. Chartres*], *1896–97, pp. 162–170*).—A somewhat detailed account of this storm.

Sunspots and rainfall, A. B. MACDOWALL (*Nature, 59* (*1899*), *No. 1538, pp. 583, 584*).—The same method used with temperature observations noted in E. S. R., 10, p. 1020, was applied to rainfall observations extending back in case of Greenwich to 1815. The results indicate "a greater tendency to wetness in years about sun-spot minima than about maxima" in the region of Greenwich, the opposite being true for the more northerly region of Rothesay. In the author's opinion, however, this contrariety is not fatal to the idea of sun-spot influence.

Light freezes, F. SOHUT (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 16, pp. 485–489*).—These are discussed especially in their relation to grape growing in France.

Climate of Alaska, A. J. HENRY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 62, pp. 50, 51*).—A summary of observations on temperature at different places in Alaska, which has already been published in the Monthly Weather Review (E. S. R., 9, p. 426).

The climate of Mexico in 1895, MORENO ANDA and A. GOMEZ (*Mem. y. Rev. Soc. Cient. "Antonio Alzate," 12* (*1898–99*), *No. 1–3, pp. 101–104*).

Eight years' observations on the effect of weather on vegetation. J. CLAYTON (*Paper read before the Bradford Sci. Assoc. Mar. 12, 1897*).

WATER—SOILS.

Underground waters of a portion of southeastern Nebraska, N. H. DARTON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 12, pp. 56, pls. 21, figs. 14*).—This is an account of field work during 1896, in which not only a detailed examination of surface geology but a careful search for all wells, both shallow and deep, was made over a district beginning in the vicinity of Lincoln, Nebraska, and extending to the vicinity of Lexington. "As far as possible, information was obtained concerning the depth of the wells, character of the strata penetrated, and the volume and quality of the water supply. . . . To a discussion of the geologic formation and their water contents is appended a statement as to the possibility of obtaining artesian water;" such facts as were procurable concerning the utilization of the available water supply in irrigation being added. "In this particular area agriculture is not regarded as dependent to any considerable extent upon the artificial application of water, but the examples cited show that in many localities irrigation on a small scale can be employed with profit."

River heights, 1896, A. P. DAVIS (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 11, pp. 100*).—This is a series of tables giving the river heights observed and recorded during 1896 by persons employed by or cooperating with the Division of Hydrography of the U. S. Geological Survey. Tables are also appended giving data relating to evaporation, seepage, meter rating, etc. Records are given for 110 streams in 22 States—Alabama, Arizona, California, Colorado, Georgia, Idaho, Kansas, Maryland, Montana, Nebraska, Nevada, New Mexico, North Carolina, Oregon, South Carolina, Tennessee, Texas, Utah, Virginia, Washington, West Virginia, and Wyoming.

Influences of rain and the nature of the soil on the yield of forage plants, A. PAGNOUL (*Ann. Agron., 25 (1899), No. 2, pp. 83-86*).—Fescue and crimson clover were grown in pots 30 cm. deep and 7 cm. square on three different kinds of soil—sandy, clay, and calcareous. The pots were all fertilized alike with superphosphate, muriate of potash, and dried blood. One-half of the pots in each case was allowed to receive a little less water than that which fell in the open air. The other half received twice as much water. The conditions otherwise were alike. With the abundant supply of moisture the yield was about three times as great with the grass and four times as great with the clover as in case of the soils receiving the scanty supply of moisture. The relation between yields of fescue with an abundant and scanty water supply was 3.5 on clay soil, 2.7 on the sandy soil, and 2.5 on the calcareous soil. With the clover the ratios were 3.8 on the clay soil, 3.7 on the sandy soil, and 3.1 on the calcareous soil. The smallest yields were obtained on the clay soil, the largest on the sandy soil. The percentage of dry matter was smallest on the soils receiving an abundant supply of water. The percentage of nitrogen was smallest in the plants grown on clay soils. The total dry matter and the total nitrogen were largest in case of the plants receiving the largest amount of water.

Manures and hygiene, MARIÉ-DAVY (*Jour. Agr. Prat., 1899, I, No. 16, pp. 574-577*).—A discussion of the danger of contamination of underground waters by manures and the means of preventing it.

Literature of Russian soils, from 1765 to 1896, P. V. OTOTSKI (*St. Petersburg: Imperial Free Economic Society, 1898, pp. 158; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Dec., pp. 711, 712*).

The condition of the soil, C. V. GAROLA (*Rap. Champs D'Expériences et Démon. [Sta. Agron. Chartres], 1894-95, pp. 91-102*).—The method of soil analysis used is described and the results of analysis of the soils of plats variously treated, examined with a view to determining the changes which they had undergone under culture, are reported.

FERTILIZERS.

The cause and significance of the decomposition of nitrates in the soil, W. KRÜGER and W. SCHNEIDEWIND (*Landw. Jahrb., 28 (1899), No. 1-2, pp. 217-252, pls. 9*).—This is an account of pot experiments by the well-known Halle method, undertaken with a view to determining whether the reduction in yield which frequently follows the application of coarse manure or straw is due to (1) unfavorable influence on the texture of the soil, (2) the addition of organisms which decompose nitrates, or (3) the addition of substances which favor the growth and development of denitrifying organisms already present in the soil.

The results with a number of crops under a variety of conditions are reported in detail and are summarized as follows:

The reduction in yield was not due to the unfavorable influence of the manure and straw on the mechanical condition of the soils, since no reduction occurred when a sufficient amount of nitrate was applied or when leguminous plants were grown. This conclusion was further confirmed by the fact that when finely ground straw or other substances which had little or no influence on the mechanical condition of the soil but contained the proper nourishment for the denitrifying organisms were applied, the decrease in yield was as marked as in the other experiments. The reduction in yield, therefore, was clearly due to the action of denitrifying organisms, but the experiments indicate that the increased activity of denitrification in the soil was not due to the organisms applied in the manure and straw, but to the fact that these substances furnished a favorable medium for the growth and development of the organisms already in the soil.

It was found that the pentosans, which are very abundant in coarse manure and straw, furnished a very available source of carbon for these organisms, being much better suited to this purpose than cellulose or fiber. Neither of these, however, furnished as favorable a medium as the more readily decomposable carbon compounds, such as glycerin, citric acid, lactic acid, etc.

No denitrification was observed in soils to which peat was added. Intensive cultivation of the soil had no effect in checking denitrification, and neither was it affected by the stand of the crop.

When the moisture exceeded certain limits it promoted denitrification. Variations in the moisture within the usual limits, however, had little influence upon the process.

The factors which exerted the greatest influence upon denitrification were temperature and the mechanical condition of the material which furnished the food for the organisms. In view of the fact that the temperature of the pots was higher and the manure used was in finer condition than is usual in field experiments, it is believed that the denitrification processes were more active in the pots than in the field.

In the authors' opinion the reduction of nitrates in the field is not a matter of very great practical significance.

On denitrification processes in nature, G. MARPMANN (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 2, pp. 67–70*).—The author reports experiments which go to show that the production of nitro and ammonia compounds from albuminates, urea, etc., and of nitroso compounds from nitrates is due to fermentation processes usually complex, but that the setting free of elementary nitrogen as well as sulphur is a purely chemical process due to the action of nitrites. When solutions of amid, amin, or ammonium compounds were mixed with nitrites in an Einhorn saccharometer, evolution of free nitrogen commenced at once and the nitrites rapidly disappeared, the evolution of nitrogen continuing as long as any nitrites remained. The theoretical reactions by which the nitrogen may be set free are explained.

The results have an important bearing upon the conservation of manure. If the manure is alkaline, ammonia is formed and escapes, but at the same time the conditions are favorable to the formation of nitrates. If the manure be acid the escape of ammonia is prevented, but the conditions favor the formation of nitrites and a consequent escape of free nitrogen.

The question to decide, therefore, is whether most nitrogen is lost by denitrification or by escape of ammonia. In the author's opinion the use of alkaline preservatives will result in less loss of nitrogen and is, therefore, preferable to that of acid substances in the preservation of manure.

Commercial fertilizers, J. H. STEWART and B. H. HITE (*West Virginia Sta. Bul. 53, pp. 111-142*).—This bulletin contains reports of analyses and valuations of 343 samples of commercial fertilizers representing 186 brands, the text of the West Virginia law concerning commercial fertilizers, and a table showing the quantity and value of the different classes of fertilizers sold in the State during each of the years from 1895 to 1898.

The sales of fertilizers in the State were greater in 1898 than during any previous year. As a rule, the composition of the fertilizers examined was well up to or above the guarantee. In some cases, however, the value of the samples submitted by the manufacturer was greater than that of samples of the same brand found on sale.

The valuation of Thomas slag, F. W. DAFERT and O. REITMAIR (*Die Bewerthung des Thomasschlackenmehles. Vienna, Budapest, Leipsic: A. Hartleben, 1899, pp. 25, pls. 2*).—Wagner's investigations on this subject are discussed, and experiments along the same line by the authors and others are reported.[1] From comparative tests of a number of different kinds of slag on oats by the Wagner pot method during 2 years the following conclusions are drawn: The effectiveness of Thomas slag, as measured by increase in yield of grain, increased with the total phosphoric acid present. The completeness and rapidity of the action of the slag depends upon its fineness and chemical character. The solubility of the phosphoric acid in weak acid solutions affords, within certain limits, a valuable basis for judging the quality of slag. Wagner's citrate and citric acid methods, however, are not absolutely reliable means of judging of the practical fertilizing value of Thomas slag. After testing various solvents, a 5 per cent solution of formic acid was adopted by the authors as serving this purpose best. With this solvent the phosphoric acid dissolved from both Thomas slag and mineral phosphates was less variable and somewhat higher than in case of Wagner's solvents, and, in the authors' opinion, more in accord with the actual fertilizing value of the materials. As a result of these studies it is recommended that slag should be sold on a guarantee of 90 per cent solubility of phosphoric acid in 5 per cent formic acid.

---

[1] See also Ztschr. Landw. Versuchsw. Oesterr., 1 (1898), p. 6.

The following methods of examining slag, worked out by N. von Lorenz, are proposed: For the determination of total phosphoric acid boil 10 gm. of the slag in 100 cc. of nitric acid (1.4 sp. gr.) in a half-liter flask for 15 minutes. Add 300 cc. of water, cool, fill flask to the mark, mix the solution, and filter. With 25 cc. of the filtered solution in a 200 cc. beaker mix 20 cc. of nitric acid (1.4 sp. gr.), and add immediately, and all at once, 75 cc. of concentrated molybdic solution. Allow the solution to remain quiet for 5 minutes, then stir vigorously for 1 minute. After standing 30 minutes, filter, wash the precipitate with a solution containing 5 parts of the molybdic solution in 100 of water, dissolve in 2.5 per cent ammonia, add 20 cc. of magnesia mixture (55 gm. of crystallized magnesium chlorid and 70 gm. of ammonium chlorid in 1 liter of 2.5 per cent ammonia), and proceed as usual.

The concentrated molybdic solution used in this method is prepared as follows: Dissolve 200 gm. of dry ammonium nitrate in 870 cc. of nitric acid (1.3 sp. gr.), stir until the temperature is about 10° C., and add in a small stream, with vigorous shaking, a solution of 400 gm. of pulverized ammonium molybdate dissolved in 1 liter of water. Before use, the solution should be allowed to stand for 48 hours in a light place at 20 to 30° C , and filtered.

For determining the phosphoric acid soluble in formic acid the method proposed is as follows: Moisten 5 gm. of the slag with 5 cc. of alcohol in a half liter flask, fill the flask to the mark with 5 per cent formic acid, and shake in a Wagner rotary apparatus for 30 minutes, and filter. If a rotary apparatus is not available the flask may be allowed to stand 2 hours, with frequent shaking. To 75 cc. of the filtered formic acid extract in a slender pear-shaped flask, ending at the bottom in a graduated cylinder, add 75 cc. of the concentrated molybdic solution, allow to stand 5 minutes, and then shake vigorously for ½ minute, taking precautions to wash down all of the yellow precipitate into the graduated cylinder at the bottom. Allow the flask to stand 2 hours at rest, and then compact the precipitate in the graduated cylinder by means of a special apparatus, which is arranged to pound the flask for 15 minutes on an asbestus support. From the volume of the precipitate thus obtained the percentage of phosphoric acid is calculated by a factor which is determined by analysis in advance. In a series of determinations reported by the authors this factor was found to be 7.

Potash and soda in plants, M. STAHL-SCHROEDER (*Selsk. Khoz. i Lyesov., 190 (1898), Aug., pp. 355-389; Jour. Landw., 47 (1899), No. 1, pp. 49-84*).—The chief aim of the author in these experiments, which were carried out on the farm of the Polytechnic Institute at Riga, was the investigation of the question of the possibility of partially replacing potash by soda in plants. The object, however, of the first two experiments was to gain some light on the question of the presence of soda in plants.

Field experiments.—The experiment field of 1¾ acres with a light, sandy soil was fertilized with manure for the last time in 1882. In 1889 it was divided into two equal plats and from that time plat 1 was fertilized from year to year with 533 lbs. of Thomas slag and 266.5 lbs. of kainit and plat 2 with 1,066 lbs. of Thomas slag and 533 lbs. of kainit per acre. The potash and soda content of the oat plants grown was as follows:

Potash and soda in oat plants.

	Roots.		Straw.		Grain.	
	Potash.	Soda.	Potash.	Soda.	Potash.	Soda.

Average of plat 2 for 6 years	.449	.139	1.906	.204	.538	.008

These experiments show that the opinion of Pagnoul that when plants receive a plentiful supply of potash in the fertilizer they do not assimilate any soda whatever is erroneous, and tend to support the view of Contejean and Guitteau that soda almost always remains in the lower parts of the plants.

Sodium is present in kainit in the form of sodium chlorid to the amount of 21 to 40 per cent. Since oats need only very small quantities of chlorin, the sodium chlorid was assimilated as a whole in very small quantity. The question arises how much sodium would be assimilated by the plants if combined with an acid which is an essential plant food. Some experiments on this question were made, which, however, were inconclusive.

Pot experiments.—In order to determine whether potash can be partly replaced in plants by soda, the following experiments were made. Peat soil deficient in potash was used. The dry matter of the soil contained 0.021 per cent of potassium oxid, 0.016 per cent of sodium oxid, 0.715 per cent of calcium oxid, 0.175 per cent of magnesium oxid, 10.943 per cent of oxids of iron and alumina, 0.430 per cent of phosphoric acid, 1.138 per cent of nitrogen, and 8.972 per cent of insoluble matter. The loss upon ignition was 76.368 per cent. Wagner's zinc vegetation pots, 20 cm. wide and 25 cm. deep, were used. The bottoms were covered with a layer of gravel 1 in. in thickness, and 4,220 gm. of the soil, corresponding to 1,118.3 gm. of dry matter, was placed in each pot. The soil was previously well mixed with 15 gm. of calcium carbonate and 13.6 gm. of superphosphate (containing 1.2 gm. of phosphoric acid). In addition, each pot received 6.84 gm. of ammonium nitrate, 0.5 gm. of magnesium sulphate, and 0.5 gm. of ammonium chlorid. Two of the 6 pots which were used for each experiment received 3.15 gm. of potassium chlorid (2 gm. K_2O), 2 received 3.8 gm. sodium chlorid (2 gm. Na_2O), and 2 neither the one nor the other of the alkalis. Peas, oats, carrots, and buckwheat were the plants experimented with.

In the experiments with peas the yields of dry matter on the pots receiving no alkali fertilizer were 9.47 and 11.51 gm., average 10.49 gm.; the yields on the 2 pots receiving potassium chlorid were 23.43 and 32.44 gm., average 27.94 gm., and the yields on the 2 pots receiving sodium chlorid were 10.65 and 11.36, average 11.01 gm. The addition of sodium chlorid resulted in an increase of 0.52 gm. of dry matter as compared with the pots which received no alkali.

Chemical analysis of the products gave the following results:

Composition of pea plants grown with and without alkalis in the fertilizer.

		Potassium oxid.	Sodium oxid	Calcium oxid.	Magnesium oxid.	Iron oxid.	Phosphoric acid.	Sulphuric acid.	Nitrogen.
	Per ct.	*Per ct*	*Per ct.*	*Per ct.*	*Per ct*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
No fertilizer	14.854	0.376	0.327	5 385	1 223	0 708	0.746	0.532	3.914
Potassium chlorid	14 653	3.243	099	2.784	534	.150	837	.523	3.865
Sodium chlorid	13 775	.448	559	4.737	1.025	.601	.731	.552	3.650

The slight increase in potash content due to sodium chlorid must be ascribed to indirect action. It is of interest to note that in the yield from the pots receiving no alkalis the lime and magnesia contents are great.

In the experiments with oats the yields of dry matter on the pots receiving no alkali fertilizer were 9.72 and 10.74 gm., average 10.23 gm.; on pots receiving potassium chlorid, 64.74 and 67.36, average 66.05 gm.; on pots receiving sodium chlorid, 13.05 and 9.26 gm., average 11.16 gm. There was an insignificant increase of yield of dry matter due to sodium chlorid. Chemical analysis of the oats gave the following results:

Composition of oat plants grown with and without alkalis in the fertilizer.

	Ash.	Potassium oxid.	Sodium oxid.	Calcium oxid.	Magnesium oxid.	Iron oxid.	Phosphoric acid.	Sulphuric acid.	Nitrogen.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct*	*Per ct.*	*Per ct*	*Per ct.*
No fertilizer	11.680	0.278	0.469	3.457	0 949	0.162	.676	0.674	2.378
Potassium chlorid	14.217	3.248	.396	1.869	1.036	172	.662	.809	1.848
Sodium chlorid	16.811	.340	3.578	1.583	.928	.144	.864	.688	2.960

The slight increase in potash where sodium chlorid was applied was probably due to indirect action. The plants from the pots receiving potassium chlorid contained large amounts of sodium oxid.

In the experiments with carrots the crop was in all cases small, in consequence of late sowing. The yields of dry matter in the leaves and roots were as follows: On the pots receiving no alkali fertilizer—leaves, 3.58 and 4.95 gm., average 4.27 gm.; roots, 4.95 and 7.82 gm., average 6.39 gm.; on the pots receiving potassium chlorid—leaves, 7.31 and 11.57 gm., average 9.44 gm.; roots, 17.76 and 25.25 gm., average 21.51 gm.; on the pots receiving sodium chlorid—leaves, 5.65 and 4.91 gm., average 5.28 gm.; roots, 5.65 and 7.23 gm., average 6.44 gm. The increase in yield due to sodium chlorid was insignificant. Chemical analysis of the leaves and roots gave the following results:

Composition of carrots grown with and without alkalis in the fertilizer.

	Ash	Potassium oxid.	Sodium oxid.	Calcium oxid.	Magnesium oxid.	Iron oxid.	Phosphoric acid.	Sulphuric acid.	Nitrogen.

Roots	4.625	.627	.753	.283	.284	.021	.480	.251	1.950
Potassium chlorid:									
Leaves	18.066	5.130	.313	4.523	.614	.102	.386	.769	3.190
Roots	9.079	4.101	.223	.303	.187	.159	.501	.262	2.023
Sodium chlorid									
Leaves	20.687	.824	4.752	4.464	1.070	.155	.611	.667	3.611
Roots	7.791	.939	1.927	.367	.341	.027	.728	.341	2.432

Here again there was only a slight increase in potash, corresponding to the increase in the general yield due to the sodium oxid.

In the experiments with buckwheat the yields of dry matter were as follows: On pots receiving no alkali fertilizer, 6.42 and 7.19 gm., average 6.81 gm.; pots receiving potassium chlorid, 29.46 and 21.57 gm., average 25.52 gm.; pots receiving sodium chlorid, 6.15 and 7.54 gm., average 6.85. The fertilizing with sodium chlorid gave a very insignificant increase in yield. The chemical analysis of the crop gave the following results:

Composition of buckwheat with and without alkalis in the fertilizer.

	Ash.	Potassium oxid.	Sodium.	Calcium oxid.	Magnesium oxid.	Iron oxid.	Phosphoric acid.	Sulphuric acid.	Nitrogen.
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
No fertilizer	12.121	0.584	0.077	3.502	1.402	1.139	1.765	0.647	4.720
Potassium chlorid	11.533	2.834	.059	2.125	.267	.714	.908	.415	3.772
Sodium chlorid	13.686	.763	.136	2.489	2.402	.358	1.382	.727	2.723

From these experiments it is clear that the formation of organic matter depended upon the minute quantities of potash, together with other fertilizing constituents present in the soil. The increase of the crop due either directly or indirectly to the introduction into the soil of sodium chlorid is scarcely worth mentioning.—P. FIREMAN.

The work of bacteria in barnyard manure (*Deut. Landw. Presse, 26 (1899), No. 26, p. 293*).—A review of the book by A. Stutzer on this subject.

Control of fertilizers during 1898, M. WEIBULL (*Tidskr. Landtmän, 20 (1899), No. 4, pp. 55–59*).

Analyses of commercial fertilizers, B. W. KILGORE ET AL. (*Mississippi Sta. Buls. 51, pp. 11; 52, pp. 18*).—These bulletins include explanations of terms used in fertilizer analyses, notes on valuation, tabulated analyses and valuations of 87 samples of fertilizers collected during December, 1898, and January and February, 1899, and guaranteed analyses of 71 brands of fertilizers registered for sale in the State.

Commercial fertilizers, W. C. STUBBS (*Louisiana Stas. Bul. 54, 2. ser., pp. 60–98*).—This bulletin gives the text of the State fertilizer law; discusses the nature and uses of various forms of nitrogenous, phosphatic, and potash fertilizers; and reports analyses of 195 samples of fertilizing materials, including ammoniated superphosphates, acid phosphates, cotton-seed meal, tankage, bone meal, dried blood, kainit, sulphate and muriate of potash, Tennessee phosphate rock, ground phosphate, boneblack, floats, slag meal, sulphate of ammonia, fish scrap, and ground shrimp refuse.

On the presence of injurious constituents in Chile saltpeter, M. WEIBULL (*Tidskr. Landtmän, 19 (1898), No. 45, pp. 801–803*).—The samples examined contained less than 1 per cent of sodium perchlorate; a complete analysis given shows 0.9 per cent of perchlorate. Nitrate of soda containing over 15 per cent of nitrogen has not been found to contain sufficient perchlorate to do any damage to crops.—F. W. WOLL.

Fertilizer experiments with Thomas slag on marshy soil, S. RHODIN (*K. Landt. Akad. Handl. Tidskr., 37 (1898), No. 5–6, pp. 285–291*).—Comparisons of Domnarfvet (Swedish) and foreign Thomas slag on barley.—F. W. WOLL.

Phosphatic fertilizers in the culture of sugar beets, MAIZIÈRES (*L'Engrais, 14 (1899), No. 16, pp. 372, 373*).—A general discussion.

FIELD CROPS.

Fertilizer, culture, and variety experiments on corn, R. J. REDDING (*Georgia Sta. Bul. 41, pp. 186–201*).—The work comprises variety and fertilizer tests and distance experiments. Similar work has been previously reported (E. S. R., 10, p. 138). The results of the experiments are given in tables.

Of 14 varieties, Bradberry Improved, Shannon Extra Early, Cocke Prolific, and Sanders Improved produced the largest yields, 33.04, 32.71, 32.23, and 31.37 bu. per acre, respectively. The results of tests of varieties during the last 7 years are given in tabular form.

A fertilizer experiment was made to determine whether corn prefers any particular form of nitrogen. The fertilizers employed were cotton-seed meal, nitrate of soda, and dried blood. These nitrogenous fertilizers were mixed with acid phosphate and muriate of potash in such proportions that all mixtures supplied equal amounts of phosphoric acid, potash, and nitrogen. The conclusion is drawn that dried blood is probably a little more effective as a source of nitrogen than nitrate of soda or cotton-seed meal, but that the cotton-seed meal is most economical.

Corn was grown in rows 4 ft. apart with single plants 2, 3, and 4 ft. apart in the row. The best results were obtained where the distance between the plants in the row was 3 ft. Other tests in spacing the plants confirmed the results of previous experiments.

General notes on corn culture are reprinted from Bulletin 34 of the station (E. S. R., 9, p. 124).

Methods and results of tillage, M. W. FULTON (*Michigan Sta. Bul. 164, pp. 79–96*).—The work here described is in continuation of experiments reported in a former bulletin (E. S. R., 10, p. 136). Experiments were made on the preparation of the soil for oats, and methods of cultivating corn. The moisture conditions on oat, corn, wheat, and clover plats were studied, and the effect of tillage on the moisture content of the soil determined. The results obtained are given in tables and discussed. The rainfall from April to October, inclusive, is reported.

Corn was grown on two series of four plats each. The soil of the first series was a sandy loam somewhat gravelly below a depth of 1 ft., while the soil of the second series was not quite so sandy at the surface and contained more clay below the first foot. In each series, plat 1 was not cultivated; plats 2 and 3 were given 3 cultivations with a weeder, 7 with a Gale cultivator, and 7 with a Planet Jr. cultivator; and plat 4 was cultivated 5 times with a Gale cultivator. The crop was cut September 10 and 12 and the yield was determined at that time. The average percentage of moisture at different depths, from June 4 to September 7, and the yields of the different plats are given in the following table:

The yields of corn and the average moisture content of soil under different methods of cultivation.

	Cultivation.	Yield of corn.		Moisture content of soil.			
		Green corn.	Dry matter.	First foot.	Second foot.	Third foot.	Average for 3 feet.
First series:		*Pounds.*	*Pounds.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Plat 1	None	2,180	723	6.16	4.70	6.66	5.84
Plat 2	Frequent, 3 in. deep	13,207	5,532	7.15	5.72	8.23	7.03
Plat 3	Frequent, 5 in. deep.	12,687	4,799	7.45	5.98	7.83	7.09
Plat 4	Ordinary, 5 in. deep	12,167	4,380	6.28	5.64	8.44	6.79
Second series:							
Plat 1	None	1,848	620	7.16	6.36	11.73	8.42
Plat 2	Frequent, 3 in. deep	12,258	4,790	8.41	6.81	12.74	9.35
Plat 3	Frequent, 5 in. deep	12,700	4,728	8.75	7.36	12.10	9.40
Plat 4	Ordinary, 5 in. deep	10,514	3,849	7.74	8.26	11.41	9.14

The corn which was not cultivated gave a very small yield and was inferior in quality. Frequent cultivation to a depth of 3 in. gave the best results.

"When the climatic conditions are normal . . . and oat ground is to be plowed before sowing it is better . . . that the plowing be done in the fall. In [these] experiments . . . there was a difference in yield of over 9 bu. per acre in favor of the plats plowed in the fall over those plowed in the spring. Rolling sandy loam for oats is indicated as a good practice whether the rolling be done before or after the oats are drilled, although the difference in yield attributable to variations in methods of preparation of the soil was small. . . .

"Wheat ground dries out very rapidly while the crop is ripening. The decrease in moisture in the upper 3 ft. was found to be 16.27 per cent within 1 week. . . . Later if the season be dry a loss of more than 15 per cent of the moisture remaining when the wheat is harvested may be expected.

"In the early spring unplowed land was found to contain more moisture than fall-plowed land adjacent. Later in the season the reverse was the case. An important saving in soil moisture was effected by early spring plowing . . . with a thorough preparation of the plowed land."

Determinations of soil moisture on a clover plat of sandy soil and an adjacent plat which had produced no crop, were made July 20. The results showed that the soil of the fallow plat contained 62.5 per cent more moisture than the clover plat.

Observations were made on the time required for a heavy rain to soak into a dry sandy soil. On July 21 1.22 in. of rain fell, and on July 26 there was a precipitation of 4.34 in. The moisture did not become normally distributed throughout the upper 3 ft. of soil until July 31.

The cost of cotton production, J. HYDE and J. L. WATKINS (*U. S. Dept. Agr., Division of Statistics Bul. 16, pp. 99*).—This bulletin gives in tabular form the average itemized cost of the production of cotton, the returns, and the net profit in each cotton-growing State or Territory; and further discusses the cost of producing cotton under different moisture, soil, and labor conditions.

Data are given to show the relation of the use of fertilizers to the cost of production and the relation of the values of lint and seed. The range of the different items which enter into the cost of production is considered, and estimates of the cost of cotton production at different periods from 1822 to the present time are given. Circulars were sent to planters living in different sections of counties producing 400 or more bales of cotton. Estimates were received from 3,846 planters, comprising land owners, renters, and share croppers, in 717 counties. Of this number of estimates 400 were rejected for various reasons.

Of the 3,335 upland plantations, 2,659 reported a profit and 676 a loss. Of 111 plantations producing sea-island cotton, 85 reported a profit and 26 a loss. From the data obtained in the estimates it was found that the average cost of producing an acre of upland and sea-island cotton in 1896 was $15.42 and $21.95 respectively. On the plantations showing a profit the cost of producing an acre of upland and sea island cotton was $15.60 and $23 02, and on the plantations reporting a loss $14.68 and $18.44, respectively. The lowest cost of producing 100 lbs. of common lint on upland plantations was found to be $5.51 in Oklahoma and the highest $6.29 in Arkansas; on sea island plantations the lowest was $11.07 in Georgia and the highest $17.89 in South Carolina; the average cost on all upland plantations being $6.03 and on all sea island plantations $13.05 per 100 lbs. Twelve estimates received from 3 counties in Texas and 1 estimate from Utah showed that the average cost of producing an acre of cotton by irrigation in 1896 was $19.92 in Texas and $40.05 in Utah.

Experiments with flax conducted by the German Agricultural Society in 1898, LEITHIGER (*Mitt. Deut. Landw. Gesell., 1899, No. 5, pp. 61-65*).—This report describes the plan, extent, and purpose of the experiments, and gives the results in tabular form. The work comprised experiments with nitrogenous fertilizers and tests of sowing flax at different rates. The results of two years' experiments show that the use of nitrate of soda and blood meal gave an increase in the yield of straw, increased the loss in retting, decreased the fiber content, and had a detrimental effect upon the quality of the fiber.

Flax sown at the rate of 181.24 lbs. per acre had a smaller loss in retting and also a smaller fiber content than flax sown at the rate of 160.57 lbs. per acre. Sowing at the rate of 212.10 lbs. per acre produced a thick stand and the crop suffered a heavier loss in retting, was lower in fiber content, and poorer in quality than flax which had a thinner stand. Sowing at the rate of 181.24 lbs. per acre is recommended for medium heavy soils in a good state of cultivation.

Culture of wheat and oats on the experimental fields at Grignon in 1898, P. P. DEHÉRAIN (*Ann. Agron., 21 (1898), No. 11, pp. 520-534*).—Three varieties of wheat—Scholley, Daltel, and Bordier—were sown on October 15 and November 6 on plats, some of which had produced potatoes and others beets the year previous. Scholley was the most productive variety in every instance. The early-sown plats and those which had grown beets the year before gave better results than those sown later or those which had yielded potatoes. A top-dressing of 200 kg. of nitrate of soda per hectare was given some of these plats in the spring, while others were left unfertilized. The results were but slightly in favor of the use of nitrate of soda. The author believes that owing to a sufficient supply of moisture during the season the conditions for nitrifying the nitrogenous matter in the soil were so favorable that the addition of the nitrate was of but little advantage. It is concluded that these results are another proof that by irrigation the outlay for nitrogenous fertilizers may be considerably diminished.

On 10 plats wheat was grown after clover, and the results show that the clover crop prepares the soil well for wheat. On these plats an application of 10,000 kg. of barnyard manure and 100 kg. of nitrate of soda per hectare was quite effective, but the application of 20,000 kg. of barnyard manure alone gave the best results. The use of 200 kg. of nitrate of soda per hectare did not show any effect. The author states that climatic conditions were more favorable to the use of barnyard manure than to the readily available nitrate.

Of 3 varieties of oats—Houdan, Salines, and Ligowo—the last mentioned gave the best results. The variety Houdan lodged about June 25, but ripened its grain.

Report on the agricultural investigations in Alaska, C. C. GEORGESON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 62, pp. 7-17, pl. 1, figs. 2, map 1*).—This report is part of a bulletin constituting a second report to Congress on agriculture in Alaska. The plan and progress of agricultural investigations carried on in Alaska in 1898 are described, and the present agricultural conditions and the possibilities of their improvement are discussed. Culture tests with field crops and vegetables were carried on at Sitka and Skagway. The field crops tested were oats, barley, buckwheat, flax, and clovers. All gave returns indicating that they can be successfully grown in that region. A large number of vegetables were tested and the climate and soil proved favorable to the growth of all excepting spinach and wax beans. In some instances at Skagway the vegetable seed failed to grow or the young plants were killed by disease. The experiences in farming and gardening of settlers in various parts of the Territory are given in a series of letters.

Soil temperatures, taken at Sitka and Skagway, and the moisture and organic matter in the water-free soil, determined by Prof. M. Whitney, in soil samples taken at Sitka and Kenai are reported.

The results of this work have been reviewed in a former number (E. S. R., 10, p. 701).

Field experiments, C. D. SMITH (*Michigan Sta. Rpt. 1897, pp. 87-90*).—The results of variety tests at the experiment station with wheat, millet, corn, oats, clover, alfalfa, Kafir corn, and sorghum during the season of 1897 are here briefly summarized. Observations on these crops have been published in the station bulletins (E. S. R., 9, p. 131; 10, p. 136).

Farm crops, C. D. SMITH (*Michigan Sta. Rpt. 1897, pp. 91, 92*).—This article is a report on the cost and labor involved in the production of various crops grown at the State experiment station. The conclusions drawn from this work have been published in Bulletin 149 of the station (E. S. R., 9, p. 1081).

Forage crops in the James River Valley in 1898, E. C. CHILCOTT and R. S. ROE (*South Dakota Sta. Bul. 61, pp. 3-16, figs. 7*).—Results of previous work in this line have been published in former bulletins (E. S. R., 10, p. 629). As in other years, the crops were grown under artesian irrigation. The grass plats established in 1896 and which have survived two winters and three summers have been preserved. Brief descriptive notes of culture tests of the following forage plants are given: Clovers, *Bromus inermis*, tall meadow grass, blue joint, alfalfa, peas, oats and peas, oats and vetch, rape, millet, sand vetch, corn and cane, and several grass mixtures. "The results obtained with brome grass, alfalfa, the clovers, and some of the meadow mixtures . . . prove without a reasonable doubt that we have found cultivated grasses and leguminous plants to take the place of the native grasses."

Plants on good and poor meadows in Wurttemberg in the light of modern theories of animal nutrition, R. BRAUNGART (*Landw. Jahrb., 27 (1898) Nos. 3-4, pp. 373-502*).—This article enumerates and describes briefly the various species of grasses and other plants growing on the meadows and pasture lands in different sections of Wurttemberg. The plants are grouped according to their feeding value, and the proportion of individual plants of each species to the total number of plants on the meadows is estimated.

The seed mixtures for permanent meadows and pastures of the moor soils of the north German lowlands and their relation to the ecology of the meadows, C. A. WEBER (*Landw. Jahrb., 27 (1898), Sup. 4, pp. 451-502*).—This article classifies the meadows of this region into four different types and gives a description of each. The forage plants found on these meadows and those recommended to be sown are described and their composition given. Ten grass mixtures are suggested, and the conditions of soil and climate to which they are adapted are pointed out and cultural methods recommended.

The influence of frost on the productivity of fall-plowed land, E. WOLLNY (*Bl. Zuckerrübenbau, 6 (1899), No. 6, pp. 82–86*).—The results of investigations show that fall-plowed land, not subsequently smoothed, was greatly benefited by the action of frost during the winter.

Breeding prolific varieties, A. KIRSCHE (*Ztschr. Landw. Ver. Hessen, 1899, No. 12, pp. 145, 146*).—A popular article by a practical breeder on the subject of breeding prolific varieties of field crops.

The varieties and forms of barley, A. ATTERBERG (*Jour. Landw., 47 (1899), No. 1, pp. 1–44*).—A classification of the cultivated varieties of barley, enumerating 188 sorts and in many instances giving their origin.

Resowing clover in spring, TANCRÉ (*Fühling's Landw. Ztg., 48 (1899), No. 8, pp. 306–308*).—This article describes the methods of resowing parts of clover fields or meadows which have been injured by frost or where the plants have been killed out by other causes. Several mixtures of grasses and clovers are suggested for this purpose.

Experiments with commercial fertilizers on corn, A. CARRÉ (*Prog. Agr. et Vit. (Ed. L'Est.), 20 (1899), No. 16, pp. 495–502*).—This article is a report on cooperative experiments with commercial fertilizers on corn carried on in France. The results obtained by the different experimenters are given in tables.

Phosphatic fertilizers in their relation to the lodging of grains, L. GRANDEAU (*Jour. Agr. Prat., 1899, I, No. 14, pp. 489, 490*).—The article states that phosphatic fertilizers give good results when applied in the spring and counteract the tendency of the grains to lodge.

Investigations and experiments on hemp, M. SAMOGGIA (*Staz. Sper. Agr. Ital., 31 (1898), No. 4, pp. 417–448*).

Chemical composition of different varieties of lupines, A. SEMPOLOWSKI (*Fühling's Landw. Ztg., 48 (1899), No. 7, pp. 245, 246*).—The chemical composition of air-dry seed of 11 varieties of lupines is given in a table.

Experiments in planting potatoes at different intervals and double cropping with cabbage, H. DAUTHENAY (*Rev. Hort., 71 (1899), No. 8, pp. 182, 183*).—Potatoes in rows 60 cm. apart and plants 50 cm. in the row gave the highest yields. Double cropping with cabbage is recommended. Lists of varieties of both crops that should be planted together are given.

Potato tests in 1898, L. S. SPENCER (*Amer. Gard., 20 (1899), No. 217, p. 125*).—Report of tests of a large number of varieties of potatoes in Illinois. A list of 42 varieties that proved satisfactory is given with descriptions; also a list of varieties deemed unworthy of further trial. The following varieties never failed to produce a good crop: *Extra early.*—Acme, Early Michigan. *Second early.*—Burpee Extra Early, Early Norther. *First late.*—State of Maine, Burr No. 1. *Second late.*—Livingston Banner, Pink Gem.

Potato culture, G. BATTANCHON (*Prog. Agr. et Vit. (Ed. L'Est), 20 (1899), No. 15, pp. 460–463*).—A popular article on potato culture in France.

Hollow potatoes (*Belg. Hort. et Agr., 11 (1899), No. 8, pp. 116, 117*).—A discussion on the occurrence of hollow potatoes and its prevention.

Distances at which sugar beets should be planted, A. GUTTMANN (*Deut. Landw. Presse, 26 (1899), No. 36, p. 289*).—A popular discussion of the subject in connection with Russian sugar-beet culture. Beets planted 25 to 27 cm. apart in rows 40 cm. apart gave better results than beets grown at shorter distances.

Sugar beets in the James River Valley, E. C. CHILCOTT and R. S. ROE (*South Dakota Sta. Bul. 61, pp. 28, 29*).—A plat of sugar beets with a stand of about 70 per cent yielded over 18 tons per acre with 20.6 per cent sugar in the juice and a purity coefficient of 94.

Modern beet-seed culture, H. K. GÜNTHER (*Bl. Zuckerrübenbau, 6 (1899), No. 7, pp. 97–104*).—This article is an historical review of the development of the sugar beet and a résumé of scientific investigations in this connection. Attention is called to the need of further investigations.

Investigations on the culture of tobacco at the experiment station of the Lokhvitz Agricultural Society, P. LOMONOSOV (*Selsk. Khoz. i. Lyesov., 192 (1899), Jan., pp. 185–208*).

Farmers and fruit-growers' guide, 1898, W. H. CLARKE (*Sydney: W. A. Gullick, 1898, 3 ed., pp. 495, ill.*).—Similar in scope and contents to the second edition (E. S. R., 9, p. 298).

HORTICULTURE.

A report of progress on investigations on the fertilizer requirements of fruit trees, BARTH-COLMAR (*Gartenflora, 48 (1899), No. 5, pp. 125, 126*).—Ninety analyses of vegetative organs of fruit trees were made to determine the fertilizer requirements of each. These results were supplemented by numerous collated analyses of fruits and researches on wood, leaf, and fruit growth. From these data the formula for a fertilizer is determined, which is believed to afford a rational basis for further fertilizer experiments on fruit trees. The calculations are made for trees with tops of 5 meters diameter and spreading over perhaps 20 square meters of ground. A table shows the increase in one year in weight of dry matter in the root wood, trunk wood, branch wood, leaves, and fruit of one such cherry, plum, apple, and pear tree, respectively. Another table shows the average percentage of nitrogen, potash, phosphoric acid, and lime in the several parts of pomaceous and drupaceous fruits. From these tables are estimated the fertilizer requirements for 1 square meter actually covered by tree tops:

The fertilizer requirements of certain fruit trees per square meter of area actually covered by tree tops.

	Nitrogen.	Potash.	Phosphoric acid.	Lime.
	Grams.	*Grams*	*Grams*	*Grams.*
Cherry	11.3	15.95	3.1	21.05
Peach	7.0	10.63	2.3	8.42
Apple	7.1	7.30	1.5	9.80
Pear	7.5	10.90	2.1	6.70

From these figures the following formula for 1 square meter of ground covered is derived: 10 gm. nitrogen, 15 gm. potash, 5 gm. phosphoric acid, and 20 gm. lime. The large proportion of potash in this formula is necessitated by the extensive leaf development of the cherry. The proportion of phosphoric acid in the mixture is greater than the yearly requirements of the plants on account of its slow availability in the soil, at least the first few seasons. It was found that in general in all fruit trees the proportion of plastic substance to the total dry matter gradually increased from the root wood through the stem wood and twig wood to the leaves. The proportion of nitrogen in all woody parts of the tree is greater than that of any other food element excepting lime, but in the leaves there is less nitrogen than potash, and this difference is still greater in the fruit. The woody parts of drupaceous trees are poorer in lime than are pomaceous trees, but the leaf is richer. This last statement is true also of the fruit, although in this case the difference is not so great. In the pits of cherries and plums nitrogen is much in excess of the ash, of which latter phosphoric acid forms the larger part. The results obtained in these experiments furnish additional evidence of the importance of potash in the production of sugar in the plant.

Olives, F. T. Bioletti and G. E. Colby (*California Sta. Bul. 123, pp. 35, figs. 7, pl. 1*).—This bulletin is intended to be a convenient summary of such practical information in regard to olive culture as is most in demand. Under the head of cultivation are discussed climate, soil, propagation, pruning, grafting, budding, and gathering the fruit. Under oil making are considered drying and crushing, the separation of the oil, and pressing and clarification. Under pickling are discussed the lye process, pure-water process, manufacture of green pickles, nutritive value of olives, and grading and sorting. A number of the best-known varieties are described and notes are given on the twig borer, black scale, sooty mold, peacock leaf-spot, dry rot, bacterial rot, and olive knot.

Investigations were made on the comparative value of ripe and green pickled olives as foods. Analyses are shown in the following table:

Analyses of edible part of ripe and green pickled olives.

	Ripe olives from California.			Green Queen olives from Spain.
	Medium sized Mission.		Larger Watery Mission.	
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
Water	64.72	65.45	72.77	78.41
Oil	25.89	25.15	18.81	12.90
Carbohydrates	4.28	3.22	2.49	1.78
Other substances	5.11	6.18	5.93	6.91

From this table it is seen that pickled ripe olives are very nutritious, much more so than green olives. They are also said to be more assimilable.

Studies were made of variations of size of fruit and amount of pit and oil in different varieties. The ratio of the smallest to the largest fruit, the pit, and oil in the flesh in each of 15 varieties are tabulated, and the averages for each of 57 are given.

The averages for varieties of which 10 or more samples have been examined are as follows:

Average size and composition of olives by varieties.

Variety.	Number of samples examined.	Number of olives per pound.	Percentage of pit.	Percentage of oil.		
				In whole fruit.	In flesh.	In pit, referred to whole fruit.
Varieties fully tested:						
Mission	112	111.6	17.2	17.56	22.51	0.61
Nevadillo Blanco	57	157.3	17.3	19.21	22.92	.99
Manzanillo	38	106.6	14.7	16.94	19.73	.55

Razzo	10	216.5	21.3	21.10	28.42	.84

It was found that the above varieties fully tested "as grown in the bay region are all of smaller size than those from any of the other regions of the State, but generally they bear the largest percentages of oil. . . . It would seem, then, that the cool bay climate does not prevent the proper functioning of the drupe in these varieties."

Hybrid plums, F. A. WAUGH (*Vermont Sta. Bul. 67, pp. 30, figs. 16*).—Hybrids have recently appeared as a new factor in the study of plums. In this bulletin the author has collected the best information obtainable regarding every hybrid of which he can learn. The importance to the science of pomology of putting these first hybrids on record is noted, as also the desirability of understanding "as well and as soon as possible the general limits, tendencies, and effects of hybridity among plums." It is believed that, aside from individual varieties, "which are mostly the intentional or unintentional products of cultivation, there are certain large groups of hybrids occurring in nature." Among such are the Wildgoose, Miner, and Wayland groups, the parentage of which the author has attempted to determine. "On purely speculative grounds we may assume that the Wildgoose group is the result of various primary crosses between the wild *Prunus americana* and *P. angustifolia*, and that the Miner group represents secondary crosses between the Wildgoose group and the Americanas. With somewhat less certainty we may assume that the Wayland group has arisen from crosses of *P. angustifolia* with the southern form of the Americana plum, *P. americana mollis*." It was found that the horticultural hybrids now known also occur in groups.

The question of what constitute trustworthy evidences of hybridity is discussed. The author opposes the commonly received opinion that hand pollination furnishes the only basis upon which hybridity may be certified. Even in cases of hand pollination it is pointed out that the results are very uncertain and that "the extrinsic characteristics of [a hybrid] are relied upon for the final proof of its parentage." It is laid down as a working principle that "for all practical, and for most scientific, purposes, intermediateness of character is the only practicable and the most reliable test of hybridity." As such the author assumes it as the sole basis of classification, which is defined to be "first of all, a systematic presentation of apparent resemblances and differences."

Proceeding from this point of view, the author abandons the natural classification of a hybrid by naming its parents and declares that "a hybrid is to be classified by referring it to the several species whose characters it exhibits." The existence of intergradient forms makes the work of hybrid-plum classification difficult. In this work 2 points must be observed: "First, one must fix in his mind certain definite types; and, second, he must group the multitudinous varieties about these types, referring them to whatever type or types they seem most to resemble."

So far as the data at hand would permit, the limits of crossing between species and of the affinities of one species for others were determined. Of 30 varieties of probable hybrid origin, 90 per cent are referred to *P. triflora.* Aside from the fact that especial efforts have been made to secure Japanese hybrids, the author considers it probable that "the Japanese plums have a special affinity for the Chickasaws and for the closely related members of the Wildgoose group." The fact is also brought out that only one hybrid is referred to *P. domestica.* The belief is expressed that the opinion for some time prevalent among fruit growers, that the Domestica plums do not cross naturally with other species and that hybrids may be produced artificially only with extreme difficulty, is probably correct. It is also believed that the Americanas have less affinity for other species than the Chickasaws, Hortulanas, or Trifloras; but it is considered settled that crosses can be effected under favorable conditions between any two species of plums. Hybridization of plums, however, is not restricted to these limits, for they have been hybridized with the cherry, peach, and apricot. It is believed that a great number of accidental hybrids will be brought to light in the next few years and that "the introduction of the hybrid plums marks an epoch in plum culture. The results promise to be even more abundant and far-reaching than those which have flowed from the hybridization of the grape." Other possibilities in plum hybridization are suggested.

The fruit of Feijoa sellowiana, E. ANDRÉ (*Rev. Hort., 71 (1899), No. 3, pp. 66, 67, figs. 2*).—Notes additional to those already given (E. S. R., 10, p. 757). This tree is still thriving in the south of France without shelter. A second year's observation has given the author occasion to modify his description of it in certain details. In 1898 about 100 fruits were obtained, which are described as follows: The largest weighed 75 gm. and was 8 cm. long and 5.6 cm. thick. The fruit is much dented, slightly and unequally furrowed, smooth at maturity, at first a deep green, becoming dark yellowish green, texture firm. The flesh is a thick, creamy yellow, of the consistency of a pear, and its flavor is suggestive of the aroma of the strawberry. It possesses a very heavy perfume.

Experiments in ringing grapevines, W. PADDOCK (*New York State Sta. Bul. 151, pp. 265–275, figs. 4, pls. 2*).—An introductory statement is made of the principles of sap movement concerned in ringing and their application in practice. Experiments were carried on for two seasons in two vineyards to test the process and its modifications. In the first vineyard the vines were trained on the two-arm Kniffin system. Both arms of most of the vines in these experiments were ringed just beyond the fifth bud, the remainder just beyond the renewal bud. In the second vineyard the vines were trained on the renewal system and the rings were made just beyond the renewal bud. The results of these experiments are given in the following résumé:

"Ringing grapevines, generally speaking, produces an earlier ripening of the fruit and larger bunches and berries.

"These results, however, depend on several factors, among which may be mentioned: Variety, season, and abundance or lack of healthy foliage, good culture or lack of it, and the amount of fruit the vine is allowed to mature.

"That some varieties suffer a loss of quality when ringed there is little doubt; other varieties do not appear to be affected in this manner by the operation. Cutting back the new growth on ringed arms appeared to result in giving better quality to the fruit.

"The process is more or less devitalizing in its effect on the vine, depending in part, at least, on the factors mentioned in the second paragraph. It has been found in practice, however, that some varieties when judiciously managed may be ringed for a number of years in succession with little injury to the vine.

"Vines grown on the renewal system would seem to be better adapted to ringing than those grown on the Kniffin plan, since with the former more wood can be left to support the vine than is possible with the latter system."

Annual flowers, G. N. LAUMAN and L. H. BAILEY (*New York Cornell Sta. Bul. 161, pp. 291–322, figs. 11*).—The primary purpose of this bulletin is to give advice as to improvement of home grounds. In any place flowers should be accessories. The author states that the main planting should be of trees and shrubs; the flowers constitute the decorations and should be planted against a background. If the motive is not so much decoration as the growing of flowers for flowers' sake, a bed may be planted, but it should be at one side of the house or in the rear and not in the middle of the lawn. Many annual plants make effective screens, as morning glories and other climbers. Cultural directions for growing annuals are given. A table gives a list of 459 flowering annuals successfully grown at Ithaca in 1897 and 1898 under usual conditions of culture. There are also given the dates of first bloom, full bloom, and last bloom at the station, together with height, habit, color, and other remarks. It is hoped that these statistics may also be useful to florists, catalogue makers, and others particularly interested in this class of plants. The following groups are specially mentioned as staple or general-purpose types: Petunias, phloxes, pinks or dianthuses, larkspurs or delphiniums, calliopsis or coreopsis, pot marigold or calendula, bachelor's button or *Centaurea cyanus*, clarkias, zinnias, marigolds or tagetes, collinsias, gilias, California poppies or eschscholtzias, verbenas, poppies, China asters, sweet peas, nemophilas, portulacas, silenes, candytufts or iberis, alyssum, stocks or matthiolas, morning-glories, nasturtiums or tropæolums.

Hints on rural school grounds, L. H. Bailey (*New York Cornell Sta. Bul. 160, pp. 271-290, figs. 17*).—This bulletin is a first move on the part of the station toward the solution of the problem of the improvement of rural school grounds, which are stigmatized as being on the average "bare, harsh, cheerless, immodest." In beginning a reform, the plan of the place is of the utmost importance. First determine definitely the general outline and fill in details afterwards. "Begin with the plan, not the plants."

The place "should be hollow, well planted on the sides, open in the interior. The side next the highway should contain little planting. The place should be a picture, not a mere collection of trees and bushes." Mass plantings and focus attention; the nursery style of scattering trees over the lawn only distributes it. Suggestions are given on how to start a reform and how to make improvements. Notes are given on making the sod, how to make a border plan, the amount of plants for the main planting, and the kinds of plants for decoration.

Report of the horticulturist, L. R. Taft (*Michigan Sta. Rpt. 1897, pp. 92-95*).—Notes are given on the station orchard, small fruits, vegetable gardening, and spraying. Apples were almost a total failure. Among cherries Brusseler Braune, Wragg, and Ville Sweet are regarded as particularly promising, and notes are given on these varieties. Among the most promising Japan plums are Abundance, Burbank, Red June, Satsuma, and Wickson; and among strawberries may be mentioned Ruby, Glen Mary, and Ideal. Unfavorable notes are given on the strawberry-raspberry which is stated to be a wild Japanese variety of raspberry and not a hybrid. As in previous years, all the most promising novelties have been tested in the vegetable garden.

Fruit raising as an industry in the United States of North America, J. Nyemyetz (*Rpt. Min. Agr. and Imp. Domains, Dept. Agr. St. Petersburg, 1898, pp. XV+388, figs. 222, map 1; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Oct., pp. 226-228*).

The construction of greenhouse benches for subwatering, W. J. Green (*Florists' Exchange, 11 (1899), No. 16, p. 140*).—A summary of work on this problem at the Ohio Station since 1890.

A new method of watering grapes, fruit trees, and ornamental trees and shrubs, P. Andieu (*Prog. Agr. et Vit., 16 (1899), No. 17, pp. 513-518, fig. 1*).—The method consists in sinking a large cylinder or inverted funnel at the base of the plant. Where water is scarce, a great saving is effected by this means.

Principles of pruning shrubs, C. Baltet and Charguerand (*Florists' Exchange, 11 (1899), No. 17, pp. 470, 471*).—This article includes Baltet's tables.

Coffee pruning (*Jour. Jamaica Agr. Soc., 3 (1899), No. 4, pp. 207-209*).

What is the best season for planting cuttings of trees and shrubs in the nursery? PEPIN (*Belg. Hort. et Agr., 11 (1899), No. 7, pp. 99, 100*).—Contrary to the usual practice the writer plants cuttings of hardy trees and shrubs in the fall. The percentage of loss is less than when planted in the spring and the results far more satisfactory. The author's method of treating cuttings is described.

Celery as a vegetable, G. WYTHES (*Garden, 55 (1899), No. 1433, p. 309*).—Cultural directions, which differ somewhat from those for celery grown as a salad.

A new cucurbit, V. DAVIN (*Rev. Cult. Coloniales, 4 (1899), No. 20, pp. 19-21, fig. 1*).—Notes on a vegetable recently introduced into France It is believed to be descended from *Cucurbita pepo* and to come from Chile. It is a twining plant with large, yellow flowers and pyriform fruit. It is easy of culture, producing abundantly and is valuable as a food. It may be prepared for the table in numerous ways. It has a flavor much like the sweet potato.

Forcing rhubarb, C. CHEVALIER (*Belg. Hort. et Agr., 11 (1899), No. 8, p. 117*).—A method for forcing rhubarb is described. Early Tobolsk is considered the best forcing variety.

Garden crops in the James River Valley, E. C. CHILCOTT and R. S. ROE (*South Dakota Sta. Bul. 61, pp. 16-28, pls. 2*).—These are a continuation of tests already reported (E. S. R., 10, p. 639). Notes are given on onions, tomatoes, cabbage, cauliflower, beets, mangos, carrots, parsnips, salsify, turnips, radishes, lettuce, peas, beans, eggplant, melons, squash, pumpkins, cucumbers, and celery. On account of unfavorable circumstances, many of the yields were small.

Vanilla culture as practiced in the Seychelles Islands, S. J. GALBRAITH (*U. S. Dept. Agr., Division of Botany Bul. 21, pp. 24, figs. 4*).—This bulletin gives the general conditions of vanilla culture as practiced in the Seychelles Islands and gives directions for starting a vanillery, for preparing the vines, for cropping, pollination of the flowers, curing, and marketing the crop.

Apple tree roots and stocks (*Gard. Chron., 3. ser., 25 (1899), No. 641, pp. 264, 265; Amer. Gard., 20 (1899), No. 229, pp. 347, 348*).—A suggestive article for the experimental horticulturist, emphasizing the incompleteness of our knowledge of the root systems of trees and influence of stocks.

About 50 varieties of apples were worked on a dozen presumably different stocks. The stocks apparently exerted an influence upon the growth of the top for the first few years. Later, however, the top became sufficiently vigorous not only to neutralize the power of the stock, but seemingly even to modify the root growth.

Eighteen named sorts of stocks for the apple, representing, however, only 8 distinct varieties, were grafted with Blenheim Orange. A record was made of the number of blossoms appearing on each tree for 4 years after blossoming. Considerable differences were observed, but the disparity was as great between the results from the stocks of the same as different varieties.

Studies on the chemical composition of different varieties of apples and pears, R. OTTO (*Gartenflora, 48 (1899), No. 9, pp. 240-247*).—Analyses are reported of 55 varieties of apples and 8 of pears that had grown under the same conditions with special reference to their comparative value in the cider and perry industries.

Peach growing in New Jersey, A. T. JORDAN (*New Jersey Stas. Bul. 133, pp. 15, pls. 2*).—A report of the present status of the peach industry in New Jersey, based upon data obtained in the fruit census of 1895. The subject matter is discussed under the following heads: Soils for peaches, injury to buds, the purchase and setting of trees, varieties, cultivation and manuring, pruning and thinning, life of an orchard, insects and diseases, picking and marketing, yields, expenses and returns. "Crawford Late, Mountain Rose, Old Mixon, Stump and Reeve Favorite are the 5 most popular of the older varieties. Of the newer varieties, Elberta, Globe, and Susquehanna are favorite sorts."

A few historical notes are also given.

Pear culture in Florida (*Florida Agr., 26 (1899), No. 19, p. 290*).—An account of a successful grower's methods.

Improvement of the persimmon, H. MARION (*Missouri Hort. Soc. Rpt. 1898, pp. 273–276*).

The evolution of the strawberry, L. H. BAILEY (*Sci. Amer. Sup., 47 (1899), No. 1206, pp. 19337, 19338*).—The author believes that the very best proofs of evolution are found in the most familiar things, although they are least often mentioned in the literature of the subject. "We have been looking so far into the past, have searched so diligently for great facts, have so urgently desired to see the missing links and have so confounded ourselves with philosophy that we have forgotten to go out and see the creation going on about us." The parental form of the garden strawberry, *Fragaria grandiflora*, itself a variety of *F. chiloensis*, is made a text on which to hang a discussion of some of the evidences of evolution.

Manual on the culture of American grapevines, P. N. STROYEV (*Rpt. Min. Agr. and Imp. Domains, Dept. Agr. St. Petersburg, 1898, pp. IV+259+VIII; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Jan., p. 225*).

On the development and maturity of the vine, L. BÜRING (*Gard. and Field, 24 (1899), Nos. 10, pp. 254, 255, fig. 1; 11, p. 272*).—A general discussion of the influence of climatic conditions, latitude, altitude, mountain ranges, soil, water, moisture, and special situations.

The effects of lightning on the vine, L. RAVAZ and A. BONNET (*Prog. Agr. et Vit. (Ed. L'Est.), 20 (1899), No. 13, pp. 393–399, pl. 1*).—Extensive botanical and horticultural observations.

A study in training the vine, G. DERROUGH (*Prog. Agr. et Vit. (Ed. L'Est), 20 (1899), No. 8, pp. 237–241, figs. 36*).—Several methods of grape training with modifications are described and figured.

A new method of grafting the vine, SANNINO (*Atti e Mem. I. R. Soc. Agr. Gorizia, n. ser., 39 (1899), No. 3, pp. 52–58*).—The method is a modification of the crown graft. The scion is a section of wood bearing two buds and is cut as for splice grafting, the cut beginning just below the lower bud and on the opposite side. The stock is also prepared as for splice grafting, the scion being inserted under the bark and at the tip of the stock. The union is said to form very rapidly and without enlargement.

How ringing affects grapes, F. H. HALL and W. PADDOCK (*New York State Sta. Bul. 151, popular ed., pp. 4, figs. 4*).—A popular edition of Bulletin 151 of the station (see p. 49).

New and rare plants for alpine gardens and rockeries, H. CORREVON (*Gard. Chron., 3. ser., 23 (1898), Nos. 576, p. 28; 578, p. 50; 586, pp. 170, 171; 593, pp. 283, 284; 24 (1898), No. 612, p. 212; 25 (1899), Nos. 634, p. 100; 635, pp. 117, 118*).—Horticultural notes on a large number of species.

The present condition of bulb culture in Bermuda, A. F. WOODS (*Florists' Exchange, 11 (1899), No. 18, p. 494*).

Third supplement to the descriptive list of chrysanthemums for winter blooming, O. DE MEULENAERE (*Troisième supplément à la liste descriptive des chrysanthèmes d'hiver. Gand: Ad. Hoste, 1898, pp. 36*).

Bigeneric orchid hybrids (*Garden, 55 (1899), No. 1431, p. 265*).—Historical notes.

Curiosities of orchid breeding, C. C. HURST (*Gard. Chron., 3. ser., 25 (1899), No. 628, p. 14*).—A discussion of the limits of hybridization in the orchid family, the systematic status of 500 primary, 270 secondary, and 30 tertiary artificial hybrids of record, and the light that this study throws on the general subject of evolution of species by natural hybridization, which the author believes has been as yet far too little emphasized.

Grafted against own-root roses, F. R. MATHISON (*Amer. Florist, 14 (1899), No. 571, pp. 1229–1232*).

FORESTRY.

The trees of Wyoming and how to know them, A. Nelson (*Wyoming Sta. Bul. 40, pp. 59–110, figs. 27*).—The author illustrates and describes 16 genera of trees represented by 31 species. The descriptions and illustrations are of such a nature as to readily aid in the identification of the arborescent flora of the State. The list of trees of Wyoming, as given in this bulletin, contains the following species: Rock pine, limber pine, Lodgepole pine, Engelmann spruce, blue spruce, Douglas spruce, Rocky Mountain juniper, desert juniper, narrow-leaf cottonwood, lance-leaf cottonwood, common cottonwood, Balm of Gilead, aspen, almond-leaf willow, western black willow, Bebb willow, paper birch, western birch, paper leaf alder, bur oak, dwarf maple, large-tooth maple, box elder, green ash, wild plum, western chokecherry, black haw, long-spine haw, western serviceberry, silverberry, and buffalo berry.

New growth on burned areas in Colorado, C. S. Crandall (*Forester, 5 (1899), No. 1, pp. 7, 8, fig. 1*).—After mentioning the very slow manner in which forest areas that have been burned over are reforested, the author calls particular attention to two regions which have been investigated by him to some extent. The first is a tract in the Cache la Poudre region which was burned over in the summer of 1881. Examined 13 years later, grasses were found abundant among the dead logs and there were a few shrubs and a scattering growth of pines, the largest of which was 20 in. high and 7 years old. From this it is apparent that it was 6 years after the fire before the first pine tree started.

The second region mentioned was a tract on the south and west of Chambers Lake which was burned over in 1890. The author passed through the district a month after the fire, and states that not a green thing remained. A second visit was made to the tract 4 years later, and, with the exception of a few straggling plants of grasses and sedges, no vegetation had appeared.

The author states that the common belief that northern slopes are more quickly reforested than southern ones, on account of the greater effect which the sun's rays have on the south slopes in melting the winter's snows and exhausting the soil moisture appears to be well founded. Differences are also noted in the effect of forest fires on north and south slopes, it being claimed that fires are more destructive on the south slopes.

A century of the Department of Forestry [of the Russian Ministry of Agriculture and Imperial Domains], 1798–1898 (*St. Petersburg, 1898, pp. 251; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Nov., pp. 467–469*).

Report on forestry, C. D. Smith (*Michigan Sta. Rpt. 1897, p. 90*).—A brief account is given of the cooperative experiments which are being carried on between the station and the Division of Forestry of the United States Department of Agriculture. A list of the species planted is given. The object of the experiments, it is stated, is to determine what distinction, if any, could be seen in trees grown from the same variety of seed collected in different localities

Report on the Department of Forestry of the Ministry of Agriculture and Imperial Domains for 1896 (*St. Petersburg, 1897, pp. III+163+81; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Nov., pp. 466, 467*).—The gross income from the exploitation of the government forests for the fiscal year was 33,700,000 rubles (about $13,480,000), and the net income 26,500,000 rubles (about $10,600,000). The number of clerks and officials of the forestry department was 3,183. The forest guards numbered 30,333 men, besides 534 laborers. From the Institute of Forestry at St. Petersburg 63 persons graduated. The number of students in January, 1897, was 402. The expenditures of the institute were 166,500 rubles (about $66,600). In 23 lower schools there were 350 pupils. The maintenance of these schools costs 91,000 rubles (about $37,600).—P. FIREMAN.

SEEDS.

Seed examination, C. F. WHEELER (*Michigan Sta. Rpt. 1897, pp. 98, 99*).—The author gives a list of weed seeds found in 2 lots of seed imported from Europe. All the weed seeds are said to be of Old World species. Those found in the crimson clover were: *Lepidium campestre*, *Lychnis vespertina*, white mustard, charlock, kidney vetch, corn chamomile, chess, quack grass, common storksbill, and summer rape.

Similar examinations were made of the weed seed found in orchard grass imported from France. The weed seeds present were: *Brassica monensis*, *Arabis perfoliata*, wild candytuft, false flax, bladder campion, *Lychnis vespertina*, geranium, yellow melilot, black medick, Norway cinquefoil, Canada thistle, burdock, ox-eye daisy, *Leucanthemum maxium*, *Tragopogon pratensis*, *Picris hieracioides*, *Crepis bienis*, great bedstraw, caraway, rib grass, sorrel dock, common sorrel, curled dock, and velvet grass.

Seeds and low temperatures (*Science, n. ser., 8 (1898), 190, p. 215*).—It is stated that H. T. Brown and F. Escombe inclosed seeds in thin glass tubes immersed in a vacuum jacketed flask containing about 2 liters of liquid air. The air was replenished so as to subject the seeds for 110 hours to temperatures ranging from −183° C. to −192° C. The seeds used were: *Hordeum distichon*, *Avena sativa*, *Cucurbita pepo*, *Cyclanthera explodens*, *Lotus tetragonolobus*, *Pisum elatius*, *Trigonella fœnumgræcum*, *Impatiens balsamina*, *Helianthus annuus*, *Heracleum villosum*, *Convolvulus tricolor*, and *Funkia sieboldiana*. They had previously been air dried, and contained when the experiment began from 10 to 12 per cent of moisture. After their prolonged exposure to the intense cold the seeds were slowly thawed, the process requiring about 50 hours. They were then tested as to their germinative power by comparison with seeds from the same lot which had not been subjected to the low temperatures. Their germinative power showed no appreciable difference from the checks, and the resulting plants, which in most cases were grown to maturity, were equally healthy in all cases.

The authors concluded from their experiment that we must regard the protoplasm in resting seeds as existing in an absolutely inert state devoid of any trace of metabolic activity, and yet conserving the potentiality of life.

Chemical processes in the germination of seeds, F. ESCOMBE (*Sci. Progress, 7 (1898), pp. 219–236; abs. in Jour. Roy. Micros. Soc. [London], 1898, No. 5, pp. 561, 562*).—The author claims that during germination amids and amido acids perform different functions. Amids result in only small amounts from direct hydrolysis, being chiefly formed synthetically by the transformation of amido-acids and of nitrogenous substances derived from the reserve carbohydrates. The synthesis of amids takes place in the dark and the further stages of proteohydrolysis are due to enzymic action. It is claimed that protein can not be regenerated from amids in darkness, although its regeneration in the light is not proved. The author believes that the metabolism of germination is in the main chemically similar to that which occurs in mature plants.

On the change in composition which takes place during the germination of oil-bearing seed, L. MAQUENNE (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 17, pp. 625–628; Ann. Agron., 25 (1899), No. 1, pp. 5–16*).—The question as to whether the glycerin formed from the fats present in oil-bearing seed is capable of giving rise to carbohydrates in young plants, and whether there are marked differences existing between the saturated acids and the unsaturated ones, led to a series of experiments on the germination of peanuts which contain arachidic acid and saturated acid, and castor beans which contain ricinoleic acid.

The seeds were germinated in the dark in wet sand in porcelain pots. Seedlings were analyzed at frequent intervals, and their composition is shown in tabular form. The oil content was shown to gradually decrease, but it took place more rapidly with castor beans than with peanuts. The carbohydrates, represented largely by cellulose, the ash and undetermined constituents increased in about the same proportion. The differences noted in the constituents of the plantlets is said to depend upon the chemical composition of the seed. The saturated fatty acids proved less adapted to transformation into sugar than the oleic acids. The production of carbohydrates from ricinoleic and related acids seemed to depend upon the presence in the molecules of the acids of allyl groups which by combustion are transformed into glycerin, a less polymerized and less condensed form.

Report of Danish seed control, 1897–98, O. ROSTRUP (*Copenhagen. 1898, pp. 37*).

Twenty-sixth report of the seed-control station, Copenhagen, Denmark, for 1898 (*pp. 44*).—Contains a number of articles on different kinds of seed, preparation of seed, influence of weeds on crop yield, etc.—F. W. WOLL.

Report of Gothenburg seed-control station for 1897–98, J. E. ALÉN (*Gothenburg (Sweden), 1898, pp. 15*).

Report of the seed-control station for 1897, P. BAESSLER (*Bericht über die Thätigkeit der Agr. Chem. Versuchstation und Samencontrolstation in Köslin für 1897. Köslin, 1898*).

Plant-culture trials and seed control, 1897, B. LARSEN (*Christiania, 1898, pp. 39*).—Report of the experiment station supported by the Royal Society for Norway's Weal.—F. W. WOLL.

Report of the Skara seed-control station, S. HAMMAR (*Ber. Verks. Skara Kem. Sta. och Frökontrollanst., 1898, pp. 27–31*).—The principal varieties of seed tested were oats, red clover, timothy, and fir.

Catechism of seed control, F. F. BRUIJNING (*Landbouwers-Catechismus vorr de Zaadcontrole. Wageningen: H. Van Gortel, 1898, 6. ed., pp. 48*).

Report of seed investigations fôr 1896 in Brüx, Kaaden-Duppau, Konotau, Podersam, and Saaz, A. NOWOCZEK (*Kaaden, 1898, pp. 36*).

Concerning the methods of testing agricultural seeds, D. SAKELLARIO (*Wiener Illus. Gart. Ztg., 24 (1899), No. 4, pp. 123–131, figs. 3*).—Describes the methods and apparatus adopted at the Vienna seed-control station.

Regulations concerning seed testing by the Holland seed-control station, A. F. VAN LYNDEN (*Reglement voor de Onderzoekingen aan de Rijkslandbouwproefstations. Wageningen, 1898, pp. 15*).

The results of seed tests made at Modena from 1895 to 1898, F. TODARO (*Staz. Sper. Agr. Ital., 31 (1898), No. 3, pp. 235–243*).

A new germination apparatus for beet seed, E. LALLEMANT (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 9, pp. 879, 880.*)

DISEASES OF PLANTS.

Club root and black rot of the cabbage and turnip, L. R. JONES (*Vermont Sta. Bul. 66, pp. 16, figs. 9*).—The author notes the occurrence of club root of cruciferous plants, and reviews its history and causes. Specimens received at the station in September were examined, and it was found that the parasite causing the disease had passed into the spore condition. These spores usually remain in a dormant state incased within the roots until the following spring, when they are liberated by the decay of the roots.

The different methods by which the germs are disseminated are commented upon, the principal means being in manure and with seedling plants and nursery stock. An infection is reported in Vermont which was traced apparently to infected soil adhering to celery plants brought from a region where the club root was known to exist. A list of plants affected by this disease is given and remedial measures suggested, among them the destruction by burning, burying, or cooking of all diseased material which is fed to stock, deep plowing of soil in autumn where the disease is known to be present, rotation of crops, suppression of cruciferous weeds, and the use of lime. During the past season an experiment was made in which 80 bu. of lime per acre was scattered over the soil, and cabbages and turnips planted. The cabbage plants came from two sources, one of which was known to be infested, and the other free from disease. The turnips and cabbages from clean soil showed very markedly the effect of the lime treatment, while the cabbages which came from infested soil showed little difference. This experiment is to be repeated.

The occurrence of black rot of cabbage in Vermont was reported in 1897. It has since been noted in a number of other places, but appears to be a rather recent infection. It has been previously described in Farmers' Bulletin 68 of this Department (E. S. R., 9, p. 489) and in Wisconsin Station Bulletin 65 (E. S. R., 10, p. 155).

Different types of plant diseases due to common Rhizoctonia, B. M. DUGGAR and F. C. STEWART (*Bot. Gat.*, *27* (*1899*), *No. 2*, *p. 129*).—The authors have demonstrated by experiments (1) that a damping-off of various seedlings is caused by a species of Rhizoctonia; (2) that a fungus agreeing in structure with the latter has been the cause of the serious root rot of sugar beets in New York during the past year and the fungus identified with this disease seems to be undoubtedly *Rhizoctonia betæ;* (3) and that an important stem rot of carnations is also found to be due to a fungus agreeing precisely in its characters with the beet Rhizoctonia.

It is claimed there is abundant experimental proof that the beet and carnation fungi are identical. The last-named fungi also produce damping-off, although not so abundantly as the fungus originally isolated from damping-off seedlings. Experiments indicate that these different types of disease are all due to the same species, the specific affinities of which can not as yet be given with certainty.

Notes on gum disease and crown gall, L. R. TAFT (*Michigan Sta. Rpt. 1897, pp. 96, 97*).—Reports have been received from various parts of the State of injuries to peach trees caused by development on the branches of knots from which gum exudes. An examination failed to show the presence of any specific disease, and the swellings appeared to be the result of injuries to or rupture of the bark. As a result of this injury, a corky, knot-like growth forms which, if the injuries are severe, results in weakening the branches, and where there is danger of breaking down it is advised to cut the branches back below the injured portions.

Many complaints have been received concerning the crown gall on nursery stock, particularly upon the peach. The exact nature of the disease is not known, but it is thought to be contagious, especially on soils rich in organic matter. When trees have galls upon the collar or upon the larger roots, it is claimed they should not be planted, as they will never make a desirable growth.

Additional host plants of Plasmopara cubensis, A. D. SELBY (*Bot. Gaz.*, *27* (*1899*), *No. 1*, *pp. 67, 68*).—The author reports a series of experiments conducted to ascertain the different host plants of this well known parasite of cucurbitaceous plants. There were grown, in addition to the cultivated varieties of cucumbers, muskmelons, watermelons, pumpkins, gourds, and squashes, specimens of a large number of other Cucurbitaceæ. The list of host plants determined is as follows:

"*Cucumis sativus, C. melo, C. odoratissimus, C. erinaceus, Cucurbita pepo, C. melopepo, C. verrucosa* (?), *Citrullus vulgaris, Lagenaria vulgaris, Coccinia indica, Bryonopsis laciniosa erythrocarpa, Mukia scabrella, Momordica balsamina, M. charantia, Melothria scabra, Trichosanthes colubrina, Sicyos angulatus,* and *Micrampelis* (*Echinocystis*) *lobata,* but not on *Benincasa cerifera* or *Cyclanthera explodens.*"

In every case the cucumbers and muskmelons were first attacked, after which the disease spread to other cucurbits. It is further observed that *Plasmopara cubensis* in clearly distinguishable from *P. australis*, whether examined upon the same host or upon the different hosts of the former.

Diseases of the vine, W. G. SMITH (*Gard. Chron., 3. ser., 25 (1899), No. 629, p. 17*).—The author states that the diseases of the grape may be classed into three groups—those due to parasitic fungi, those attributable to injurious insects, and those for which neither fungi nor insects offer a sufficient explanation. This last class of diseases, which is said to be due to physiological causes, is to be considered in a series of articles, the present paper dealing with shanking and blanching.

Shanking, which is a widely distributed disease, is probably the same as that described in France under the name "*maladie pectique*" and that described under the name "shelling" or "rattles" in New York Cornell Sta. Bul. 76 (E. S. R., 6, p. 732). It is characterized by the falling of the grapes as they approach maturity, the fruit breaking away where it joins the stalk, or by the fruit simply shriveling up and remaining attached. A weakened root system, excess of nitrogenous fertilizers, and possibly a deficiency in potash are thought to cause this trouble.

Blanching, or "chlorose," is recognized by the leaves becoming yellow or completely blanched, the loss of color generally beginning near the margin and spreading inward between the veins. The young twigs are frequently attacked like the leaves and dry up. The woody branches are retarded in growth and the new leaves remain small and blanched.

Experience in France seems to indicate that this disease is worst on calcareous soils. On clay or siliceous soils chlorosis only appears during cold, wet springs. The disease is said to be diminished by any mode of cultivation which promotes good drainage in the soil and strengthens the growth of the vines. Above all, applications of sulphate of iron should be applied about the roots of the grapes. Different varieties of grapes are affected to different degrees, and the subject of resistant varieties is said to be worth considering.

Plant diseases, C. F. WHEELER (*Michigan Sta. Rpt. 1897, pp. 99, 100*).—Brief notes are given on several diseases of farm crops which have not hitherto been observed on the college farm. A turnip disease, due to *Alternaria brassicæ*, became very injurious in the turnip fields of the college in August. The leaves were covered with dark-colored spots, which increased until the leaves were destroyed. Bacteria subsequently attacked the roots, causing a wet rot and the complete destruction of the crop.

A millet disease, due to *Sclerospora graminicola*, was noticed for the first time on German millet. Later the same disease was found attacking green fox-tail grass.

A lettuce disease (*Marsonia perforans*), which is confined to greenhouses, is reported as troublesome in the houses of a lettuce grower at Grand Rapids.

During the latter part of May red clover was found to be attacked by *Glœosporium* sp., the affected plants in many cases having their leaves entirely destroyed. Fully half of the plants in the clover plats were more or less affected.

The most important fungus diseases of cultivated plants, V. K. VARLIKH (*St. Petersburg, 1898, pp. X+140; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Jan., p. 228*).

Pathological notes, L. SAVASTANO (*Bol. Soc. Nat. Napoli, 11, No. 11, pp. 109–127; abs. in Ztschr. Pflanzenkrank., 8 (1898), No. 6, pp. 350–353*).—Notes are given on an Opuntia rot, bacterial disease of grapes, an olive disease, rot and gummosis of Japanese medlars, canker of poplar trees, California grape disease in Sorrento, fig mildew in Campania, rot of grape stock in Sorrento, and stunting of the fruits of limes.

Concerning the diseases of the peach, C. MOHR (*Ztschr. Pflanzenkrank., 8 (1898), No. 6, pp. 344, 345*).—Notes are given on some diseases to which peach trees are subject, especially *Exoascus deformans.*

A leaf disease of olives, V. VENNUCCINI (*Bol. Ent. Agr. e Patol. Veg., 5 (1898), pp. 85–87; abs. in Ztschr. Pflanzenkrank., 8 (1898), No. 6, pp. 353, 354*).—Notes the attack of *Cycloconium oleaginum* on olive leaves. All varieties are not equally susceptible. Spraying with Bordeaux mixture is recommended as a preventive treatment.

Grape diseases in Brazil, F. NOACK (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 1–10, pl. 1, figs. 4*).—Notes are given on attacks on grapes of *Peronospora viticola, Cercospora viticola, Oidium tuckeri, Glœosporium ampelophagum, Melanconium fuligineum,* root rot, a mildew caused by *Apiosporium brasiliense,* n. sp., and injuries due to wind.

Grape anthracnose in Tunis, CASIEN (*Bul. Dir. Agr. et Com., 4 (1899), No. 11, pp. 70–72*).—Notes the occurrence of the disease and recommends winter treatment with iron sulphate and summer applications of a solution of iron sulphate and lime.

Anthracnose and brunissure, F. DEBRAY (*Bul. Agr. Algérie et Tunisie; abs. in Bul. Soc. Bot. France, 3. ser., 5 (1898), No. 1, pp. 92, 93*).—Notes are given on *Sphaceloma ampelinum* and *Pseudocommis vitis.*

Concerning brunissure, DEBRAY (*Bul. Soc. Bot. France, 3. ser., 5 (1898), No. 5, pp. 253–288, pls. 2*).—A report is made of diseases of a number of plants said to be induced by *Pseudocommis vitis.*

The microparasites of wheat (*Bol. Inst. Agr. Estado de São Paulo em Campinas, 10 (1899), No. 1, p. 22*).

Culture experiments with heterœcious rusts, VII, H. KLEBAHN (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 14–26, figs. [illegible]*).—Experiments are reported with *Peridermium strobi, P. pini, Melampsoridium betulinum,* and *Æcidium laricis,* and of *Pucciniastrum epilobii,* the teleutospore form of the æcidial stages on fir trees. The author makes a new genus, Melampsoridium, of those rusts having æcidia of the Peridermium type.

On the duration of the winter spores of some rusts, J. ERICKSSON (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), Nos. 9, pp. 376–388; 10, pp. 427–432; abs. in Ztschr. Pflanzenkrank., 9 (1899), No. 1, p. 49*).—The duration of the vitality of these spores is as a rule quite short, being not much more than a year. The substance of this paper has already been given (E. S. R., 10, p. 57).

Cæoma fumariæ in its genetic relationship with the Melampsora of Populus tremula, F. BUBAK (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 26–29*).

Epidemics of the potato disease in Finland, G. GROTENFELT (*K. Landt. Akad. Handl. Tidskr., 37 (1898), No. 5–6, pp. 291–295, maps 4*).

The prevention of potato rot in cellars (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 57, 58, fig. 1*).—Notes are given on methods for storing potatoes so as to remove some conditions for the development of rot.

On the preparation of fungicides, L. DEGRULLY (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 14, pp. 428–429*).—Formulas and directions for the preparation of a number of fungicides are given, including a solution in which sulphate of cadmium is substituted for copper sulphate. The latter is highly commended, although but few tests seem to have been made of it.

A new fungicide and insecticide, M. and A. CAMPAGNE (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 16, pp. 502, 503*).—Equal parts of alkaline turpentine and triturated copper sulphate are said to possess great value as a combined fungicide and insecticide.

Concerning some copper fungicides, L. DEGRULLY (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 17, pp. 511, 512*).—A formula for what is claimed to be an absolutely neutral fungicide is given as follows: Water, 100 liters; copper sulphate, 2 kg.; carbonate of soda (Solvay 90°), 350 gm.; and ammonia (22° Baumé), 1 liter. This mixture is said to be easily prepared and applied and is quite efficient.

A comparison of copper fungicides, P. SORAUER (*Ztschr. Pflanzenkrank.*, *9* (*1899*), *No. 1, pp. 55–57*).—The author quotes and comments upon the investigations of Barth-Colmar on the relative value of 16 copper fungicides recommended by the trade for the prevention of plant diseases. In tabular form are given the actual composition, cost, and real value of the fungicides.

On the fungicidal action of acetate of copper compared with sulphate of copper, A. VIGNA (*Staz. Sper. Agr. Ital.*, *31* (*1898*), *No. 12, pp. 62–69*).

On the use of powders and sprays in the treatment of fungus diseases, L. DEGRULLY (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 16, pp. 481–484*).—The claims relative to the merits of both forms of fungicides are reviewed, and the author concludes that for the prevention of black rot and similar diseases liquid fungicides are to be preferred.

Comparison of powdered and liquid fungicides, P. COSTE-FLORET (*Prog. Agr. et Vit.* (*Ed. L'Est*), *20* (*1899*), *No. 18, pp. 543–545*)

ENTOMOLOGY.

Report of the apiarist for 1896–97, R. L. TAYLOR (*Michigan Sta. Rpt. 1897, pp. 105–126*).—The author gives his idea of a model beehive. Besides being inexpensive, light, and simple, he recommends that certain of the sections should not be over 3 in. deep in order that they may be easily removed and replaced with empty sections and thus prevent swarming. The Aspinwall non-swarming hive gave rather good results for 2 years, but is too expensive, costing nearly 2½ times as much as the ordinary L hive. The device for the prevention of swarming is very simple. A great deal of additional room is given to the brood chamber without increasing the space, which can be occupied by comb. "This is accomplished by alternating at the approach of the swarming season all combs of the brood chamber with frames of wooden comb which has no septum and in which, consequently, nothing can be stored."

On the subject of the possible injury to grapes by bees, the author has made a number of observations, and concludes that bees never harm uninjured grapes. Of 30 varieties of grapes, with which the author experimented, he found that injury was almost entirely confined to the Delaware and Lady, which varieties are especially liable to crack open during a wet season. The bees which were observed sucking the juice from grapes with ruptured skins were noticed to work almost entirely upon compact clusters, and very seldom upon loose clusters. The author placed paper sacks around about 1,000 clusters of grapes of 13 different varieties in such a way that the bees could not gain entrance, leaving a slit in the bottom of each sack for the escape of any water which might enter. Toward the close of the experiment it was found that clusters inclosed in sacks were suffering more than those which were left uncovered, and the author concludes that the sucking away of the juice of the grapes by the bees is a direct benefit rather than an injury in that these juices are prevented from flowing upon sound grapes, and thus increasing the amount of injury by the cracking of the skin.

The author made some experiments in feeding back extracted honey after the best of the honey season was over, to determine whether unfilled combs could be in that way filled out economically. The conclusion of his experiment is that the extracted honey was fed back with a profit of nearly 62 per cent.

Experiments were tried in wintering bees in the cellar at a high temperature. During the winter the temperature seldom went below 45° F., and for the greater part of the time it ranged between 45 to 50°. The bees, which numbered 180 colonies, were put into the cellar during the first half of November. There was no unusual loss of bees until the end of February. From that time on the number of dead bees on the cellar bottom increased rapidly. The removal from the cellar was begun March 29 and was concluded April 14. Examinations disclosed the following condition: 13 colonies dead or nearly so; 2 starved; 2 dead from weakness resulting from lack of queens; one with a bottom board had apparently smothered. The dead bees from the cellar floor measured 6 well packed bushels "amounting to a loss on an average of 3 pts. of bees from each colony." During the winter there was an average consumption of honey to the amount of about 15½ lbs. per hive.

The author gives a somewhat detailed description of foul brood, and the methods of preventing it are mentioned. The method preferred by the author is that of transferring the bees to another hive and then sterilizing the old hive by heat. Honey taken from a foul brood colony was fed to another rather weak colony and the result showed that the disease had not been transmitted by this procedure. A queen from a colony affected with foul brood was introduced into another colony without infecting the second colony.

In the opinion of the author it is seldom necessary to observe any other precautions than to sterilize by heat the hive in which foul brood occurs, after removing the bees.

Supplementary report of the apiarist for the summer of 1897, J. M. RANKIN (*Michigan Sta. Rpt. 1897, pp. 127, 128*).—Two queen bees were imported from Mississippi from colonies badly infested with bee paralysis. One of the colonies into which one of the queens was introduced showed some signs of the disease, which would indicate that the disease may be introduced from the South.

In an experiment with different sorts of foundation it was found that the bees begin to work first on the drawn foundation, but later in the season they prefer the thin.

Some breeding experiments were carried on to determine the question whether the tongues of bees could be increased in length. Results were obtained which were encouraging.

Sweet potato insects, E. D. SANDERSON (*Maryland Sta. Bul. 59, pp. 129–146, pls. 13*).—The bulletin contains popular accounts of the life history, habits, and means of prevention of a number of insects which feed upon the sweet potato. The sweet potato root-borer (*Cylas formicarius*) has not yet been reported in Maryland, but sweet potato growers are warned against its possible importation. A number of cutworms attack sweet potatoes, among which *Agrotis messoria* is perhaps the most important. As remedies against this insect, the author recommends deep fall plowing, scattering bunches of grass or clover sprayed with Paris green at the rate of 1 lb. to 100 gal. of water before setting the plants, and the spreading of a poisonous mash, composed of 1 lb. of Paris green to about 2 qt. of cheap molasses and 50 lbs. of wheat bran.

The sweet potato flea beetle (*Chætocnema confinis*) is reported as being exceedingly injurious to the sweet potato in the State. The remedies suggested are the dipping of the plants before setting into a solution of arsenate of lead and the spraying of the plants after they are set out with Bordeaux mixture, which seems to be distasteful to the beetles. The arsenate of lead is to be made in the following proportion: 11 oz. of acetate of lead, 4 oz. arsenate of soda, dissolved in 100 gal. of water.

A number of tortoise beetles prey upon the sweet potato. The species mentioned are *Cassida bivittata*, *C. nigripes*, *Coptocycla bicolor*, *C. signifera*, *C. clavata*, and *Chelymorpha argus*. Brief notes are given by way of description and accounts of the habits and life histories of all these species. The remedies which are recommended are the arsenate of lead method, as described above for the flea beetle, and spraying with Paris green at the rate of ½ lb. of the poison and ½ lb. of lime to 40 gal. of water.

A species of sawfly (*Schizocerus ebenus*) is reported as sometimes attacking the sweet potato. Paris green, as recommended for the tortoise beetle, is to be used against the sawfly.

The sweet potato plume moth (*Pterophorus monodactylus*), the cucumber flea beetle, the tobacco worm, and *Macrosila cingulata* are also mentioned as enemies of the sweet potato.

The army worm and other insects, F. M. WEBSTER and C. W. MALLY (*Ohio Sta. Bul. 96, p. 26, pls. 4*).—The authors give notes on the economic importance and life history of the army worm (*Leucania unipuncta*). *Winthemia 4-pustulata* is said to be the most important parasite of the army worm in Ohio. Regarding the life history of the army worm the authors make the following statements:

> "The eggs are deposited during late April or early May, by female moths, which either passed the winter as such, or emerged in spring having wintered as pupæ. It is of course possible that larvæ might, in exceptional cases, winter over also. The worms from these eggs would develop and give rise to a second brood of moths, which, ovipositing, would produce a second brood of worms during July, this being the destructive brood of 1896. The moths developing from this second brood of larvæ, and ovipositing in August or September, would produce a third brood of larvæ, and the moths from these would constitute the first brood of moths of the following spring."

In Ohio, outbreaks of the army worm occur most frequently after cold wet springs. The natural enemies and the common artificial remedies are enumerated and described.

Occasionally species of sawflies attack wheat and various cultivated grasses. Three species of economic importance are found in Ohio, viz, *Pachynematus extensicornis*, *Dolerus arvensis*, and *D. collaris*.

There are probably three broods of the corn or bollworm (*Heliothis armigera*) per year in the southern part of the State and two in the northern. Two dipterous parasites, *Frontina armigera* and *F. frenchii*, attack the larva. Fall plowing is perhaps the best artificial remedy.

The painted hickory borer (*Cyllene pictus*) has been reared from the wood of hickory and osage orange. Strong soapsuds applied to the bark of the trees in May would doubtless destroy the eggs.

Larvæ of the raspberry cane borer (*Oberea bimaculata*) were found not only in the stems of the raspberry but also in those of apple, pear, and witch-hazel. The authors believe that the insect requires 2 years to complete its development. The destruction of old canes after berry picking is recommended as the best remedy.

An article on the peach scale (*Diaspis amygdali*) which was previously published in Canadian Entomologist, April, 1898, is reprinted.

The raspberry sawfly, and preliminary notes on the grapevine flea-beetle, V. H. LOWE (*New York State Sta. Bul. 150, pp. 219–265, pls. 7*).—The raspberry sawfly (*Monophadnus rubi*) is reported as having caused serious injury to raspberries, and to the young plants in the nurseries especially. The food plants of the insect are the raspberry, blackberry, and the dewberry. The plants suffer some injury from the laying of the eggs on the under side of the leaf. The young larvæ when hatched eat small irregular holes into the leaves, and as they become larger devour all the leaf except the midrib. They also attack the developing buds. The different stages of the insect are described. The eggs are said to hatch in from 7 to 10 days. Pupation takes place in the latter part of June. The pupal stage lasts only a few days, and there is but one brood annually. The insect is perfectly free from parasitic attacks.

The larvæ of this sawfly may be jarred or brushed from the bushes, or the ground may be cultivated in the fall so as to expose the cocoons to the heat of the sun, or the raspberries may be sprayed with arsenical compounds or with hellebore.

A bibliography of the subject is appended.

The author gives descriptions of the various stages and an account of the life history of the grapevine flea-beetle (*Haltica chalybea*). The methods recommended for combating this insect are the scattering of air slaked lime about the base of the vine, so as to kill the larvæ when they attempt to enter the ground, and spraying with arsenical poisons. The first application of Paris green should be a short time before the buds begin to swell, and should be in the proportion of 1 lb. to 50 gal. of water, with the addition of enough lime to make the mixture milky. When the larvæ first appear on the leaves, another application should be made in the proportion of 1 lb. to 150 gal. of water.

Notes on the San José scale and black peach aphis, L. R. TAFT (*Michigan Sta. Rpt. 1897, pp. 95, 96*).—During the winter of 1896 and 1897 specimens of San José scale were received from a number of sections of the State, and several centers of infection were located, all of which it is claimed were infested from nursery stock received from New Jersey. Directions were given for treatment, and the work was thoroughly done, so that further spread was to a great extent checked.

The black peach aphis is reported to have spread through a great number of orchards throughout the State, destroying thousands of trees. Various insecticides have been tested, including bisulphid of carbon, kainit, tobacco, salt, and wood ashes, and it is believed, considering its fertilizing value, that salt and wood ashes are to be recommended as the best treatment. Tobacco water is considered second best, and it is recommended that trees be soaked in tobacco water before being planted.

The San José scale, U. DAMMER (*Gard. Chron., 3. ser., 25 (1899), No. 629. p. 26*).—A review is given of a paper read by Professor Frank before the Berlin Horticultural Society on the San José scale and its allies.

On account of the somewhat prevalent belief that the *Aspidiotus conchæformis*, which is widely scattered about Europe, is but a geographical form of the American *A. perniciosus*, Frank has investigated the subject and has arrived at the conclusion that the European form is a true species, quite different from the American. In his investigations on this subject he received from America at different periods twigs of the peach densely beset with the true San José scale, and his investigations led him to conclude that instead of three generations yearly, in which a female breeds about 600 young scales, as is claimed by most American investigators, he found but one generation, and that only about 30 young are produced, from which he decides that the American theory is erroneous. He further states that it is questionable whether the San José scale can live in Europe.

Orchard fumigation, C. W. WOODWORTH (*California Sta. Bul. 122, pp. 33, figs. 22*).—The bulletin contains a history of the discovery of the insecticide value of hydrocyanic-acid gas and of its various applications for fumigating orchards. The credit for this discovery is claimed for California, the two chief workers having been D. W. Coquillett and A. D. Bishop.

The great problem in the use of hydrocyanic-acid gas is to prevent injury to the foliage, and after a long series of experiments by the gentlemen just named the present three chief features of orchard fumigation were devised, namely, the formula for the gas, the method of generating, and the night work. It was found that the foliage was much more liable to injury by fumigating during sunlight than at night.

As to the quantity of gas to use, a great variety of opinions prevail, and tables are given of the amounts used by Morse, by Coquillett during several successive experiments, by T. B. Johnson, and by W. G. Johnson of the Maryland Station, as well as by the author.

As to the tents for covering the trees, common duck canvas is used at present, most of the tents being made of 8 oz. canvas, such as is used for light sails. For making the canvas gas-tight three different methods have been tried, i. e., treating the tent with boiled linseed oil, applying sizing and paint, and saturating the canvas with a decoction of the leaves of prickly pear cactus. The latter method has certain advantages in that the canvas is not rendered stiff. A great variety of tents have been used for covering trees. The bell tent has a dome-shaped top and is manipulated by means of a derrick. The hoop tent has a rounded top and the shape of the bottom of the tent is maintained by a strong hoop of three quarter-inch gas pipe bent into circular form. The box tent has a square top and is without weights at the bottom. It is manipulated by means of a pole called a lifter. The sheet tent seems to have advantages over all the others, its only disadvantage being the fact that it possesses considerable surplus canvas. It is manipulated by means of poles and is without weights at the bottom. In manipulating these tents and in preparing the gas and charging the generator a gang of 4 or 5 men has been found most efficient; 2 or 3 men handle the tents, 1 man manages the generator and measures the acid, and the fumigator introduces the chemicals into the tent. The whole responsibility rests upon the fumigator, since it depends entirely upon his judgment as to how much of the chemicals shall be used. He has to estimate by the eye the cubical contents of the tent and say how much hydrocyanid should be used. Careful directions are given for estimating the amount of chemicals to be used from the size of the tree.

In conclusion, a bibliography is given of articles on the subject of orchard fumigation.

The effect of a slight diminution of heat during the last days of the larval stages upon the cocoons of the silkworm, F. LAMBERT (*Ann. École Nat. Agr. Montpellier, 10 (1897–98), pp. 206–220*).—A diminution of heat to the amount of 2 to 3° C. was found to prolong the larval life about 3 days and to produce an increase in the weight of the cocoons from about 7 to 8½ per cent on the average. The silk was equal and in many cases superior to that of cocoons which had been maintained at the constant temperature of 21° C.

Entomological circulars, J. B. SMITH (*New Jersey State Bd. Agr. Ent. Circs. 1–20*).—Twenty short popular circulars on the subjects of economic entomology with titles as follows: Directions for treating the tulip soft scale; Arsenical poisons and how to use them; Kerosene as an insecticide; The cottony maple scale; Whale-oil soap and its uses; How to treat the San José scale; The elm-leaf beetle; The bagworm or drop worm; The vaporer moth; Cabbage worms; Cutworms; The codling moth; Arsenate of lead; The apple borer; Lime as an insecticide; Tobacco as an insecticide; The plum curculio; Asparagus beetles; The scurfy scale; The oyster-shell bark-louse.

Fruit inspection, D. JONES (*Queensland Agr. Jour., 4 (1899), No. 3, pp. 190–193*).—Calls attention to the necessity of inspection and investigation into the best methods of eradicating insect pests.

Report of the injurious insects and plant diseases in 1898, W. M. SCHÖYEN (*Beretning om Skadinsecter og Plantesygdomme i 1898. Christiania, 1899, pp. 34, figs. 21*).—The author gives popular notes on various insect enemies of field and garden crops, shade and ornamental trees, as well as fruit trees. Among the insects noted are the frit fly, wireworms, cutworms, cabbage butterfly and cabbage-root maggot, and two species of Argyresthia, which are reported as injuring apples.

The State entomological station of Sweden, C. GRILL (*Ent. Tidskr., 19 (1898), No. 3–4, pp. 129–142*).

Report of the State entomologist of Sweden for 1897, S. LAMPA (*Ent. Tidskr., 19 (1898), No. 1, pp. 1–48, ill.*).

Principal insects injuring cabbage, Y. SHREINER (*Rpt. Min. Agr. and Imp. Domains., Dept. of Agr. St. Petersburg, 1898, pp. 32; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Jan., p. 227*).

Norwegian Hymenoptera, E. STRAND (*Ent. Tidskr., 19 (1898), No. 2, pp. 71–112*).

The North American Mutillidæ, W. J. FOX (*Trans. Amer. Ent. Soc., 25 (1899), No. 4, pp. 219–300*).—This paper is in the nature of a monograph of the family and gives the principles of its classification as well as analytical tables and descriptions of new species.

The plant lice of sugar cane in Java, L. ZEHNTNER (*Meded. Proefstat. Suikerriet West Java, 38, pp. 21, pls. 2*).—Gives biologic and economic notes together with descriptions of *Aleurodes longicornis* and *A. lactea*.

The Orthopteran genus Schistocerca, S. H. SCUDDER (*Proc. Amer. Acad. Arts and Sci., 34 (1899), No. 17, pp. 441–476*).—The author gives the characters which separate this genus from Acridium, and an analytical table for determining the various species of the genus. Descriptions are given of all the species of the genus known to the author, including a number of new species.

Diagnosis of new Lepidoptera from Africa, C. AURIVILLIUS (*Ent. Tidskr., 18 (1897), No. 3–4, pp. 213–232; 19 (1898), No. 3–4, pp. 177–186*).

The frost butterfly (Cheimatobia brumata), J. PEYRON (*Ent. Tidskr., 19 (1898), No. 1, pp. 49–53*).

Two new termites from the western coast of Africa, Y. SJÖSTEDT (*Ent. Tidskr., 19 (1898), No. 3–4, pp. 204, 205*).—Preliminary communication, in German. *Termes acanthothorax* n. sp. and *T. mülleri* n. sp.—F. W. WOLL.

A new termite from Cameroon (Termes niger n. sp.), Y. SJÖSTEDT (*Ent. Tidskr., 19 (1898), No. 2, p. 128*).

Two small-fruit pests, F. H. HALL and V. H. LOWE (*New York State Sta. Bul. 150, popular ed., pp. 5, pls. 2, figs. 3*).—A popular summary of Bulletin 150 of the station (see p. 63).

The results of two years' work on the San José scale, W. B. ALWOOD (*Trans. New York State Agr. Soc., 1897, pp. 549–569*).—Soap and kerosene washes and hydrocyanic-acid gas were tried and shown to be efficient remedies.

Inspection and remedial treatment of San José scale, W. B. ALWOOD (*Virginia Sta. Bul. 79, pp. 73–94, figs. 3*).—The scale has become established at 291 points in

35 counties of the State. The infested stock came from nurseries in 13 different States. The scale was first introduced into Virginia in 1888. The remedies which the author used were "destruction of infested plants, fumigation of nursery stock, lye, soap and kerosene washes, and wax applications." The author found that pure kerosene could be safely applied through a small atomizer.

Combating insect and fungus diseases, W. M. SCHÖYEN (*Tidsskr. Norske Landbr., 5 (1898), No. 12, pp. 638–650*).

Paris green, W. C. STUBBS (*Louisiana Stas. Bul. 54, 2. ser., pp. 98–104*).—Text of the State law regulating the sale and purity of Paris green with analyses of 34 samples collected by the Commissioner of Agriculture.

A preliminary note on the cocoon fungus, H. NOMURA (*Bot. Mag. [Tokyo], 11, (1897), pp. 31–33; abs. in Ztschr. Pflanzenkrank., 8 (1898), No. 6, p. 361*).—In a brief note it is stated that silk cocoons are frequently seriously attacked by *Aspergillus flavus* and *A. glaucus*.

Concerning a fungus disease of Porthesia chrysorrhœa, G. LINDAU (*Schr. Naturf. Gesell. Danzig, n. ser., 9 (1898), No. 3–4, pp. 36, 37*).—Describes attacks of *Empusa aulicæ* on this insect and reports the possible value of this parasite in combating the destructive attacks of the insect.

FOODS—ANIMAL PRODUCTION.

Chemical examination of canned meats, H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Circ. 5, pp. 7*).—Statements are made concerning the examination of 13 samples of canned beef of different sorts. No borax, boric acid, sulphites and sulphurous acid, or salicylic and benzoic acids were found. Corned beef and luncheon beef contained small amounts of saltpeter. Common salt was also found, but the amount did not appear to be excessive. "It is a matter of common information that in the preparation of corned beef, salt and saltpeter are always used, whether it be in a large packing house or in a private family."

The appearance of the meat when the cans were opened is discussed at some length.

> "Very little fat was found in the interior. In the samples examined the whole external surface of the contents of the package presented a perfectly normal appearance; there was no indication of the action of any ferments of any kind nor any discolorations not due to natural causes.
>
> "The packages of meat having been broken in two, not cut, the fractured surface showed no gelatin and only a few patches of fat, the great mass of material consisting of the red flesh of the meat.
>
> "On opening the cans it was found in many instances that the tins on the inside were discolored and it was first considered that actual erosion had taken place. A careful microscopic examination of the surface, however, showed that this assumption was an error. In no case was the surface of the tin found to be eroded, and the discolorations were due doubtless to the natural effect of the meats upon the tin surface."

On the influence of sugar on muscle exhaustion, J. PRANTNER and R. STOWASSER (*Centbl. Innere Med., 20 (1899), No. 7, pp. 169–182, dgm. 1*).—The authors report a number of investigations, in which they were themselves the subjects, on the value of sugar as a muscle food and a protector of protein. By means of a mechanical device a weight was raised and lowered. This exercise brought into action the muscles of the upper extremities and even of the trunk and legs. Before performing the muscular work, 30 gm. of grape sugar was taken in weak tea. In control experiments an amount of dulcin equaling the sugar in sweetness was taken. The investigators did not know whether they had consumed sugar or dulcin. More work was performed when sugar was consumed than in the other cases.

A second group of experiments was made in which work was performed with Gaertner's ergostat. The subjects worked until they were thoroughly tired. The effect of sugar was then tested with work of the sort described above. In these cases the effect of sugar was very noticeable. When sugar was added to a diet which sufficed for nitrogen equilibrium, the amount of nitrogen excreted in the urine was diminished. In the author's opinion sugar is useful as a muscle food for those who have a single muscular task to perform, rather than for those who are engaged in constant, though severe, manual labor.

Danish feeding experiments with swine, 1895–1898, F. Friis (*42 Rpt. Kgl. Vet. and Landbohöjsk. Lab. Landökon. Forsög, Copenhagen, 1899, pp. 162*).—Twenty-nine experiments, which were conducted on the same general plan as the earlier investigations (E. S. R., 5, p. 428; 7, p. 242), were made during 1895–1898 with 709 pigs. They were divided into 131 lots. A number of problems were studied.

Roots for swine.—The feeding value of ruta-bagas, turnips, mangelwurzels, and grain (barley, rye, or Indian corn) was studied in 11 experiments with a total of 305 pigs.

Some of the lots were fed grain only. Others were fed a ration in which ¼ of the grain was replaced by roots, .09 to 1 lb. (dry matter) of roots being substituted per pound of grain. In all cases the liquid portion of the ration consisted of buttermilk, skim milk, and whey, alone or mixed. The average duration of the various tests was 100 days. The pigs weighed on an average at the beginning of the test 69.9 lbs. and at the end 161.8 lbs. The average daily gain per head was as follows: Lots fed grain, 0.96 lb.; lots fed Eckendorf mangelwurzels, 0.94 lb.; lots fed Bangholm ruta-bagas, 0.92 lb.; lots fed Bulloch turnips, 0.88 lb.; and lots fed Yellow Tankard turnips, 0.89 lb. The conclusion was drawn that roots may be fed as a part of the ration to pigs with satisfactory results. If a larger proportion of roots to grain had been fed, the gains doubtless would have equaled those made on exclusive grain feeding.

The dry matter and sugar content of the different kinds of roots was determined. The feeding value of the roots corresponded very nearly to their dry-matter content; the roots rich in sugar produced somewhat better results than those low in sugar, but the increase in live weight followed more closely the dry-matter content than the amount of sugar in the roots. The quality of the pork produced on the roots was excellent.

Barley vs. wheat.—Three tests with a total of 80 pigs were conducted to compare barley and wheat, 2 of these lasting 130 days and one 90 days. Either skim milk or whey was fed with the grain. The average weight of pigs at the beginning of the tests was 51.3 lbs. and at the end 183.9 lbs. The lots fed barley only gained on an average 1.09 lbs. per day, those fed wheat 1.13 lbs., and the lots fed these grains half-and-half 1.11 lbs. The wheat, therefore, produced slightly better results than barley. Similar results were obtained at the station with corn (E. S. R., 8, p. 256). The quality of the pork produced was excellent in all cases on both kinds of grain.

Molasses feed compared with barley and Indian corn.—Molasses feed was compared with barley and with Indian corn. The molasses feed was made from ½ beet molasses, ⅜ wheat bran, and ⅛ palm-nut meal, and was the same kind as used in the feeding experiments with cows at the station (E. S. R., 9, p. 275). In the 7 tests reported, 154 pigs were included. The average duration of the tests was 93 days. The average live weight of the pigs at the beginning of the tests was 73.3 lbs.; at the close, 173.4 lbs. The lots fed barley alone gained on an average 1.19 lbs. a day; those fed ½ barley and ½ molasses feed, 1.12 lbs., and those fed ½ barley and ⅝ molasses feed (the amount of molasses feed in normal ration increased by ⅛ the weight of the ration fed), 1.24 lbs. When barley was compared with a ration in which barley was replaced by molasses feed in the proportion of 1:1, the average daily gain was as follows: On barley, 1.16 lbs.; on barley and molasses feed, 1.07 lbs. When ¾ barley and ¼ molasses feed was fed, intermediate results were obtained.

Three tests, in which swine molasses feed (⅞ molasses and ⅛ palm-nut meal) and Indian corn were compared, showed that the former in every case produced smaller gains than the latter. Considering the cost of the different foods, the molasses feed produced the cheaper gain.

The results obtained in slaughter tests showed no appreciable difference in the effect of the different feeds. The pork of the animals fed molasses feed was somewhat softer than that of the barley-fed animals, while the reverse was true when corn and molasses feed were compared. It appears, therefore, according to the author, that the addition of molasses feed to a corn ration tends to improve the quality of the pork produced.

Blood-molasses feed vs. grain.—Five tests with a total of 100 pigs were made to compare blood-molasses feed with grain. The average length of the tests was 100 days. The average weight of the pigs at the beginning of the tests was 77 lbs. and at the end 169.2 lbs. The different tests were made with feeds of different origin and on somewhat different plans, but on the whole the blood molasses feed did not equal barley in feeding value when substituted for this in the ratio of

1:1. The quality of the pork of the pigs fed blood-molasses feed was generally poor. The average number for softness of pork (E. S. R., 7, p. 245) for 4 experiments was 1.9 for the grain-fed lots and 3.1 for the molasses-fed lots.

The conclusion is drawn that in the Danish (and English) market this means a loss of 1 to 2.7 cts. per pound.

Palm-nut meal vs. Indian corn.—Three tests with a total of 70 pigs were made to compare palm-nut meal and Indian corn. The average duration of the tests was 80 days. The average live weights of the pigs at the beginning was 94 lbs. and at the close 180.7 lbs. When barley was fed alone the average daily gain per head was 1.11 lbs., when $\frac{5}{6}$ corn and $\frac{1}{6}$ palm-nut meal was fed it was 1.11 lbs., with a ration of $\frac{2}{3}$ corn and $\frac{1}{3}$ palm-nut meal it was 1.13 lbs.; when corn was fed until the pigs weighed 120 lbs. and then was replaced by $\frac{3}{4}$ corn and $\frac{1}{4}$ palm-nut meal the average daily gain per pig was 1.11 lbs., and if $\frac{1}{2}$ corn and $\frac{1}{2}$ palm-nut meal was substituted for corn meal the average daily gain per pig was 1.13 lbs. The mixed rations of corn and palm-nut meal produced the same gains as barley. This was in accordance with the results of earlier tests comparing barley and corn and barley and palm-nut meal.

Slaughter tests were made which, in the author's opinion, indicate that palm-nut meal can entirely overcome the tendency of corn to produce soft pork, both when $\frac{1}{3}$ of the ration is palm-nut meal the whole time and when $\frac{1}{2}$ the ration is palm-nut meal after the animals have reached a live weight of 120 lbs.

A study of all the tests conducted with swine at this station in which corn was fed would, in the author's opinion, seem to confirm the theory that corn produces the softest pork in cold weather. Earlier tests with sunflower-seed cake, which has also been found to produce a soft pork, lead to a similar conclusion. The temperature in the hog house, therefore, seems to be an important factor in the production of first class pork.

The food consumed per pound of gain in these and previous experiments was studied in considerable detail. More food was required per pound of gain as the pigs increased in size. The amount of food required per pound of gain in different seasons of the year was also studied. Pigs of medium weight required 4 lbs. of food per pound of gain in summer and 4.3 lbs. in winter. When they were heavier the corresponding amounts were 4.7 and 5.1 lbs.

The report contains a study of the yield and chemical composition of the different root crops used in the experiments reported above. The following table shows the average composition of some of the foods used.

Composition of feeding stuffs for pigs.

	Water.	Protein.	Ether extract.	Nitrogen free extract, excluding sugar.	Sugar.	Crude fiber	Ash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Molasses feed	21.05	7.68	1.79	21.53	27.60	13.36	6.99
Swine molasses feed	20.18	6.25	.57	19.69	33.37	11.98	7.98
Blood molasses feed	16.99	16.27	1.56	31.35	16.69	9.72	7.42

Turnips, Yellow Tankard	90.83	.54	2.52		3.74	1.37	1.00

—F. W. WOLL.

Pig-feeding experiments, N. J. R. DUNSTAN (*Agr. Dept. Univ. Col., Nottingham,* [*and*] *Midland Dairy Inst., Kingston, pp. 9*).—Two feeding tests with pigs conducted at the Midland Dairy Institute farm, Kingston, Notts, are reported. The first test was made with 3 lots of 6 pigs each. The pigs were from 3 litters and so divided that each lot contained 2 pigs from each litter. The tests were made to compare separator skim milk and whey when fed with maize meal, and to determine whether it was more profitable to feed whey and separator skim milk or to sell it for the usual price, which, for the whey, was about 0.67 ct. per gallon and for the skim milk 2.02 cts. per gallon. The daily ration per head fed to lot 1 at the beginning of the test was 5¼ lbs. of maize meal and water *ad libitum.* The pigs in lot 2 were fed 3½ lbs. maize meal and a gallon of separator skim milk daily, with water *ad libitum*, and the pigs in lot 3, 4 lbs. maize meal and 2 gal. whey, with water *ad libitum.* The maize meal was scalded and allowed to soak for a few hours before feeding. When fed it was mixed with the whey and milk. After 20 days the quantity of maize meal fed was increased 1 lb. The test covered 60 days. The maize meal fed was valued at $22.71 per ton. The results of the test are summarized in the following table:

Results of pig-feeding experiments.

	Weight at beginning	Increase in live weight	Relation of dead to live weight	Profit per lot	Cost of food per pound of gain
	Pounds	*Pounds*	*Per cent.*		*Cents.*
Lot 1	843	413	78.3	$18.61	6.30
Lot 2	810	184	76.8	22.24	5.73
Lot 3	854	526	78.4	28.81	5.90

At the close of the test the pigs were slaughtered and judged by an expert. The principal conclusions drawn from the test were as follows: "As to feeding value the maize and whey ration stood first, maize and skim milk second, the maize alone being very far behind." A gallon of separator skim milk and a little less than 2 gal. of whey have the same value as food for pigs. It was much more profitable to feed skim milk and whey than to sell them at the prices prevailing at the time of the experiment. Further, it would be profitable to purchase skim milk and whey at the prevailing prices to supplement maize.

The second test was made with 2 lots of 4 pigs each. The pigs were all from the same litter. The object was to compare barley meal and maize meal when fed with equal quantities of whey. At the beginning of the test the pigs in lot 1 were fed 20 lbs. of barley meal and 8 gal. whey per head daily; those in lot 2, 20 lbs. maize meal and the same amount of whey. After 20 days the grain ration was increased 1 lb. The test covered 63 days. The financial statement is based on barley meal at $26.28, maize meal at $22.71 per ton, and whey at 0.67 ct. per gallon. The total weight of lot 1 at the beginning of the test was 737 lbs.; of lot 2, 731 lbs. The total gain for the two lots was 332 and 402 lbs., and the ratio of dressed weight to live weight 78.6 per cent and 80.9 per cent, respectively. The cost of food per pound of gain of lot 1 was 6.97 cts., and for lot 2, 4.85 cts. The total profit for lot 1 was $13.18, and for lot 2, $24.82. At the close of the test the pigs were sold, slaughtered, and judged by an expert.

> "The barley-fed pigs were leaner in flesh and set better than those fed on maize. The flesh of the maize-fed pigs was fatter than those fed on barley, but set nicely and was of good quality and very suitable for the pork trade. . . . The barley-fed pigs would have been better for the 'curing trade,' but it is very doubtful whether such an increase in price could have been obtained to compensate for the extra cost of producing the better quality pig. . . .
>
> "It will be seen that in fattening pigs some 6 months, old maize meal is a more profitable food for the production of pork than barley meal (when feeding stuffs cost about the prices quoted), and that maize meal produces greater weights of increase than barley meal. Although the pigs fed on barley meal produced the firmer and better quality pork, yet, as long as the butcher makes no difference in price for the two differently fed pigs, it will be noticed that more weight of pork can be produced by the use of maize meal and that at a cheaper rate than employing barley meal in the same quantities."

Investigations on the metabolism of the horse at rest and performing muscular work, N. ZUNTZ, O. HAGEMANN, ET AL. (*Landw. Jah. b.*, *27* (*1898*), *No. 3*, *pp. 440*, *pls. 7*, *fig. 1*).—In this publication the authors report in detail their experiments with horses, some of which have been reported in previous publications.[1]

Experiments are reported in which the balance of income and outgo of nitrogen and carbon was determined, as well as a large number in which the respiratory quotient was determined. The respiratory quotient has been found to vary under different conditions, and furnishes a delicate means of judging of the changes which take place within the body, or the effects produced, for instance, by internal and external muscular work. In some of the experiments the horses performed no work; in others work of various sorts on a level or on an incline was performed. Especial attention was given to determination of the amount of work required for respiration, for the beating of the heart, as well as the energy expended in chewing and digesting food of different sorts.

---

[1] A number of the investigations and the methods followed were noted in Bulletin 45 of this Office, p. 411. For earlier work see E. S. R., 5, p. 822; 8, p. 156. A paper by Professor Zuntz, based in part on this experimental work, appeared as a leading article in the Record (7, p. 538).

Hay and maize as food for horses were compared. Some of the deductions were the following: Maize increases metabolism, markedly stimulating respiration and perspiration. When hay only is fed and work is performed, profuse sweating is induced, the temperature rises, and there is a trembling of the muscles. The effect is less marked when maize only is fed.

Some of the authors' general conclusions are of especial interest. It appears from the investigation that 38.3 per cent of the energy of the food is converted into mechanical work by the horse. On account of the energy required by the beating of the heart and for respiration, which factors increase with muscular work, only about 34 per cent is, however, available for external muscular work.

The authors believe that 3,201 gm. of nutrients is sufficient for a horse weighing 500 kg. and performing no work, when the food contains 1,382 gm. of crude fiber. Further, it is believed that a horse performing no work and weighing 500 kg. requires in twenty-four hours 1,100 gm. of nutrients in addition to that expended for the labor of digestion, this factor requiring not less than 2,100 gm. of nutrients. In these calculations the total nutrients equal the sum of fat multiplied by 2.4, protein, and carbohydrates. The authors found that different foods require different amounts of energy for the labor of chewing and digesting them. On the basis of their investigations, the real nutritive value of a number of common feeding stuffs was calculated. The results are shown in the following table:

Calculated nutritive value of one kilogram of different feeding stuffs.

Feeding stuffs.	Dry matter.	Crude fiber.	Total digestible nutrients.[a]	Labor expended in chewing and digestion.		True nutritive value.	
				In terms of energy.	In terms of nutrients.[a]	In terms of energy.	In terms of nutrients.[a]
	Per cent.	*Grams.*	*Grams.*	*Calories.*	*Grams.*	*Calories.*	*Grams.*
Medium hay (average quality)	85	260	391	828	209	721	182
Alfalfa hay cut at beginning of bloom	84	266	453	866	219	928	234
Red clover hay	84	302	407	944	239	667	168
Winter wheat straw	86	420	181	1,177	297	460	—116
Oats (medium quality)	87	103	615	492	124	1,943	491
Maize	87	17	785	325	82	2,784	703
Field beans	86	69	720	439	111	2,412	609
Peas	86	59	687	402	102	2,319	586
Air-dry disembittered lupines	86	157	645	646	163	1,908	482
Linseed cake	88	94	690	495	125	2,239	565
Potatoes	25	10	226	107	27	787	199
Carrots	15	16	113	82	21	365	92

[a] Protein, plus carbohydrates, plus crude fiber, plus fat multiplied by 2.4.

As will be seen, the nutritive value of straw is negative in the above table. The authors call attention to the investigations which showed that so long as heat alone is considered, the digestible nutrients in straw should be given their full value as shown by the heat of combustion. Provided the labor of digesting a mixed ration does not exceed 2,100 gm. (or 8,316 calories) the digestible nutrients in straw have a positive value. Provided the labor of digestion is greater than this an excess of straw would only increase the internal muscular work so that approximately 116 gm. of nutrients per kilogram is of no value for the body.

From the table the amount of any food or combination of foods required for maintenance may be calculated, according to the authors, as follows: When a horse weighing 500 kg. is fed hay alone, 8.2 kg. would be necessary since, as previously stated, 3,200 gm. of nutrients are required for maintenance. As shown by the table, a kilogram of hay contains 391 gm. total nutrients.

If the ration consists of 3 kg. of hay and 1 kg. of straw and it is desired to make up the balance with potatoes, the amount necessary may be calculated as follows:

	Grams.
Three kilograms of hay furnish total nutrients amounting to....	1,173
One kilogram of straw furnishes total nutrients amounting to...	181
Total..	1,354

Since the horse requires for maintenance 3,200 gm. nutrients, there remain 1,846 gm. total nutrients to be supplied by potatoes. This, divided by 226, the total nutrients in a kilogram of potatoes, gives 8.2 kg. as the amount which must be added to the ration.

The authors note that defects in external conformation and movements necessitate an increased amount of muscular exertion. This has an important bearing upon the purchase of horses. Too low a stall temperature also increases the amount of material required for maintenance. In many cases observed by the authors, this increase was hardly covered by a kilogram of oats daily. Some of the conclusions drawn have to do with the best form of mechanical appliances for utilizing external muscular work. The authors discuss the experiments of other investigators in detail and compare the results with their own.

Economic feeding of working horses, T. H. WALTON (*Agr. Gaz., New South Wales, 9 (1898), No. 2, pp. 169-172*).—Experiments are reported on the successful feeding of molasses to over 400 horses at the Rarawai Sugar Plantation in the Fiji Islands. As high as 30 lbs. of molasses was fed per head daily at different times, but the ration finally adopted consisted of 15 lbs. of molasses, 3 lbs. of bran, and 4 lbs. of maize. In addition green cane tops were fed. The health of the horses was excellent. Molasses did not cause diarrhea, but rather constipation, which was counteracted by feeding bran.

Feeding molasses effected a saving of over $45 per head per annum.

Such a saving, however, in the author's opinion, was possible only by reason of large quantities of waste molasses and valueless cane tops available on the spot.

The composition of Fiji cane molasses and green cane tops is recorded, and was as follows:

Composition of Fiji cane molasses and green cane tops.

	Water.	Protein.		Fat.		Carbohydrates.		Crude fiber.		Ash.
		Digestible.	Indigestible.	Digestible.	Indigestible.	Digestible	Indigestible.	Digestible.	Indigestible.	
	Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Molasses	26.0	2.5	0.0	0.0	0.0	61.5	0.0	0.0	0.0	10.0
Green cane tops	75.2	1.1	0.6	0.3	0.3	9.5	4.1	4.4	3.0	1.5

The conclusions drawn from the investigation are as follows:

> "For working horses the sugar in cane molasses is a satisfactory substitute for starchy food, being readily digested and transformed into work. Fifteen pounds of the molasses can be given to a 1,270 lb. working horse with advantage to the health of the animal and to the efficiency of its work. It produces no undue fattening, softness, nor injury to the wind. The high proportion of salts in it has no injurious effect. An albuminoid ratio as low as 1 : 11.8 has proved highly suitable for heavy continuous work when a sufficient quantity of digestible matter is given."

Special report on the market for American horses in foreign countries (*pp. 94, pls. 6*).—This report, made by the Secretary of Agriculture to the President, December 12, 1898, is designed to stimulate the export trade in American horses. It contains special articles on Great Britain's purchases of cavalry horses in Argentina, American horses in Belgium, requirements for German army horses, a statement of experience and observation in shipping horses to Germany, horses in France, summary of a communication regarding American horses used by the large horse companies in Paris, France; American horse trade of Great Britain, horse trade with Great Britain, American horses in Denmark, the demand for and kind of horses suited for European uses and the present status of the horse trade in different countries, export of horses from the Chicago market, and a report regarding the export of horses from Buffalo, New York, and vicinity. The bulletin also contains a résumé of the individual reports.

European nations, with the exception of Russia and Hungary, do not produce as many horses as they need. The deficiency is largely made up from exports from Canada and the United States. The American export trade in horses has developed very largely within the last 5 years. In 1893 the total number of horses exported from the United States was 2,967, valued at $718,607; in 1897, 30,532 horses were exported, valued at $4,769,265. Of this number "about 4,000 were exported to Belgium, 1,000 to France, Germany, and Holland, and 20,000 to Great Britain." Ninety per cent of all horses exported to Great Britain were draft horses, 7 per cent high-class coachers, and

3 per cent trotting and light carriage horses. Of the total number shipped to Germany 95 per cent are draft horses weighing 1,500 lbs. or upwards, the remaining 5 per cent being made up of high-class carriage, running, and trotting horses. Most of the latter are reshipped to Austria. Eighty-five per cent of the horses shipped to France are what are termed "cabbers;" the other 15 per cent are about equally divided between draft horses and trotters. About 2 per cent of the shipments to Belgium are trotting or light buggy horses, 23 per cent street-car horses weighing 1,200 lbs., and 75 per cent draft horses, weighing 1,600 lbs. and upward. Many horses are required in Europe for cavalry and other army purposes, as well as for various uses in civil life. The requirements for these different purposes are discussed in considerable detail.

The cost of shipping horses is discussed at some length.

> "It costs from $30 to $40, after the horse is purchased in Chicago, Buffalo, or elsewhere in the eastern half of the United States, before he can be disposed of in London, Antwerp, Paris, or Hamburg. This charge is as great on a cheap as on a high-priced horse; hence, even if there were a demand for them, the profit on cheap horses would be too small to justify the risks. Therefore the horses shipped abroad, while of the same breed and used for the same purpose as those sold for domestic trade, are on the whole a better lot of individuals. . . . It takes some time for the imported horse to recover from the effects of the sea voyage, and doubtless prices would be higher if that time were allowed to elapse before the horses were put up for sale. There would, however, be some expense attached to it, the buyers considering an addition of £2 (about $10) to the price of the horse a fair estimate of the expense required to get him in condition for work."

The economy of using animal food in poultry feeding, W. P. WHEELER (*New York State Sta. Bul. 119, pp. 229–218*).—Tests are reported with chickens, pullets, cockerels, and young ducks to compare rations in which the protein was derived from animal and from vegetable sources. The animal food used was dried animal meal.

The first test with chickens was begun with two lots of 42 each and covered 20½ weeks. At the beginning of the test the chickens were a few days old. A record was kept of any chickens which escaped from the pen in which they were confined, as well as those which died during the test. Lot 1 was fed a ration of animal meal together with some skim milk, wheat, cracked corn, oat meal, and mixed grain consisting of 12 parts of corn meal, 4 parts of wheat flour, 2 parts of ground oats, and 1 part each of wheat bran, wheat middlings, pea meal, and old-process linseed meal. Lot 2 was fed wheat, cracked corn, oat meal, and mixed grain consisting of 6 parts of pea meal, 4 of old-process linseed meal, and 2 each of wheat bran, ground oats, and high-grade gluten meal, and 1 part each of wheat middlings and corn meal. Toward the close of the test a mixture of 2 parts each of old-process linseed meal, wheat bran, ground oats, gluten meal, and 1 part each of wheat middlings and corn meal was substituted for the above. The chickens were also given some skim milk to add to the palatability of the ration. Each lot was fed green alfalfa.

The financial statement is based on corn meal, wheat bran, and wheat middlings at $13 per ton, ground oats at $16, linseed meal at $20, coarse flour at $26, gluten meal at $23, pea meal at $13.50, animal meal and dried blood at $40, and green fodder at $2 per ton. Wheat was rated at 80 and corn at 38 cts. per bushel, and fresh bone at 80 cts. per 100 lbs.

In the first 12 weeks of the first test the chickens fed animal meal gained 50 per cent more than those fed the grain ration. They consumed more food, but required less dry matter per pound of gain. The cost of a pound of gain in the lot fed animal meal was 4½ cts.; in the lot fed grain, 5½ cts. During the first 8 weeks of the test the cost of a pound of gain was 7½ and 11⅕ cts., respectively. The chickens fed animal meal reached 2 lbs. in weight more than 5 weeks before the others, and reached 3 lbs. in weight more than 8 weeks before the chickens fed the grain ration. Three pullets in the lot fed meat meal began to lay 4 weeks earlier than any in the lot fed grain.

The second test was begun with two lots (Nos. 3 and 4) of 33 chickens each and continued for 14 weeks. The chickens were 6 weeks old at the beginning of the test. A preliminary test of 3 weeks' duration, made with 12 chickens, preceded the test proper. The rations were similar to those mentioned above. Lot 3 was given the ration containing the animal meal.

In the second test differences in the two lots similar to those in the first test were noted, although they were not so striking. The principal conclusions of the second test are shown in the following table:

Comparative gains of chickens on animal and vegetable food.

	Dry matter required per pound of grain.	Cost of food per pound of gain	Time required to gain first pound.	Time required to gain second pound.
	Pounds.	*Cents.*	*Days.*	*Days.*
Lot 3 (meat meal)	4.6	5.6	47	30
Lot 4 (grain)	5.2	7.1	61	38

"As with the first two lots, more food was eaten under the ration containing the most animal food. The nutritive ratio of this ration was somewhat the wider, although the amount of protein supplied per fowl was about the same under both rations."

A test covering 56 days is reported with two lots of 19 cockerels about 3 months old at the beginning of the trial. The rations fed and the experimental conditions were practically the same as in the tests with chickens.

"The two lots were alike at the start and averaged almost exactly the same in weight. As in the other feeding trials, the amount of protein supplied per fowl was about the same for the two lots, but the nutritive ratio was somewhat wider with the animal meal ration.

"The gain in weight was not very regular nor very great for either lot, although for short periods some rapid gains were made. Those birds having the animal meal ration gained in weight during the trial about 20 per cent more than the others.

"During the first 8 weeks the consumption of food by the lot fed animal meal (lot 1) was about 28 per cent greater than that of the lot fed grain (lot 2) and the gain in weight was about 40 per cent greater. One pound gain in weight was made by lot 1 for every 8 lbs. of water-free food consumed, and 1 lb. gain by lot 2 for every 8.8 lbs. of water-free food. During the last 4 weeks more food was still eaten by lot 1 but the gain made was considerably in favor of lot 2 as well as the cost of gain. The gain in weight for this period, however, was not economically made by either lot."

A test under conditions similar to those noted above is also reported with two lots made up of 32 and 33 ducklings respectively. Lot 1 was fed the animal meal and lot 2 grain. The test began as soon as the ducklings had learned to eat and was continued until growth became very slow. In this and other experiments data are reported in full in tabular form.

"During the first 10 weeks 2¼ times as much food was eaten by lot 1 as by lot 2 and the total increase in live weight was about four times as great. One pound gain was made by lot 1 for every 3.1 lbs. of water-free food consumed and 1 lb. gain by lot 2 for every 5.2 lbs. of water-free food. The cost of food for each pound gain was about 3.7 cts. for lot 1 and 7.2 cents for lot 2, a difference not far from 95 per ct. in favor of lot 1. The use of the animal meal increased the cost of the one ration, for while it constituted less than one-fifth of the total food beside the alfalfa it represented considerably over one-third of the total cost of the ration. . . .

"The slow growth made by lot 2 for so long a time (during 15 weeks) did not prevent a more rapid gain being made when the ration was more favorable. This is shown by the results of feeding lot 2 for 4 weeks on the animal-meal ration after the contrasted feeding was finished. The growth made by this lot was then rapid and the gain in weight nearly as great as that which had been made by lot 1 2 months earlier when the average size was about the same as that of the older birds from lot 1 during this later period. The disadvantage of living on the inferior ration was, however, never entirely overcome, and the birds failed to reach the size ultimately attained by the birds having from the start the animal-meal ration.

The average weight of 1 lb. was reached by lot 1 3 weeks sooner than by lot 2, the average weight of 2 lbs. over 5 weeks sooner, and the average weight of 3 lbs. over 8 weeks sooner. At 7 weeks of age the average weight for lot 1 was over 3 lbs. and for lot 2 less than 1 lb. At 9 weeks of age the average weight for lot 1 was about 4.5 lbs. and for lot 2 about 1.5. At 11 weeks of age the average weight for lot 1 was 5 lbs. and for lot 2 it was 2 lbs."

Fattening and marketing of poultry, A. H. CATHCART (*Jour. Roy. Agr. Soc. England, 3. ser., 10 (1899), pt. 1, pp. 156–171*).—This article treats of the poultry industry in the East Riding of Yorkshire; poultry fattening at Birdsall, Yorks; the sale of fowls by weight, and the by-products from chickens. Feeding experiments at Birdsall are briefly reported. In one test 32 chickens in 3 weeks consumed 188 lbs. of meal, 7¾ lbs. of fat, and 7¼ gal. of skim milk. At the beginning of the test the chickens weighed from 3 lbs. 3 ozs. to 4 lbs. when fasting and gained from 10 ozs. to 1 lb. 9½ ozs. In the author's opinion, to obtain a fine quality of poultry it is necessary to confine the fowls in cages for 3 weeks. If, however, it is desired to produce flesh at a minimum cost, it is considered more economical to confine the birds only a fortnight.

The author believes that proper attention to the by-products from chickens would materially increase the profits in fattening poultry. It is suggested that chickens' feet be used for the manufacture of jelly and the necks for soup making; that the livers be sold separately; that the feathers from cocks' necks be utilized for tying artificial flies for fishermen, and that the feathers be utilized in other ways. The gizzards are regarded as nutritious and a salable product. It is further suggested that the offal be used for fattening pigs. The value of the droppings as manure is also spoken of.

History and present status of instruction in cooking in the public schools of New York City, Louise E. Hogan (*U. S. Dept. Agr., Office of Experiment Stations Bul. 56, pp. 70, pls. 12*).—The teaching of cooking as a branch of manual training has been introduced into many primary and grammar grade public schools. This bulletin, which contains an introduction by A. C. True, gives the history of the development of this movement in the public schools of New York City, together with a somewhat detailed account of the course of instruction and exercises, including compositions and drawings, prepared by pupils as part of their class-room work.

Examination of the principal sorts of flour used for bread making, G. Fascetti (*Staz. Sper. Agr. Ital., 31 (1898), No. 4, pp. 367–376*).—The author reports the determination of water, total nitrogen, cellulose, ash, and gluten in samples of Italian flour of different grades.

Flour and bread from a botanical standpoint, T. F. Hanausek (*Wiener Illus. Gart. Ztg., 24 (1889), No. 4, pp. 109–119*).—The author describes the seeds, etc., which may be found as impurities in flour and bread.

Chemical composition and nutritive value of Norwegian cereals, F. H. Werenskiold (*Norsk Landmandsblad, 17 (1898), No. 52, pp. 577, 578*).

Banana flour, A. Petermann (*Bul. Assoc. Belge Chim., 13 (1899), No. 3, pp. 147, 148*).—Banana flour is briefly described, and an analysis made by Grégoire is recorded. The percentage of composition was as follows: Water, 5.60; protein, 3.13; fat, 1.73; nitrogen-free extract, 82.39; crude fiber, 1.22; and ash, 5.93. The nitrogen-free extract contained 7.19 per cent of glucose, 3.34 per cent of dextrin, and 45.76 per cent of starch.

Physiological chemistry for medical and other students, F. Bottazzi (*Chimica Fisiologica per uso dei Medici a degli Studenti. Milan (1898), vol. 1, pp. XV + 428; vol. 2, pp. XII + 465; rev. in Nature, 59 (1899), No. 1532, p. 267*).

Muscular work, Destree (*Quar. Jour. Inebriety, 1899, Jan.; abs. in British Med. Jour., 1899, No. 1999, Epit., p. 64*).—Experiments were made on the effect of alcohol, caffein (in the form of tea and coffee), and kola on the production of muscular work. The work was measured with a Mosso ergograph.

Sugar in the nutrition of man and animals (*Rev. Sci. [Paris], 4. ser., 11 (1899), No. 13, pp. 409, 410*).—L. Grandeau's work for the Société d'Agriculture is briefly reviewed.

Hay of Norwegian fodder plants, F. Werenskiold (*Tidsskr. Norske Landbr., 6 (1899), Nos. 1, pp. 35–43; 2, 82–86*).—Includes analyses of mountain hay (*säterhö*), meadow hay, and marsh hay (*myrhö*).—F. W. Woll.

Analyses and feeding value of whale-flesh meal, fish guano, and fish meal, F. H. Werenskiold (*Norsk Landmandsblad, 17 (1898), No. 51, pp. 568–570*).

Mechanical equivalent of materials constituting the ration of draft horses, P. Vuillier (*Bul. Syn. Pyrénées Orientales, 1898, June 16; abs. in Mes. Agr., 4. ser., 10 (1899), No. 8, pp. 118, 119*).—The composition and digestibility of different feeding stuffs are discussed, as well as their value as sources of energy.

The use of sodium dioxid in studying the respiratory function, Desgrez and Balthazard (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 6, pp. 361–363*).—Experiments are briefly reported with animals confined in air-tight chambers on the possibility of supplying oxygen by the decomposition of sodium dioxid by water. The alkali formed from the sodium dioxid absorbed the carbon dioxid eliminated in the respiratory products. The experiments were successful.

Farm animals, L. J. TRONCET and E. TAINTURIER (*Le bétail. Paris: Librairie Larousse* [*n. d.*], *2. ed., p. 188, figs. 100*).—This is a popular volume on the horse, mule, sheep, and other farm animals, with a special section on accidents and diseases.

Molasses as a food for animals, E. WERY (*L'Engrais, 14* (*1899*), *No. 17, pp. 400–402*).—A general summary, quoted from *La Sucrerie Belge,* of some of the recent work on this subject.

Experiments on the feeding value of sugar beets, G. SORESI (*Staz. Sper. Agr. Ital., 31* (*1898*), *No. 6, pp. 602-619*).—The yield, size, and composition of a number of sorts of sugar beets are recorded, and rations are suggested which are made up in part of beets.

Ground bone as a food for young cattle (*L'Engrais, 14* (*1899*), *No. 13, p. 304*).—A brief account of experiments by A. Gouin and A. Andouard reported to the Société Nationale d'Agriculture de France on the successful feeding of ground bone to calves.

Maize, rye, barley, and oats as food for horses, G. DE MARNEFFE (*L'Ing. Agr. Gembloux, 9* (*1898*), *No. 5, pp. 239–247*).—A test made with two lots of 15 horses each is reported on the comparative value of oats and barley. Lot 1 was fed 9 kg. of oats per head daily, and lot 2 was fed 5 kg. of oats and 4 kg. of ground barley. The test covered 8 months. The average weight of the horses in lot 1 at the beginning of the test was 473 kg., and of those in lot 2, 469 kg. During the test the average gain per head of lot 1 was 6 kg., and of lot 2, 29 kg. No bad effects due to barley were noticed. The value of maize for horses is discussed at some length, and the experience of a Brussels cab company on the successful use of maize as part of a ration is quoted.

Investigations on continuous crossing, R. SENEQUIER (*Ann. Agron., 24* (*1898*), *No. 11, pp. 497–510, figs. 13*).—Experiments begun in 1889 are reported on the continuous crossing of Larzac and Barbarine sheep.

The farmyard, L. J. TRONCET and E. TAINTURIER (*La basse-cour. Paris: Librairie Larousse* [*n. d.*], *pp. 160, figs. 80*).—Chickens, turkeys, pigeons, ducks, geese, etc., are described and discussed in a popular way. The volume also contains chapters on feeding, hygiene, accidents, and diseases.

Breeding and rearing ducks, J. J. MCQUE (*Agr. Gaz. New South Wales, 9* (*1898*), *No. 2, pp. 199–202, pl. 1*).—The author discusses the subject largely from the standpoint of his personal experience.

The American standard of perfection as adopted by the American Poultry Association, containing a complete description of all the recognized varieties of fowls, J. H. DRENENSTEDT, editor (*Amer. Poultry Association, 1898, pp. 251.*)

Will poultry thrive on grain alone? F. H. HALL and W. P. WHEELER (*New York State Sta. Bul. 149, popular ed., pp. 7*).—This is a popular summary of Bulletin 149 of the station (see p.76).

Bulletin of the United States Fish Commission (*Vol. 17, pp. 426, pls. 22, figs. 18*).—This volume contains a number of special articles on fish and fisheries, as well as the proceedings of the National Fishery Congress held at Tampa, Florida, January, 1898, and the papers read before the congress.

The utilization of waste products and waste places. II, The Clam, G. W. FIELD (*Rhode Island Sta. Bul. 51, pp. 65–70, fig. 1*).—The author believes that clams could be profitably cultivated on many mud flats. The best methods of extending and fostering this industry are discussed.

DAIRY FARMING—DAIRYING.

The period of gestation in cows, H. H. WING (*New York Cornell Sta. Bul. 162, pp. 325–334*).—Observations were made on the period of gestation of a single herd of cows and its descendants during a period of about 10 years. The herd contained an average of about 20 cows, about two-thirds Holsteins and one-third Jerseys, with high grades of these breeds, a few natives, and mixed and crossbred cattle. The observations are reported in detail and summarized as follows:

> "Of 182 births the average period of gestation was almost exactly 280 days. The shortest period was 264 days, the longest 296 days. Approximately equal numbers of births occurred on each day from the 274th to the 287th, inclusive.
>
> "The period of gestation was the same for male and female calves.
>
> "The period of gestation where twins were born was 5 days less than the general average and 8 days less than the average of the single births of the same cows.
>
> "Many cows show a well-marked individual characteristic as to period of gestation, which may be several days longer or shorter than the average."

Feeding experiments with brewery residue for milch cows, E. RAMM and E. MÖLLER (*Milch Ztg., 28 (1899), No. 7, pp. 97–99*).—This material (Brauschlempe) is said to be a new product prepared by a process which utilizes all of the residues obtained in manufacturing beer, including the yeast and the sediment from the cooling of the wort. It is in the form of brown horny pieces similar to macaroni, and for use in the experiments was ground to a meal. It had the following composition: Water, 10.25; protein, 47.2; fat, 0.9, and ash 6.90 per cent.

The feeding experiment was made with 8 cows, 6 kg. of the residue being compared with 6 kg. of peanut meal in alternating periods. The results are given in detail and summarized. The live weight and the yield of milk were very nearly the same on the two feeding stuffs, the average being slightly higher with the brewery residue. The percentage of fat in the case of every cow was slightly lower on the brewery residue than on the peanut meal, the average difference being about 0.26 per cent, so that the daily average per cow was 33 gm. less fat and 45 gm. less of total solids on the brewery residue. Considering the very rich character of peanut meal, the showing for the brewery residue is thought to be very satisfactory.

Butter made while the cows were on the brewery residue was found to be normal in composition, and to be free from any peculiar taste or other characteristic.

It is calculated that with peanut meal at 8 marks ($1.92) per 100 lbs. the brewery residue would be worth 7 marks and 66 pfennigs ($1.88).

The turnipy taste of milk, N. RITLAND (*Milch Ztg., 28 (1899), No. 6, p. 88; Nord. Mejeri Tidn., 14 (1899), No. 2, p. 17*).—A brief account of a Norwegian experiment. Two cows which were on pasturage were fed turnips out of doors and milked in the stable, and later they were fed hay and turnips in the stable and milked out of doors, the object being to test the absorption of the turnipy odor. No grain was fed at any time. The amount of turnips fed was as high as 1 hectoliter (2.84 bu.) per cow daily. Tests of the milk at different times by a number of persons failed to reveal any turnipy taste in the milk. The conclusion is reached that the characteristic taste often observed when turnips are fed is due entirely to the absorption by the milk of the volatile ingredients of the turnips.

A study of the milk supply of Chicago, JANE ADDAMS and H. S. GRINDLEY (*Illinois Sta. Circ. 13, pp. 18*).—A study was made of the cost and composition of milk as furnished to consumers in two districts of Chicago. Determinations of the fat and total solids in 185 samples of milk collected in the winter of 1896–97 in the neighborhood of Hull House and Lewis Institute, and of the fat, total solids, and casein in 100 samples collected in the spring of 1898 in the Hull House district are tabulated. The analyses are considered in connection with a discussion of variation in the composition of normal milk, milk standards, and adulteration, cost, and nutritive value of milk, and the results of the study summarized:

"Of the 272 samples of milk which have been examined and which were sold as whole milk, the variation in total solids ranges from 6.24 to 18.44, a difference of 12.20 per cent. The variation in fat ranges from 0.5 to 10.40, a difference of 9.90 per cent. The solids-not-fat vary from 4.2 to 10.6, a difference of 6.4 per cent. The average percentage of fat in 272 milks is 3.17. In 263 samples the average percentage of total solids is 11.71 and the average percentage of solids-not-fat is 8.54.

"Of the 272 samples, 134, or 49.26 per cent, contain less than 3 per cent of fat, and 181, or 66.54 per cent, contain less than 12 per cent of total solids. Of the 272 samples sold as whole milk only 90, or 33.09 per cent, may be considered as legal according to the city ordinances, and 235, or 86.40 per cent, are below the average of the American analyses of whole milk. In other words, two-thirds of the milk sold was adulterated or below the low requirements of the city."

Butter and butter adulterants, C. B. COCHRAN (*Jour. Franklin Inst., 147 (1899), No. 2, pp. 85–97, pl. 2*).—In distinguishing butter from oleomargarine the author relies quite largely upon the refractive index, amount of volatile fatty acids, and the Valenta test (temperature at which the fat becomes turbid when treated with an equal volume of strong acetic acid). "I have never as yet met a single case in which any one of these tests did not sharply distinguish between butter and oleomargarine." Other tests, as iodin number, saponification number, color tests, etc., are used in doubtful cases. A table is given showing the limits of variation in results usually obtained by these tests for butter, lard, and cotton-seed oil. The author found the Valenta test of much assistance in detecting small amounts of lard in butter.

"A series of tests made at the same time on different samples of fresh butter of known purity will give very uniform results. Stale butters give low results; adulterated butters usually give high results. On account of the liability of the acetic acid to lose strength by absorption of water whenever testing samples of butter of unknown origin, comparative tests should be conducted on fresh samples of known purity. If this precaution is taken I believe the results furnished by the Valenta test will prove to be very important."

A table shows the results of the Reichert test, the Valenta test, and the reading of the Zeiss butyro-refractometer for 8 samples of pure butter obtained from different sources, and for the same after the addition of 10 per cent of lard.

"In every case but one the additions of 10 per cent of lard has raised the results of the Valenta test decidedly above those obtained from pure butter, and this single exception is satisfactorily explained by the fact that this sample was old and very rancid when the test was made. . . . A difference equally marked will be shown in the Valenta test if the butter is adulterated with oleomargarine, oleo oil, tallow, or other animal fats foreign to butter."

A study was made of the crystallization of fats from solution in various liquids. It is believed that if the conditions are kept uniform the crystallization from amyl alcohol will have a uniform characteristic appearance.

The use of cotton-seed oil as a butter adulterant under the name of "cream ripener" is noted, and an experiment is reported in which butter was made from natural cream and cream to which some of the "cream ripener" was added. There was an increased yield with the cream ripener, which is attributed "partly to the difficulty of removing buttermilk, the butter obtained in this case being unusually hard to work." The results of various tests of this butter are reported, and the conclusion is reached that "5 per cent of this oil will give reactions so strong that its presence can not be due to the feeding of cotton seed or to the introduction of cotton-seed oil as a solvent for the coloring matter used in coloring the butter." A number of samples of butter suspected of containing cream ripener were examined and found to give very marked color reactions.

The detection of renovated, or process, butter is described, considerable weight being laid upon the microscopic examination by polarized light, although this is not considered conclusive. The results of examination of 3 samples of renovated butter are given.

"In renovated butters the turbidity temperature, as shown by the Valenta test, is lower than that usually found in fresh butter, and in the Jean modification of the Valenta test a greater amount of acetic acid is dissolved by fresh butter fat. Renovated butters also usually contain a high percentage of free fatty acids."

Commercial butter cultures, H. HAYWARD and M. E. MCDONNELL (*Pennsylvania Sta. Bul. 41, pp. 19*).—Experiments were conducted to determine the effects of Hansen's Lactic Acid Ferment, B 41, the Boston Butter Culture, and a skim-milk starter prepared at the station, upon the flavor of butter made from pasteurized and unpasteurized cream. Incidentally the flavor of butter made from pasteurized and unpasteurized cream under certain varying conditions was compared.

The data are given for six trials made with each culture in cream pasteurized by heating at 150° F. for 20 minutes, and for five trials with each culture in unpasteurized cream. No direct comparison between lots of the same cream pasteurized and unpasteurized and ripened with the same cultures were made.

The butter from each lot was scored for flavor by three judges soon after making, but was not scored again, so that the effect on the keeping quality was not determined.

A table shows the number of bacteria per cubic centimeter in the control lots in each case, the number destroyed by pasteurizing, the number per cubic centimeter that were added in the starters, and the percentage of purity of each culture after it was added to the cream. In the unpasteurized lots it was observed that "it apparently made no difference in the flavor of the butter whether the percentage of the culture bacteria added was 4 or 80 per cent of the total number present." The results are discussed at considerable length, and are summarized as follows:

> "(1) In the light of these experiments, butter cultures may be divided into two classes, the acid-forming and the nonacid forming.
>
> "(2) In pasteurized cream, the nonacid-forming cultures gave results slightly inferior to those obtained with the unpasteurized control lots, ripened spontaneously.
>
> "(3) In unpasteurized cream, the nonacid-forming cultures gave results slightly if any better than those obtained with the control lots, ripened spontaneously.
>
> "(4) In pasteurized cream the acid-forming cultures gave results slightly better than those obtained with the unpasteurized control lots, ripened spontaneously.
>
> "(5) In unpasteurized cream the acid-forming cultures gave results but slightly if at all better than those obtained with the control lots, ripened spontaneously.
>
> "(6) The use of an acid-forming culture seemed to result in greater uniformity in flavor, in butter made from pasteurized cream.
>
> "(7) Of the acid-forming cultures, the skim-milk starter gave results practically as good as did the more expensive commercial cultures, although it was not so conveniently prepared.
>
> "(8) As good, if not better, flavored butter was made from unpasteurized cream ripened with a skim-milk starter as from pasteurized cream ripened with a commercial starter.
>
> "(9) The amount of acid developed in the cream had a very important bearing upon the flavor of the butter. As a rule, the best flavored butter was made from cream in which the development of acid had exceeded 0.55 per cent.
>
> "(10) Close attention to details, cleanliness, and the careful selection of milk at the weigh room promise more in improving the flavor of our butter than pasteurizing and the use of pure cultures."

Heated milk for butter making, H. HAYWARD and F. F. PEPPER (*Pennsylvania Sta. Bul. 15, pp. 5*).—Ten trials were made, to test the comparative values in butter making of separating milk at temperatures of 86° and 155 to 158° F. The milk was heated to these temperatures by means of a Larkey heater. The cream from both lots received the same treatment. A skim-milk starter was used. The data for the experiment, including the scoring of the butter for flavor by three judges, are tabulated. While no advantage in butter making was found to result from heating the milk to 155 to 158° before separating, a considerable disadvantage was found in handling skim milk so treated on account of its souring quickly unless cooled at once, which is not thought practicable.

Report of Danish permanent butter exhibitions for 1898, F. Friis (*Copenhagen, 1899, pp. 42*).—During 1898, 713 creameries participated in these exhibitions, 2,110 tubs of butter being judged in all. The average percentage of water in the butter was 13.93 per cent, the determinations ranging from 10 to 20.05 per cent; 42 tubs, or 2 per cent of the total number, contained more than 16 per cent of water. All but 5 of the creameries exhibiting practiced pasteurization, and all but 11 used commercial lactic starters.

Churning experiments with cream pasteurized at 80, 85, and 90° C.—In most cases Danish butter is manufactured from cream pasteurized at about 75° C. (167° F.); during late years, however, the tendency has been toward pasteurization at higher temperatures. The experiments here reported were made for the purpose of ascertaining the influence of pasteurization at high temperatures on the quality of the butter, especially as regards its keeping quality. The experiments were conducted at 4 different creameries, 43 single trials being made. The cream was pasteurized at the ordinary temperature (75° C.) and at 80, 85, and 90° (176, 185, and 194° F., respectively), and cooled to about 12° C. (54° F.). The butter was scored first the day after it was made, and again 14 days later. The first scoring of the butter from cream pasteurized at 75° C. was taken as *n* in each trial, and the butter from cream pasteurized at higher temperatures was compared with it, the result being indicated by *n* + where the latter was superior. Similarly, in the second scoring all the butter was compared with the *n* of the first scoring. In stating the keeping quality, *d* was taken as the decrease in score between the two scorings of the 75° pasteurized product. The total score in the Danish system of scoring is 15. The average results are shown in the following table:

Summary of results of pasteurization trials in butter making.

Cream pasteurized at—	Number of trials	First scoring		Second scoring		Keeping quality.	
		75° C.	Higher temperature	75° C.	Higher temperature.	75° C.	Higher temperature.
80° C. (176° F.)	3	*n*	*n* + 0.3	*n* − 3.8	*n* − 2.1	*d*	*d* + 1.4
85° C. (185° F.)	21	*n*	*n* + .4	*n* − 2.8	*n* − 1.5	*d*	*d* + .9
90° C. (194° F.)	19	*n*	*n* + .2	*n* − 2.0	*n* − 1.3	*d*	*d* + .5
Average		*n*	*n* + .3	*n* — 2.9	*n* — 1.6	*d*	*d* + .9

Both the flavor and the keeping quality of the butter from cream pasteurized at higher temperatures were better than in case of butter from cream pasteurized at 75° C. The keeping quality of the former was superior in 29 out of 43 cases, the same as that of the lower pasteurized product in 9 cases, and inferior in this respect in 8 cases. The "cooked taste" which appears in butter from cream pasteurized at high temperatures, according to the author, will disappear in the course of a short time. The cooling of the cream practiced in these experiments was not considered sufficient, but could not be carried further under existing conditions in the creameries where the work was done. Rapid and rigid cooling is essential in high-temperature pasteurization.

The chemical analyses which were made fail to show any appreciable difference in the fat content of the buttermilk or the water content of the butter from pasteurization at the different temperatures.—F. W. WOLL.

Some observations on the formation and improvement of dairy cattle, H. L. O. WINBERG (*K. Landt. Akad. Handl. Tidskr., 37 (1898), No. 5-6, pp. 296-308*).

Type more important than breed, C. L. BEACH (*Hoard's Dairyman, 30 (1899), No. 6, pp. 112, 113, figs. 8*).—The record is given for different types of cows in the herd of the Storrs Agricultural College, with illustrations of cows and remarks on the feeding and net profit.

"In comparing breeds with types, we find the range in amount of butter produced to be, with the Jerseys 371, Ayrshires 266, or a difference of 105 between the highest and lowest. The variation due to type is 273 lbs.

"In a similar way, the range in the cost of 1 lb. of butter between the breeds is 4 cts., while the range between the types is 8½ cts.

"The range in net profit between breeds is $16.25, while the range between types is $41.07.

"We may conclude, then, that the form or type, more than breed, will determine the ability of a cow to produce butter economically."

Brief manual of dairying and stock raising, A. A. KALANTER (*St. Petersburg, 1898, pp. II + 252, figs. 120; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Oct., p. 229*).—The book gives among other things information about the existing schools of dairying, traveling dairies, etc.

Questions of dairying in the Caucasus (*Tiflis: Imperial Agricultural Society of the Caucasus, 1897, pp. II+32+77+204+22; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Jan., pp. 229, 230*).

Feeding experiment with fermented skim-milk feed, L. F. NILSON (*K. Landt. Akad. Handl. Tidskr., 37 (1898), No. 5-6, pp. 309-342*).—Detailed report of the feeding experiments with 30 cows, of which an abstract has already been given (E. S. R., 10, p. 487).—F. W. WOLL.

Feeding experiments with Tropon residue for milch cows, E. RAMM and E. MÖLLER (*Milch Ztg., 28 (1899), No. 2, pp. 17-19*).—This material is obtained as a by-product in the manufacture of the new protein preparation Tropon, which is made from a mixture of animal and vegetable material. The by-product is said to resemble pea bran in appearance and to contain 89.22 per cent of dry matter, 22.01 of protein, and 9.07 of fat. It was fed in an experiment with 8 cows in comparison with an equal amount of peanut meal. The results of the short trial show that although it contained considerably less digestible protein, the Tropon residue "completely replaced the peanut meal," and the conclusion is reached that it is of equal value to peanut meal.

The college herd (*Michigan Sta. Rpt. 1897, pp. 86, 87*).—This contains a condensed record of the individual cows of the herd, reference to the application of the tuberculin test to the herd and the purchase of a new herd, and some deductions from the herd record, previously given in greater detail (E. S. R., 9, p. 1081)

Influence of feed on quantity and quality of milk, C. F. CURTISS (*Northwest. Cream. Jour., 1 (1899), No. 9, pp. 12-14*).

Influence of spaying on milk production, FLOCARD (*Abs. in Dairy, 11 (1899), No. 124, p. 123*).—Between 1879 and 1888 the author performed the operation on 1,950 cows, with a loss of only 9; and from 1888 to 1897 he operated on 2,505 cows, without a single accident. He notes the increase in yield of milk and richness of spayed cows, and that "a spayed cow fattens more readily, its flesh is better, is heavy, rosy, and streaked with fat, and its juice is abundant and rich."

Refrigeration in dairying, F. Seret (*L'Ing. Agr. Gembloux, 9 (1899), No. 8, pp. 485–487, fig. 1*).

Contribution to the question of detecting butter adulteration, T. Pfeiffer (*Chem. Ztg., 23 (1899), No. 5, pp. 39, 40*).—The author reports the case of butter known to be pure which was considerably below the limit of volatile fatty acids. He is unable to account for this occurrence, as the cows were well nourished, but suggests that it may have been due to the clover and grass fed.

Testing milk for nitrates, E. Ackermann (*Schweiz. Wchnschr. Chem. u. Pharm., 1898, p. 285; abs. in Ztschr. Angew. Mikros., 4 (1899), No. 10, pp. 269, 270*).

How shall we drink our milk, sterilized, pasteurized, or raw? C. W. Sorensen (*Dairy, 11 (1899), No. 124, pp. 102, 103*).—After treating popularly of the methods and results of sterilizing and pasteurizing, and of the prevention of infection by proper handling of milk, the author concludes as follows:

"In plain language, pasteurization is but a cure for dirt and disease, and the public has a right to something more than this. It has a right to the prevention of this dirt and disease. Sterilization is essentially objectionable, and pasteurization, to be efficient, costs money. It is true that the preventive measures I would have adopted also cost money. But I state emphatically, from actual experience, that such prevention is not only better but cheaper than any such cure. Let the public awake to its right to pure milk, raw yet undefiled, and dairymen will find it in the long run to their own truest interest to cater in an enlightened spirit for this legitimate and natural demand."

An artificial milk, C. Meyer (*Berlin. Klin. Wchnschr., 1898, No. 19; abs. in Hyg. Rundschau, 9 (1899), No. 6, p. 308*).—Instead of using milk as a basis, as is the case with most artificial preparations, the constituents of milk (albuminoids, milk sugar, butter fat, salt, and water) are mixed in definite proportion. The mixture has the appearance and taste of natural milk and an alkaline reaction. The casein is prepared from cows' milk and curdles with acid in a finely divided condition; it is completely digested by pancreas in from 2 to 3 hours. Experiment showed that the fat was resorbed to a satisfactory degree and the loss of nitrogen was not greater than under ordinary conditions. The artificial milk is intended for infants and invalids.

Churn to prevent over churning (*Dairy, 11 (1899), No. 121, p. 126, figs. 3*).—A description of an invention patented in Germany by F. Lengowski and F. Komnick.

Pure cultures vs. home-made starters, J. R. Campbell (*Dairy, 11 (1899), No. 124, p. 107*).—A lecture on the author's experiments in using pure cultures in cheese making. His conclusion is that a pure culture is needed for the production of a proper curd, and that it is immaterial how this is procured. He calls attention to some precautions to be observed in using home-made starters.

On the handling, application, and manufacture of pure-culture starters, L. F. Rosengren (*Mejeri Praktiken, 1898, No. 23; Nord. Mejeri Tidn., 13 (1898), No. 48, pp. 691–693*).

Swedish butter exhibitions during 1898 (*Tidskr. Landtmän, 19 (1898), No. 50, pp. 895–903*).—During the year 335 creameries took part in the exhibitions, 1,303 tubs having been exhibited, scored, and analyzed. The average water content was 13.5 per cent, the range being from 10 to 22.9 per cent; 2.3 per cent of the tubs contained over 16 per cent of water.—F. W. WOLL.

Denmark's butter export, 1897-98, B. Bøggild (*Tidsskr. Landökon, 17 (1898), No. 7–8, pp. 472–481*).—The export from October 1, 1897, to September 30, 1898, amounted to 143,058,018 Danish pounds, and the export over and above imports to 108,954,370 lbs., an increase of over 16,500,000 lbs. over that of 1896–97. Denmark sent 139,500,000 lbs. of butter to England during 1897-98.—F. W. WOLL.

VETERINARY SCIENCE AND PRACTICE.

Investigations on sheep pox, L. DUCLERT (*Ann. École Nat. Agr., Montpellier, 10 (1897–98), pp. 103–170*).—The disease known as sheep pox is restricted entirely to sheep, only one observer having produced the disease in goats. All other animals have a complete natural immunity from the disease. The author believes that cowpox and the smallpox of man are perhaps caused by the same or very similar germs, but that sheep pox is of a different nature. The micro-organism which causes the disease has not been determined. Certain corpuscles supposed to be the cause of the disease were found by Guarnieri, but this supposed discovery was later discredited. The author records a large number of experiments in which he produced the active virus in the subcutaneous tissue of sheep and reproduced the disease by injecting this virus into sheep. It was found that the virus could be attenuated by subjecting it to a temperature of 25° C. Immunity from the disease was produced by injection of this attenuated virus.

Abortion in cows, T. W. CAVE (*Agr. Dept. Univ. Col., Nottingham, [and] Midland Dairy Inst., Kingston, pp. 8*).—The author discusses accidental and contagious or epizootic abortion, quoting at some length the experiments and conclusions of Bang, and reports the treatment of contagious abortion in the Midland Dairy Institute herd. Twenty-four cows were given 1 dram of pure carbolic acid twice a week. It was dissolved in a quart of hot water, diluted with 2 gal. cold water, and sprinkled over the food. No bad effects were noticed. After a month the dose of carbolic acid was increased to three times a week, and during the third month of the test it was reduced to two times per week. The cows were then pastured and the carbolic acid was discontinued until the following winter, when it was again given twice a week. In addition to this treatment the sheds were disinfected and the cows were treated with disinfectants and the stables also disinfected. Whenever a cow aborted she was removed to a separate shed, the afterbirth burned as soon as discovered, and the surroundings thoroughly disinfected. No aborting cow was allowed service again. The treatment began in February, 1897. Cases of abortion occurred till the end of the following June and then ceased. Up to October, 1898, no cases of abortion had occurred among the cows treated. As a control on the value of the treatment, 6 heifers at pasture received no treatment. Every one of these aborted.

The cure and prevention of rinderpest, G. TURNER and W. KOLLE (*Dept. Agr. Cape Good Hope, Report on the Cure and Prevention of Rinderpest, 1898, pp. 87*).—Experiments were tried in protecting cattle by means of the simultaneous injection of virulent blood on one side of the animal and a dose of serum on the other. The number of animals experimented with was 9,007, and the deaths resulting from these inoculations numbered 128. The number of animals which did not show evident signs of rinderpest under this treatment did not exceed 10 per cent. It was found necessary to mix serum from 90 to 100 animals in order to secure a constant strength. Large doses of serum were found to confer immunity for several months. If the animal was already infected with the disease, a larger dose of serum was required.

Immunity was produced also by injecting virulent blood and following it one or two days later by an injection of serum, or the serum may be injected first and the virulent blood at varying intervals afterwards.

Tuberculin experiments at Hamra, Sweden, O. STENSTRÖM (*Tidskr. Landtmän, 10 (1899), Nos. 1, pp. 8–11; 3, pp. 43–46*).—Three new tuberculin preparations were tested with reference to their value in diagnosing tuberculosis in cattle. All were prepared from sterilized pure cultures of tubercle bacilli. No. 1 was dissolved in water, No. 2 in 4 per cent glycerin, and No. 3 in a 5 per cent carbolic acid solution. Fifteen animals which had been found tuberculous in previous tests with common tuberculin were injected with 5 cc. of these tuberculin preparations, each preparation being tried on 5 animals. All preparations proved good diagnostic agents for bovine tuberculosis. No. 2 was perhaps the strongest of the three, producing in every case a rise in temperature of 2 to 3° C. This preparation also gave a decided reaction in cases of cows that had been rendered immune by previous injection with large quantities of common tuberculin. The injections in these trials were made about 5 months after the first injections. When the 5 animals that had reacted with preparation No. 2 were injected again a week later only 1 of the cows reacted, showing that by repeated injections this tuberculin may fail to give a reaction in case of tuberculous cows.

In studying the question of the time interval in which tuberculin will fail to give a reaction with tuberculous animals, 30 tuberculous cows were separated into 3 groups of 10 each. One group received 1 gm. of tuberculin per head every other day except the first 3 times when ½ gm. was used, the second group received ½ gm. each once per week, and the third group received ½ gm. each once a month, and later twice a month.

The experiment was discontinued December 19, 1897, when the animals in the different groups had received the following quantities of tuberculin per head: Group 1, 128.5 gm. in 130 injections; group 2, 20.5 gm. in 41 injections; group 3, 8 gm. in 16 injections. Group 1 failed to give a reaction after the fifth examination, while in the case of the animals in the other two groups no reaction was obtained after the first examinations. In the author's experiments, common tuberculin was not found to possess any therapeutic properties.—F. W. WOLL.

The serum treatment of swine plague and hog cholera, E. A. DE SCHWEINITZ (*U. S. Dept. Agr., Bureau of Animal Industry Bul. 23, pp. 18*).—Several years ago the author isolated 2 albuminoid substances and several amins which would produce immunity against hog cholera and swine plague when injected into hogs. In experiments which were tried with these substances about 50 per cent of the treated animals lived. This was not considered entirely satisfactory, and later the author isolated certain enzyms or soluble ferments. These were much more effective in producing immunity, and serum from animals which had been rendered immune by these enzyms could in turn be used for immunizing other animals. It was found that hogs could be immunized by long continued injection of the ordinary intestinal bacillus (*B. coli communis*). With serum from one animal other animals may be rendered immune, but in order that the antitoxic substances may be continually found in the blood serum it is necessary to give the animal continued injections of the cell contents or products of the germ.

Extended field experiments were tried in Page County, Iowa. The serum for the work was prepared from cattle, horses, mules, and donkeys, but, as the author remarks, "experiments had shown that the serum prepared for the purpose of curing hog cholera was useful in protecting or curing small experimental animals from hog cholera only, and that serum prepared for the purposes of curing swine plague was useful in protecting from swine plague only." In consequence of this fact the author prepared a mixed serum for curing hog cholera and swine plague. This was especially advisable since it is difficult to distinguish in the field between hog cholera and swine plague.

The quantity of the serum used for pigs weighing from 40 to 60 lbs. was 10 cc. Out of 196 animals treated with the mixed serum, 161 were saved, or about 82 per cent. In the herds which were not treated only 15 per cent recovered. In 1898 further work was done along the same lines. Thirty five herds, containing 1,727 animals, were treated; 403 died, which was a loss of 23.16 per cent. The number of animals in check herds was 3,197; only 600 of these survived, or 81.24 per cent was lost.

The Bureau of Animal Industry is enabled to produce this serum at a cost of about 15 cts. per dose, but only in limited quantities for the present. In order to prevent the carrying of the contagion from one herd of swine to another, careful disinfection of the premises is recommended, as well as of the farmer's boots, clothing, wagons, etc.

On the importance of the lymphatic system for the modern doctrine of infection and immunity, L. MANFREDI (*Arch. Path. Anat. u. Physiol.* [*Virchow*], *155* (*1899*), *No. 2, pp. 335–378*).—Records a number of experiments with toxins and concludes that the lymphatic glands have the power of attenuating the virus of infectious diseases.

Influence of the lymphatic glands in the production of immunity against infectious diseases, L. MANFREDI and P. VIOLA (*Ztschr. Hyg. u. Infectionskrank.*, *30* (*1899*), *No. 1, pp. 64–94*).—The lymphatic glands possess a natural resisting power against the virus of most infectious diseases, and they help materially to bring about immunity against these diseases.

Contributions to the question of the specific action of immunizing serum, C. MANN (*Arch. Hyg.*, *34* (*1899*), *No. 3, pp. 179–191*).—Concludes that agglutination and immobilization of bacteria does not prevent their growth.

The importation and exportation of live stock, D. Bernier (*Rev. Facult. Agron. y Vet. La Plata, 1898, No. 2, pp. 52-75*).—Contains various and detailed suggestions on quarantine laws. Recommends the thorough inspection of export and import animals and the use of tuberculin and mallein.

The histological alterations in cases of poison by ricin, G. Cruz (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 11 (1899), No. 2, pp. 238-258, pls. 2*).—Guinea pigs were the subjects experimented upon. Ricin was given by means of hypodermic injections. Autopsies were made a few hours after death, and detailed descriptions are given of the microscopic effects upon all tissues.

On the rôle of leucocytes in poisoning by a soluble arsenical compound, Besredka (*Ann. Inst. Pasteur, 13 (1899), No. 3, pp. 209-224*).—An increase in the number of leucocytes after injection of the poison indicates a resistance on the part of the organism to the poison and a probable recovery. A decrease in the leucocytes indicates the opposite condition. Arsenious acid was the poison used and the experiments were on rabbits and guinea pigs.

Some interesting cases observed in the inspection of meat in Stockholm, G. Kjerrulf and S. Nystedt (*Svensk Vet. Tidskr., 4 (1899), No. 3, pp. 109-112*).—Records the finding of measles (*Cysticercus tarandi*) in the meat of reindeer, and a *Helminthiasis nodularis* in the intestines and peritoneum of cattle which was produced by the young of *Œsophagostoma inflatum.*

A preliminary note upon certain organisms isolated from cancer and their pathogenic effects upon animals, H. G. Plimmer (*Proc. Roy. Soc. [London], 64 (1899), No. 411, pp. 431-436*).—The author experimentally produced malignant tumors in rabbits and guinea pigs by an organism isolated from cancer in man.

Clinical study of vertigo, G. Chenier (*Rev. Vet. Toulouse, 24 (1899), No. 5, pp. 277-285*).—Reports clinical observations on this disease in horses and in man.

Investigations on the ciliated infusoria which occur in the stomach of ruminant animals, A. Guenther (*Ztschr. Wiss. Zool., 65 (1899), No. 4, pp. 529-572, pls. 2*).—Various species of infusoria are carried into the stomach of sheep, cattle, and goats on hay and in water. The hay can be sterilized with boiling water. The physiological effect of the presence in the stomach of great numbers of these infusoria is not yet determined.

Is the presence of smut spores on fodder injurious? G. Staes (*Tydschr. Plantenziekten, 4 (1898), No. 4, pp. 116-128*).—Compiled information is given from various sources, from which it is concluded that smuts are not injurious to animals as a rule.

The stock owners' indebtedness to the microscope, C. J. Pound (*Queensland Agr. Jour., 4 (1899), No. 3, pp. 202-216*).—Gives a general account of the progress of our knowledge on the diseases anthrax, tetanus, actinomycosis, and tuberculosis.

The pathological-anatomical changes in the organs of animals after infection with the bacillus of the black plague of man, F. V. Karaulof (*Sci. Mem. Kazan Vet. Inst., 16 (1899), No. 2, pp. 92-108*).—The author calls attention to the striking similarity between the bubonic plague of man and the rinderpest of cattle. Experimental tests were made in inoculating rats, mice, pigs, cattle, dogs, cats, horses, and birds with the bacillus of the black death of man. The materials for the inoculation were the following: The black death bacillus in pure cultures, small pieces of various organs of subjects which died of the black plague, and dust collected from houses in which the black plague had existed.

The cattle plague and bubonic plague with investigations of Dr. Koch, Critzman (*Ann. Hyg. [Paris], 41 (1899), Jan., pp. 29-39*).—Records experiments in immunizing cattle and two species of monkeys. The antipest serum is shown to have curative as well as immunizing value. The immunity lasts from 3 to 5 months.

Serum treatment for rinderpest, D. Hutcheon (*Veterinarian, 72 (1899), No. 856, pp. 260-269*).—Records a series of experiments in combating rinderpest during which defibrinated sterilized salted blood from immunized animals and regularly prepared serum were used.

Cattle tuberculosis, T. M. LEGGE and H. SESSIONS (*London, 1898, pp. 78*).

The hereditary transmission of tuberculosis, E. N. Y BALBUENA (*Vet. Españ., Madrid, 42 (1899), No. 1486, pp. 33-37*).—The writer believes he has evidence of hereditary transmission of tuberculosis, and maintains that all diseases which are characterized by morphological and dynamic changes of any part of the organism may be inherited.

Tubercular disease in dairy herds, G. S. THOMPSON (*Jour. Agr. and Ind., South Australia, 2 (1899), No. 7, pp. 560-563*).—Gives a general history of our knowledge of tuberculosis and advises thorough testing of all dairy cattle with tuberculin.

Researches on the histogenesis of the tubercle and the curative action of tuberculin, A. BRODEN (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 11 (1899), No. 1, pp. 1-53, pls. 4*).—Tuberculin increases the natural power of resistance of the organism in its struggle against the bacillus and is not to be considered a new specific force which is not present in the organism.

Tuberculosis, J. W. BRITTLEBANK (*Agr. Students' Gaz., n. ser., 9 (1898), No. 3, pp. 69-74*).—Gives general recommendations concerning the use of tuberculin.

New contributions on the subject of the value of tuberculin as a diagnostic agent for tuberculosis, D. VAN DER SLUIJS (*Tijdschr. Veeartsenijk. en Veeteelt, 26 (1898), No. 1, pp. 19-26*).—Gives clinical records of a large number of tuberculin tests.

Results of the application of the tuberculin test to Her Majesty's dairy cows at Windsor, J. MCFADYEAN (*Jour. Comp. Path. and Therap., 12 (1899), pt. 1, pp. 50-56*).—Gives the temperature record of 40 cows under the tuberculin test.

Investigations for determining the value of ordinary tuberculin, W. DÖNITS (*Klin. Jahrb., 7 (1898), No. 2, pp. 225-234*).—By using a large series of guinea pigs it is possible to determine the value of a given tuberculin by the minimal fatal dose and to compare the strength of different tuberculins. The author criticises the ordinary methods of determining the strength of different tuberculins.

Anthrax (*Jour. Bd. Agr. [London], 5, No. 4, pp. 455-458*).—Recommends the thorough destruction of the carcasses of all animals which have died of anthrax.

The influence of lecithin and organic bodies containing lecithin (yolk of egg and brain) on the biology of the splenic fever bacillus, W. TARANUCHIN (*Russk. Arch. Pathol., Klin. Med. i Bact., 6 (1898), No. 1*).

New investigations on malaria, Texas fever, and the tsetse fly disease, G. H. F. NUTTALL (*Hyg. Rundschau, 8 (1898), No. 22, pp. 1084-1103*).

A case of ergotism, M. ROBIN (*Rec. Med. Vet., Paris, 8. ser., 6 (1899), No. 5, pp. 149-151*).—Gangrene of the extremities began to show in this case on the fourteenth day. Treatment was entirely unsuccessful.

Hygiene of domestic animals, H. GEORGE (*Jour. Agr. Prat., 1 (1899), No. 17, pp. 602-605*).—Gives an account of the poisoning of cattle with rape-seed cakes, and multiple gangrene in a cow caused by eating ergotized rye.

Experiments on immunity to foot and mouth disease, SIEGEL (*Deut. Med. Wchnschr., 24 (1898), Nos. 47, pp. 749, 750; 48, pp. 766-768*).

Investigations on the destruction of the contagion of foot and mouth disease in manure, HECKER (*Berlin. Tierärztl. Wchnschr., 1899, Jan. 5, pp. 6, 7*).—Infected manure may be sterilized by covering with noninfected horse manure for 8 days to the depth of one-third to one-half meter.

On typical and so-called contagious abortion, M. STREBEL (*Schweiz. Arch. Tierh., 40 (1898), No. 5, pp. 203-215*).

Laryngeal syngamus of cattle, M. A. RAILLIET (*Compt. Rend. Soc. Biol., Paris, 10. ser., 6 (1899), No. 8, pp. 174-176*).—Describes as new under the name *Syngamus laryngeus*, a syngamus found in the larynx of domestic cattle.

Aphthous fever and methods for preventing the same, F. MERCIER (*La fièvre aphtheuse et les mesures a prendre pour éviter la contagion. Beauvais, 1898, pp. 12*).—

Describes the disease and gives an account of how contagion may be carried with suggestions as to prevention.

Trembling, or peripheral enzootic neuritis of sheep, C. Besnoit (*Rev. Vet. Toulouse, 24* (*1899*), *No. 5, pp. 265–277*).—Gives the history of our knowledge of this disease together with the diagnosis and an account of the symptoms.

The diseases of horses—their pathology, diagnosis, and treatment, H. Dalziel (*London, 1898, pp. 102*).—A dictionary of equine materia medica is added.

On the treatment of Morbus maculosus of horses with Argentum credé, P. Meissner (*Berlin. Tierärztl. Wchnschr., 1899, Mar. 16, pp. 133–135*).—Intravenous injections of 0.5 gm. Argentum credé are recommended for the disease.

Diseases of the pig, O. Hilfreich (*Das Kranke Schwein. Neudamm, 1898, 2. ed., pp. 90, pl. 1, figs. 25*).—The symptoms and treatment of diseases of swine are given, as well as information on judging the flesh of diseased pigs.

Experimental investigations on hog cholera and swine plague, Karlinski (*Ztschr. Hyg. u. Infektionskrank., 28* (*1898*), *No. 3; abs. in Centbl. Bakt. u. Par., 1. Abt., 25* (*1899*), *No. 1, pp. 26–29*).—A number of experiments with pigs and other animals are reported.

On vaccination against swine plague and the cure of this disease by serum, O. Schreiber (*Berlin. Tierärztl. Wchnschr., 1899, Mar. 9, pp. 110*).—The author has used a serum which will cure both swine plague and hog cholera and will also produce immunity to either disease.

Concerning a nonmotile hog-cholera bacillus, Theobald Smith (*Centbl. Bakt. u. Par., 1. Abt., 25* (*1899*), *No. 7, pp. 241–244*).—Gives the appearances and behavior of this bacillus on different culture media.

Combating chicken cholera, P. Willach (*Deut. Tierärztl. Wchnschr., 7* (*1899*), *No. 14, pp. 125–128*).—By thorough disinfection of the premises and by giving of lysol internally, an outbreak of chicken cholera was entirely checked.

AGRICULTURAL ENGINEERING.

Irrigation in Mesilla Valley, New Mexico, F. C. Barker (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 10, pp. 51, pls. 11, figs. 5*).—This bulletin discusses the location, history, and climate of this valley and the methods of irrigation and cultivation in common use.

Mesilla Valley lies on both sides of the Rio Grande, and extends from Fort Selden on the north to within 3 miles of El Paso, Texas, on the south—about 55 miles. For the greater part of its length it is from 5 to 7 miles wide. "Along its entire course it is bounded on the east and west by lofty ranges, the highest of which—the Organ Mountains, distant some 12 miles to the east of the valley—rise to a height of 8,000 ft. above sea level, or 4,000 ft. above the agricultural lands along the river."

The main source of water supply is of course the Rio Grande, the characteristics of which are described in some detail. It is liable to become dry after July 1, thus emphasizing the need of storage reservoirs. Several such reservoirs have been projected, but not yet built. The water of the Rio Grande carries a large amount of sediment, which is of high fertilizing value,[1] but renders furrow irrigation very unsatisfactory by silting up the bottoms and sides of the furrows and thus retarding the percolation of the water.

---

[1] New Mexico Sta. Bul. 12 (E. S. R., 5, p. 1002).

The methods of agriculture by irrigation as practiced in this valley are believed to be, by the author, the oldest that exist in the United States, being largely an inheritance from the Mexicans, who learned them from the Spaniards.

> "The irrigating canals or ditches in the Mesilla Valley, of which there are 8, are what are termed 'communal ditches;' that is, they were built and are owned, kept in repair, and regulated by the members of the community who hold lands under them. . . . No scientific method of apportioning the water, either by measurement or by time, has been adopted. . . . When water is abundant, everyone helps himself whenever he needs it; and should it be scarce, as is sometimes the case, the mayordomos arrange to let each farmer have what appears to them a fair share, that share being fixed rather by the needs of the individual than by his share of interest in the ditch."

Flooding in checks is the method most commonly used, the furrow system frequently proving unsatisfactory, for the reasons stated above.

Pumping water for irrigation has been resorted to in but few cases in the valley, "although abundant water can be obtained almost everywhere at depths varying from 14 to 85 ft., this depth depending upon the height of the land above the level of the river bed."

The use of barnyard manure has been found very beneficial—in fact, indispensable, especially for vegetables. The benefit from the manure is ascribed to its physical effect and biological action.

"The methods of irrigation and cultivation in common use by the natives of the valley are discussed with a considerable degree of detail."

Irrigation systems in Texas, W. F. HUTSON (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 13, pp. 68, pls. 10, figs. 12*).—This paper is based upon field work carried on during May and June, 1897. It includes an introduction by F. H. Newell; general statements regarding the retardation of development, use of water, distribution of rainfall, and climatic and geographic divisions, and descriptions of irrigation works and projects of the eastern Gulf coast region, central Texas, San Antonio and vicinity, Nueces River and lower Rio Grande, Llano Estacado, Pecos Valley, and Trans-Pecos Texas.

> "The variety of geologic and climatic conditions and the mixed population in Texas have given rise to many methods of practice, so that there may be found representatives of nearly every system of irrigation occurring in the United States. Every degree of excellence may be noted, from that of modern machinery for raising water down to the most primitive devices for supplying it to the field. In the arid and semiarid portions of the State the methods of the early Spanish settlers are employed. Most of the cultivation is done by Mexican laborers or tenants, who cling to the old systems. Thus, on most of the ditches the distribution of the water is by the Spanish method of days and hours, each holder of a water right having the use of the ditch in his turn."

The more important facts relating to irrigation in Texas are summarized in the following table:

Comparison of capacity and cost of various systems of water supply in Texas.

Name.	System.	Pump.	Lift in feet.	Capacity, second-feet.	Acreage.		Cost.		
					Irrigable.	Irrigated.	Total.	Per acre.	Annual per acre.
Catron	50 H. P. engine	Menge	8	11.14		500	$1,500	$3	
Stubenrauch	8-foot windmill		25		15	7	300	43	
Do	12 foot windmill[a]				30		485	16	
Lytle	Dam and ditch				300		25,000		
Lewis	do				50	10	200	20	
Metcalf	do					470		7	$0.75
Glenn	do				350	250	3,500	14	
McGee	do				250	75	1,500	20	
Swinden	80 H. P [b]	Centrifugal		6.84	400				
Baker	32 H. P. engine[d]	Worthington		2.72	80	75	2,000	27	[c]6.00
Willis	Turbine			.11		5			
Aldridge	20 H. P. engine[e]			1.00	75				
Lindsey	30 H. P. engine[f]			1.87		40	2,000	50	
Vanderstucken	18 H. P. engine	Menge		2.60		100	1,500	15	
Richards	Water wheel			.20		3			
Garrett	do			.32		12

Grand Falls	do							15	1.25
El Paso					30,000	3,000	220,000		2.00

[a] Combined water power and irrigation.
[b] With reservoir.
[c] Approximate.
[d] Operating cost, $7 a day of 12 hours.
[e] Can water 5 acres per day.
[f] Operating cost, $3 per day of 11 hours.
[g] Water rights held at $15.
[h] Costs 12½ cts. per hour to operate.
[i] Pumps into reservoir.
[j] Operating expenses, $4.25 per day.

Water rights of the Missouri River and its tributaries, E. MEAD, J. E. FIELD, and J. M. WILSON (*U. S. Dept. Agr., Office of Experiment Stations Bul. 58, pp. 80, pls. 2, figs. 4*).—This is the first of a series of bulletins to be prepared in accordance with the provisions of the clause in the appropriation act for this Department for the current fiscal year authorizing the collection "from agricultural colleges, agricultural experiment stations, and other sources, including the employment of practical agents, of valuable information and data on the subject of irrigation, and publishing the same in bulletin form." After consultation with experiment station officers and irrigation engineers in the region specially interested in the subject of irrigation, it was decided that the investigations provided for by the above act should, for the present, be confined to two general lines: (1) The collation and publication of information regarding the laws and institutions of the irrigated region in their relation to agriculture, and (2) the publication of available information regarding the use of irrigation waters in agriculture as shown by actual experience of farmers and by experimental investigations, and the encouragement of further investigations in this line by the experiment stations. In accordance with this plan, the first bulletin discusses the laws which control the diversion and use for irrigation of the waters of the Missouri River and its tributaries, explaining the methods by which users establish and enforce their rights to a common supply, and pointing out the legal and physical complications which conflicting or imperfect State laws have created. The vast extent of the irrigated region and the peculiar problems presented by different large areas made it unadvisable to attempt to cover the whole field in a single bulletin. It was deemed preferable for this first bulletin to select a single region covering portions of several States in which there was in general sufficient likeness in the agricultural conditions as affected by irrigation to render it possible to make a clear and definite statement of the problems of water rights and of the directions in which improved legislation is required. The area embraced in the discussion includes Colorado, Kansas, Montana, Nebraska, North Dakota, South Dakota, Wyoming, and the Northwest Territories of Canada. The bulletin discusses principles and explains the methods of procedure which farmers must follow in the different States in making and recording water right filings.

Abstract of laws for acquiring titles to water from the Missouri River and its tributaries, with the legal forms in use, E. MEAD (*U. S. Dept. Agr., Office of Experiment Stations Bul. 60, pp. 77*).—This bulletin, the nature of which is explained in its title, is supplementary to Bulletin No. 58 of this Office (see above), and with it forms a manual of instruction regarding the methods of procedure in acquiring water rights in the Missouri River watershed.

Draft of farm implements, M. W. FULTON (*Michigan Sta. Bul. 165, pp. 97-100*).—The tests here reported were of wagons, subsoilers, harrows, and mowers. The draft was determined by means of a self-recording dynamometer.

Comparative tests were made of broad (4 in.) and narrow (1⅝ in.) tires on different kinds of roads. "The results all favor to a very marked degree the wide tires. While upon a gravel road, hard, smooth, and well packed, the difference in draft is but 6.62 per cent, using a narrow tire as a basis, upon sod or raw ground, the difference is so marked as to be decisive." On sod the draft was 23.35 per cent in favor of wide tires; on corn stubble, 32.83 per cent. These tests were all made with wagons carrying a load of 4,500 lbs. A comparison was made of the draft of a wagon with the load equally distributed on all four wheels and with the load placed over one axle. "The results seem to show that where the road is firm and smooth it is immaterial whether the load is evenly distributed over the 4 wheels or not, but where the ground is soft the draft is increased if the weight is very largely upon the front or the hind wheels." In trials of hitching the horses to the whiffletrees in the ordinary manner and to the end of the tongue, the result showed no marked difference in draft which could be attributed to the difference in point or method of attachment. Removing the grease from the skeins and boxes of the wheels and adding a little grit increased the draft of a wagon 22.34 per cent.

"Late in the fall of 1896 a test was made of the draft of two forms of subsoil plows. In one case the loosening of the subsoil was accomplished by forcing through it a flat tongue-shaped piece of steel. In the other curved teeth stir up the subsoil. Three teeth were used, each approximately an inch in width, and so curved as to dig to a considerable depth below the bottom of the furrow left by the ordinary plow. Subsoiler No. 1 was provided with a wheel which maintained a uniform depth. No. 2 with the curved teeth had no appliance for regulating the depth, and in practice it was found impossible to keep it from gouging in deep in the softer places and running somewhat shallower than desired in others.

"The average draft on 4 trials of each subsoiler at an average depth of 10 in. below the bottom of the furrow left by the ordinary plow was for No. 1 504 lbs. and for No. 2 606 lbs."

In comparative tests of a floating spring-tooth harrow having 15 teeth and a riding spring-tooth harrow with 17 teeth, the following results were obtained on freshly plowed sandy loam, harrowed to a depth of 3 in.: With the driver riding the draft of the wheel harrow was 513 lbs.; with the driver walking the draft was 346 lbs. The draft of the floating harrow, under the same conditions, was 402 lbs. On an unplowed compact loam, harrowing to a depth of 4 in., the average draft of the wheel harrow was 570 lbs. with the driver riding and 513 lbs. with the driver walking. Under the same conditions the average draft of the floating harrow was 608 lbs. The harrows were about 5 ft. 9 in. wide.

In comparative trials of two 5-foot cut mowers on a field of clover and timothy, yielding about 2 tons per acre, the average draft was 244 and 246 lbs.

Notes on irrigation, E. C. CHILCOTT and R. S. ROE (*South Dakota Sta. Bul. 61, pp. 29-31, pl. 1*).—These notes describe the method of irrigation practiced in connection with growing forage and garden crops in the James River Valley in 1898 (E. S. R., 10, p. 629). General directions for irrigating are given.

Trials of farm machinery at Ultuna Agricultural College, H. JUHLIN DANNFELT (*Tidskr. Landtman, 19 (1898), Nos. 47, pp. 837-843; 48, pp. 860-863; 49, pp. 873-879; 51, pp. 920-923; 52, pp. 934-938; 20 (1899), No. 1, pp. 6-8*).—Trials of mowing machines, horse rakes, and potato diggers. No details are given of the trials.—F. W. WOLL.

The steam plow in Finland, C. J. MYRSTEN and J. JERNSTRÖM (*Biet, 19 (1898), No. 11, pp. 255-272*).

Report of trials of refrigerating machines, September, 1898, E. P. BONNESEN (*Tidsskr. Landökon, 1899, No. 2, pp. 49-86*).—Trials with carbonic-acid, ammonia, and sulphurous-acid machines. The first kind proved the most efficient, and the ammonia machine next.—F. W. WOLL.

STATISTICS—MISCELLANEOUS.

Organization lists of the agricultural colleges and experiment stations in the United States, with a list of agricultural experiment stations in foreign countries (*U. S. Dept. Agr., Office of Experiment Stations Bul. 59, pp. 115*).—This bulletin contains the organization list of agricultural colleges and experiment stations in the United States, a subject list of publications of the experiment stations received by the Office during 1898, the Federal legislation relating to the colleges and stations, the rulings of the Post-Office, Treasury, and Agricultural Departments as to the construction of the act of Congress of March 2, 1887, establishing the stations, and a list of agricultural experiment stations and kindred institutions in foreign countries compiled from various sources.

A report on the work and expenditures of the agricultural experiment stations for the year ended June 30, 1898, A. C. TRUE (*U. S. Dept. Agr., Office of Experiment Stations Bul. 61, pp. 113, pls. 14*).—This includes a critical review of the conduct and general management of the stations, with brief abstracts of all station publications received during the fiscal year ending June 30, 1898; and general statistics relative to organization, publications, principal lines of work, revenue, expenditures, etc.

Tenth Annual Report of Michigan Station, 1897 (*Michigan Sta. Rpt. 1897, pp. 79-397*).—This includes a financial statement for the fiscal year ending June 30, 1897, a report by the director, departmental reports, parts of which are noted elsewhere, and reprints of Bulletins 135-144 of the station on the following subjects: Fertilizer analyses (E. S. R., 8, p. 584), fattening lambs (E. S. R., 8, p. 1008), feeding corn smut to dairy cows (E. S. R., 8, p. 1007), pig feeding (E. S. R., 8, p. 1011), bacteria (E. S. R., 9, p. 121), ropiness in milk (E. S. R., 9, p. 183), forage crops and wheat (E. S. R., 9, p. 131), small fruit trials at the college (E. S. R., 9, p. 354), fruit tests at South Haven (E. S. R., 9, p. 353), and vegetables old and new (E. S. R., 9, p. 350).

A second report to Congress on agriculture in Alaska (*U. S. Dept. Agr., Office of Experiment Stations Bul. 62, pp. 51, pls. 11, figs. 2*).—This contains a review by the director of the progress made in investigating the agricultural capabilities of Alaska during 1898, and reports on agricultural investigations (p. 42), botanical survey (p. 28), and climate (p. 31).

Third report of committee on methods of teaching agriculture (*U. S. Dept. Agr., Office of Experiment Stations Circ. 39, pp. 7*).—This report, submitted to the Association of American Agricultural Colleges and Experiment Stations at Washington, D. C., November 15, 1898, gives a syllabus for a course of instruction in agronomy (plant production).

Land-grant and other colleges and the national defense, C. W. DABNEY (*U. S. Dept. Agr., Office of Experiment Stations Circ. 40, pp. 15*).—An address delivered before the Association of American Agricultural Colleges and Experiment Stations at Washington, D. C., November 15, 1898 (E. S. R., 10, p. 706).

Report of the Ministry of Agriculture and Imperial Domains for the fourth year of its existence, ending March 30, 1898 (*St. Petersburg, 1898, pp. 300*).

Report of the agricultural experiment station "Zapolye," Petersburg Government, Loozhski district, 1897, J. J. SOKHOTSKI (*St. Petersburg, 1898, pp. 82*).

Contribution to the study of the natural and scientific principles of agriculture in the forest and steppe region of European Russia, P. BARANOV (*St. Petersburg, 1898, pt. 1, pp. IV+XV+148; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Dec., pp. 713, 714*).

Primitive agriculture in Finland during historic times, G. GROTENFELT (*Det primitive Jordbrukets Metoder i Finland under den historiska Tiden. Helsingfors, 1899, pp. 444, ill.*).

NOTES.

FLORIDA STATION.—The new board of control appointed by the governor on May 18 is constituted as follows: President, E. A. Foster, of Gainesville; vice-president, G. W. Wilson, of Jacksonville; secretary, F. E. Harris, of Ocala; E. D. Biggs, of Pensacola; C. A. Carson, of Kissimmee, and J. D. Calloway and L. Harrison, of Lake City.

MAINE STATION.—Horace L. White has resigned his position as assistant chemist of the station, and E. R. Mansfield has been appointed in his stead.

MARYLAND STATION.—At the recent meeting of the board of trustees, held June 9, provision was made for assistants in chemistry and horticulture. The college farm was united with the station farm, to be run under the direction of the station. It was decided to abandon all investigations in veterinary science, the veterinarian confining his work to the general oversight of the health of the animals on the farm and acting in the capacity of consulting expert. An appropriation was made for continuing the work in connection with irrigation experiments.

MICHIGAN COLLEGE AND STATION.—By a recent action of the board the director of the station is relieved from all teaching in the college except in the special courses in the winter. He is made superintendent of institutes and extension lecturer. Greater emphasis is to be laid on experimental work and there is to be a clearer line of demarcation between the station and college. H. W. Mumford has been advanced to the full professorship of agriculture. L. R. Taft will have an assistant professor of horticulture and will devote a larger part of his time to the experimental work in his department.

MISSOURI COLLEGE AND STATION.—Walter Williams has been appointed a member of the governing board of the station, *vice* G. B. Rollins, retired. The legislature recently enacted a law taxing collateral inheritances 5 per cent for university endowment, which it is believed will in time yield a handsome endowment. Appropriations aggregating $142,700 were also made, including $95,000 for maintenance, $25,000 for laboratories and libraries, $1,200 for student labor, and $10,000 to be added to a private donation from W. L. Parker, of Columbia, for the building of a $25,000 hospital. The legislature also established the chairs of architecture in the agricultural college, anatomy in the medical school, and domestic economy in the agricultural college. The first two chairs will be filled this summer and the last in the autumn of 1900. The faculty of the agricultural college lately decided to offer the degree of Bachelor of Science in agriculture to all students doing one year's work in sciences allied to agriculture in addition to securing the regular degree of Bachelor of Agriculture, heretofore offered. This gives those who desire it a degree of higher standing, entitling students to do work for the Master's degree anywhere in the country. The college is offering this summer a school in agriculture and horticulture for teachers of Missouri, lasting six weeks—from July 15 to August 26—covering the elements of these sciences as they may be taught in the public schools. The State Superintendent of Education of Missouri not only accepts grades made here, but has also placed the study of the elements of agriculture in the list of subjects to be taught in the county institutes for teachers throughout the State.

OKLAHOMA COLLEGE AND STATION.—G. E. Morrow, president, director, and agriculturist; Henry E. Glazier, vice-director and horticulturist, and J. H. Bone, associate agriculturist in the college and station, retired from their work June 30. A. C.

Scott, professor of English and literature in the college, has been elected president, and John Fields, associate chemist of the college and station, has been made director and chemist of the station. G. L. Holter, chemist of the college and station, will devote his time exclusively to the college work.

TENNESSEE STATION.—R. L. Watts, horticulturist of the station, has been made secretary, and A. M. Soule, formerly assistant professor of agriculture in the Agricultural and Mechanical College of Texas, has been appointed agriculturist of the station.

TEXAS COLLEGE AND STATION.—By a recent action of the legislature this college is to have eight members of the board instead of six, the members being elected for terms of 6 years, two retiring at the same time. An appropriation of $31,000 was made for the erection and equipment of an agricultural-horticultural building, to be commenced at once. Among other things, a new dormitory to cost $24,000 and a sewage system costing $5,000 were provided for.

A STATE EXPERIMENT STATION IN UTAH.—The last session of the legislature passed an act creating a State experiment station and appropriating $6,000 to start the work. This station is located in Washington County and is placed under the control of the State board of horticulture. It is supported entirely by State funds and has no connection with the agricultural experiment station at Logan, Utah.

VERMONT STATION.—W. A. Orton, assistant botanist, has severed his connection with the station to accept a position in the Division of Vegetable Physiology and Pathology of this Department.

AGRICULTURAL EXPERIMENT STATIONS IN JAPAN.—A brief account of the organization and work of agricultural experiments in Japan was given in E. S. R., 10, p. 101. A recent communication from S. Kikkawa, director of the San-in Experiment Station, gives some additional information regarding the development of these institutions. There are now in the Empire of Japan 10 experiment stations under Government control, besides 19 branch stations the chief work of which is to teach farmers the application of the results obtained by the higher experiment stations. As rice is the most important crop of the country, the experiments and investigations of the stations are naturally devoted chiefly to that plant. Each station, however, has certain other lines of work peculiar to itself. Thus among the crops to which the San-in Station pays particular attention is one known locally as umakoyashi (*Medicago denticulata*). This plant has been selected for experiment by the San-in Station because its cultivation and utilization as a green manure is a matter of special importance in the district in which the station is located. Analyses made by this station show the plant to contain 0.78 per cent of nitrogen, comparing favorably in this respect with clovers and other leguminous plants.

EXPERIMENT STATION RECORD.

VOL. XI. NO. 2.

Brief mention has been made of the establishment by the British Government of an Imperial Department of Agriculture for the West Indies, with Dr. Daniel Morris, formerly assistant director of the Royal Gardens at Kew, as commissioner. The first number of the *West Indian Bulletin*, the official organ of the new department of agriculture, just received, gives the history of the movement and an account of the department, its purposes, aims, etc. The experimental and educational work which it is instituting, its field of operation, and the problems presented to it, make the new department worthy of more extended notice than our previous information permitted.

It will be remembered that the extreme depression of the sugar industry in the West Indian Colonies, which caused many sugar plantations to be abandoned and threatened others, led the British Government to appoint a West Indian Royal Commission in December, 1896, to investigate the condition of the islands and suggest measures for relief. The report of the Royal Commission pointed out the causes of the "critical" condition, and emphasized the need of improving and cheapening sugar production by the introduction and improvement of varieties of cane, better methods of culture, and the prevention of excessive losses in the manufacture of sugar in some cases by using more efficient machinery. It also strongly recommended the introduction of other farm industries where possible, and the teaching of agriculture in different classes of institutions. The commission commended the work of the botanic stations already established in a number of the islands, and recommended that they be enlarged and extended and placed under a central department of agriculture, which was to be charged with the promotion of the agricultural interests of the colonies in general.

The recommendations of the commission in this and other matters have been adopted and carried into effect. The British Government appropriated £4,500 for the new department for the first year, and it is estimated that in future an annual grant of £17,500 will be required to carry out the recommendations of the commission as adopted. "The cost of the department for a period of ten years will be provided from Imperial funds, and grants will also be made in aid of the public revenues of Trinidad and Tobago (for the benefit of the latter islands), British Guiana, Barbados, the Windward Islands, and the Leeward Islands, to provide for or to assist in the maintenance of agricultural and botanical establishments, industrial schools, or other kindred purposes."

The headquarters of the department are at Barbados. Its duties as outlined are twofold: "(1) To endeavor to restore the sugar industry to a condition in which it can be profitably carried on, and (2) to encourage the establishment of other industries in such colonies as afford suitable conditions to supplement the staple industry."

In inaugurating its experimental work, advantage will be taken of the beginning previously made in experimenting in cane growing and the improvement of cane at a number of places, and this work will be greatly developed and extended. Four "principal" or "central" experiment stations and eight "local" stations for the improvement of the sugar cane will be established on the island of Barbados. The object of the central stations will be the growing of seedlings and improvement of varieties, and the carrying on of fertilizer experiments. The more promising varieties will be given a practical trial at the local stations to test their adaptability and value in different soils and localities, and also as a demonstration to the planters in each parish. Experiments on similar lines have been arranged for at Antigua and St. Kitts, while the work previously inaugurated at Trinidad will be largely extended and the necessary chemical assistance provided.

The botanic stations placed under the control of the department are those at Tobago, Grenada, St. Vincent, Barbados, St. Lucia, Dominica, Montserrat, Antigua, and St. Kitts-Nevis. The expense of their maintenance has been transferred to Imperial funds. The object of these stations is to test and distribute promising economic plants for the region, introduce new or little-known plants for experimental cultivation, and conduct experiments on the improvement of sugar cane. In addition they distribute information, and send out lecturers for institute work.

The excessive losses in sugar manufacture on the smaller islands, under the crude methods employed, is emphasized by the statements that there is "an average of over 2,000 pounds of sugar per acre left in the canes after crushing, which is burnt in the megass;" and that owing to heavy losses in boiling, "for every 100 pounds of crystallizable sugar contained in the juice, not more than an average of 75 pounds of ordinary muscovado sugar is now produced." It is said that at present about 13 tons of cane are required to produce a ton of sugar on these smaller islands, while with efficient machinery 9 tons would suffice. The remedy recommended by the Royal Commission is the establishment of central factories equipped with the best machinery, and it is the expectation of the department to establish one or two experimental factories at an early date.

The new department will also promote agricultural education in the islands, which heretofore has received little attention. The plan of the Royal Commission to establish agricultural schools in connection with the botanic stations has been carried out by opening a school at Dominica, and others will be started at St. Vincent, St. Lucia, and

St. Kitts-Nevis as soon as the necessary land is obtained. Furthermore, "the department is prepared to offer grants to enable certain institutions to employ teachers in agricultural science, and possibly provide a number of scholarships for the most promising pupils;" and in cooperation with the central educational authorities in each colony, the teachers in the elementary schools will be given a course of instruction in the principles of agriculture, to enable them to give simple instruction and conduct school gardens. It is proposed to attach an agricultural instructor to each of the botanic stations, who will travel about holding meetings and demonstrations, and imparting information on improved methods directly to the planters; and in addition instructors or experts in special lines, as budding and pruning fruit trees, curing tobacco, bee keeping, etc., will be employed to spend a month or two on each island.

The publications of the department will also be a means of diffusing popular information. They will include handbooks on the cultivation of special crops, bulletins, and leaflets, the latter especially being in very simple, clear language. The *West Indian Bulletin*, mentioned above, will be issued by the department periodically. The first number of this journal contains an introductory, an account of the establishment of the department, and a report of the first agricultural conference, held at Barbados. The latter contains a number of papers of merit on different features of cane growing, central factories, agricultural education, etc.

It will be seen that a very liberal and comprehensive plan has been adopted for acquiring and diffusing information, and that no effort is to be spared to make the department of the greatest direct benefit to the planters and to bring the teachings of agricultural science home to them. The progress of the new department in its various branches will be a matter of much interest to people of this country, especially in view of our interest in islands adjacent to those for whose benefit it was established. The experience there will prove of value, as well as the actual contributions to agricultural science and practice.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Official methods of analysis of fertilizers and feeding stuffs adopted by the Belgian State laboratories and the agricultural experiment stations of Holland and the Grand Duchy of Luxemburg (*Bul. Min. Agr.* [*Belgium*], *No. 5, pp. 22*).—This is a revision, made at a conference in January, 1899, of the methods already noted (E. S. R., 10, p. 304). The only changes of consequence are (1) the insertion of directions for determining water-soluble phosphoric acid by digestion, (2) a modification of the method for determining citrate-soluble phosphoric acid, and (3) more detailed directions for determining the fineness of slags.

The method for determining water-soluble phosphoric acid is as follows: Triturate 20 gm. of the substance with 20 to 25 cc. of cold distilled water in a glass or porcelain mortar. Pour off the liquid into a liter flask and repeat the operation several times, finally transferring all of the material to the flask. Make the volume to about 900 cc. and shake in a rotary apparatus for ½ hour. In default of a rotary apparatus allow to stand for 2 hours, shaking several times. In case of double superphosphate, continue the digestion for 24 hours, shaking from time to time. Make the volume to 1 liter, filter, and use 50 cc. of the filtrate for determination of phosphoric acid by the molybdate or citro-mechanical method.

The method for the determination of phosphoric acid in the combined water and citrate extracts is modified as follows: Boil the mixture of the water and citrate extracts (50 cc. of each) for 5 minutes with 10 cc. of hydrochloric acid (1.10 sp. gr.) or 15 cc. of nitric acid, nearly neutralize the acid with ammonia, and determine phosphoric acid by the citro-mechanical method, adding 10 cc. of Petermann's citrate solution.

In the revised method for ascertaining the fineness of slag the material is first put through a sieve having round holes 1½ mm. in diameter. The material which does not pass this sieve is discarded as worthless. A portion (50 gm.) of the slag which passes the sieve is shaken for 15 minutes in a second sieve having meshes 0.0289 mm. square for the determination of the fineness. A second portion is used without further preparation for the determination of phosphoric acid, correction being made for the part which does not pass the coarse sieve.

Detection of the adulteration of bone superphosphate, H. Lasne (*Staz. Sper. Agr. Ital., 31* (*1898*), *No. 3, pp. 270–314, pls. 9*).—This article gives detailed directions for microscopical and chemical examinations. It is claimed that, as a rule, the microscopical examination, together with determinations of phosphoric acid, lime, alumina, and manganese, will be sufficient for a decision as to the purity of the material. When additional evidence is desired the fluorin may be determined.

The principal adulterants to be guarded against are stated to be gypsum, mineral phosphates, bone ash, precipitated bone, and mineral phosphates, residue from the manufacture of gelatin and glue, and various nitrogenous substances, such as dried blood, horn, etc.

According to the author, the ratio of the phosphoric acid to the lime in pure bone superphosphate should be from 1:1.3 to 1:1.35. A higher ratio than 1:1.35 indicates the addition of gypsum, natural phosphates, or residues from gelatin or glue manufacture; a lower ratio than 1:1.3, the addition of precipitated phosphate; but this rule should be applied with caution, as a mixture might be used which would fall within the limits given.

In pure bone superphosphate, however, the alumina should never exceed 0.1 per cent. It should contain no manganese, less than 0.1 per cent of calcium fluorid, 0.05 per cent of calcium chlorid, and 0.3 per cent of insoluble residue free from nitrogen.

Scattered particles of carbon indicate the presence of bone ash; the presence of hair and particles of epidermis and calcium chlorid, refuse from glue works, and the presence of 1 per cent of nitrogen (calculated to original substance) in the insoluble residue indicates the addition of nitrogenous matters, such as meat, horn, etc.

The methods proposed for some of the principal determinations are as follows:

Phosphoric acid.—Dissolve the material without previous calcination in hydrochloric acid, and evaporate to dryness to remove silica. Take up in the usual way and make up to a convenient volume. (See E. S. R., 7, p. 853.) To a quantity of the filtered solution corresponding to 0.5 to 1 gm. of the superphosphate, diluted to about 100 cc., add 25 cc. of ammonium citrate, 60 cc. of ammonia (22° B.), and 20 cc. of a solution of magnesium chlorid (25 gm. per liter of water). After shaking 15 minutes, or standing 4 hours, precipitation is complete. The author prefers, however, to allow the solution to stand 12 hours. Proceed as usual. This method is considered preferable to the uranium and molybdic methods.

Water-soluble and citrate-soluble phosphoric acid.—Treat 1.25 gm. of the material 2 or 3 times with water in a glass mortar without grinding, filtering the solution into a 125 cc. flask. Then grind the substance with about 50 cc. of water, allow to stand, and pour the clear solution into the filter. Wash by decantation at least 6 times, using in all about 125 cc. of water. To the filtered extract add a few drops of hydrochloric acid and make the volume up to exactly 125 cc. Place the filter in the vessel containing the residue from the extraction with water, add 50 cc. of ammonium citrate, and allow to digest for 12 hours, shaking occasionally at the beginning of the operation. Filter and make the solution up to 125 cc. Phosphoric acid is determined by the method described above in 100 cc. portions of the solution thus obtained and of the solution obtained by extraction with water, citrate being added only in case of the aqueous extract.

Lime.—To a clear solution of ½ gm. of substance, add ammonia to the point of persistent turbidity. Clear up the solution by adding a few drops of dilute hydrochloric acid; slowly add neutral ammonium oxalate and keep the solution at about 100° C. for 1 or 2 hours. After cooling, collect the calcium oxalate on a filter and weigh first as carbonate and then as oxid of calcium. The precipitate thus obtained contains a trace of phosphate. To remove this, redissolve and precipitate again by the addition of a very small amount of ammonia. Collect the precipitate on a filter, calcine, weigh, and deduct the weight from that first obtained. A trace of calcium remains in the solution from the oxalate precipitate. To recover this, oxidize the solution with nitric acid and bromin water, and precipitate with a very small amount of ammonia. Combine the precipitate thus obtained with the preceding. Dissolve both in nitric acid and precipitate the phosphoric acid with molybdic acid. Add ammonia to the filtrate from this precipitate to remove iron, alumina, and traces of molybdenum, and precipitate lime in the filtrate from the precipitate obtained by ammonia with oxalate in the usual way, adding the weight of lime to that previously obtained. The accuracy of the lime determination is vitiated if any considerable amount of manganese is present. This is removed by dissolving the calcined material in nitric acid and adding potassium chlorate to the boiling concentrated solution.

Alumina.—The method proposed for the determination of alumina has already been noted (E. S. R., 7, p. 915).

Fluorin.—Fluorin is determined by treating the substance with strong sulphuric acid in presence of an excess of silica, the silicon fluorid being collected in caustic soda by means of a current of dry air. To determine the amount of fluorin absorbed by the soda solution, precipitate the silica with carbonate of ammonia, filter, and remove remaining traces of silica by evaporation in presence of an ammoniacal solution of oxid of zinc. Precipitate the solution freed from silica with calcium chlorid in presence of an excess of sodium carbonate, calcine gently the precipitate obtained, treat with an excess of acetic acid, evaporate to dryness, and treat with dilute acetic acid. The calcium fluorid remains undissolved and is weighed.

Chlorin.—Mix 20 gm. of the phosphate with half its weight of pure lime and calcine gently in a crucible, the surface of the material being covered with a thin layer of lime. Dissolve the contents of the crucible in dilute nitric acid in a closed flask, filter the solution, and precipitate the chlorin with silver nitrate.

Nitrogen.—Determine nitrogen by the Kjeldahl method. It is occasionally desirable to determine ammoniacal nitrogen. For this purpose, the author prefers caustic soda in very slight excess for use in distillation, claiming that all of the ammoniacal nitrogen is not obtained by the use of magnesia.

Insoluble residue.—The method of treating the insoluble residue has already been noted (E. S. R., 8, p. 560).

Directions are also briefly given for the determination of sulphuric acid, carbon dioxid, magnesia, iron, zinc, manganese, nickel, and cobalt.

This paper was awarded the prize offered by the Association of Italian Fertilizer Syndicates for the best methods of detecting adulteration of bone superphosphate.

The constitution of the ammonium-magnesium phosphate of analysis, F. A. GOOCH and MARTHA AUSTIN (*Amer. Jour. Sci., 4. ser., 7 (1899), No. 39, pp. 187–198; Ztschr. Anorgan. Chem., 20 (1899), No. 2, pp. 121–136*).—As a preliminary to the main inquiry the authors studied the solvent effect of ammonium chlorid solutions of varying strengths on the ammonium-magnesium phosphate precipitate. It was found that as little as 0.0001 gm. of magnesium oxid was detected by means of microcosmic salt in 500 cc. of faintly ammoniacal water containing as high as 60 gm. of ammonium chlorid. From these results "it is plain that strongly ammoniacal liquids are entirely unnecessary in the precipitation of the ammonium-magnesium phosphate under the conditions."

In the study of the influence of varying amounts (none to 60 gm.) of ammonium chlorid on the precipitation of magnesium in the cold by means of microcosmic salt, 3 methods of procedure were followed. (1) The liquid was made faintly ammoniacal after the addition of the precipitant, and the precipitate was filtered off immediately after complete subsidence; (2) the precipitate first thrown down was redissolved in a very little hydrochloric acid and reprecipitated by dilute ammonia (the operation being repeated several times); and (3) the supernatant liquid was poured off through the filter (which was to be subsequently used to collect the phosphate) after the precipitate had subsided, and the insoluble phosphate was dissolved in hydrochloric acid and precipitated again, after dilution, by the addition of a slight excess of dilute ammonia. The results by the first and second methods always showed a plus error. Theoretical results were obtained by the third method, when no ammonium chlorid was added before reprecipitation. In other experiments the influence of varying amounts of ammonia was studied. In the author's opinion the results seemed to point "to a general tendency on the part of free ammonia, ammonium chlorid, and excess of the phosphate to produce a salt rich in ammonia and deficient in magnesia, which, for a definite amount of magnesia precipitated, must leave upon ignition a residue weighing more than the normal phosphate. If it be assumed that a salt of the symbol $(NH_4)_4Mg(PO_4)_2$ (the next natural step to the normal salt NH_4MgPO_4) is present in the precipitate, the residue which such a salt would leave upon ignition would be the metaphosphate $Mg(PO_3)_2$." It is estimated that the amount of metaphosphate necessary to account for the error in some of the precipitates was as high as 10 per cent.

In investigations on the determination of phosphoric acid in soluble phosphates by means of magnesia mixture, it was found that complete precipitation took place in faintly ammoniacal solutions even when dilute and charged with large amounts of ammonium chlorid, provided the magnesia mixture was used in sufficiently large excess.

In the precipitation of monosodium phosphate by magnesia mixture, following the same methods of procedure used above in the precipitation of the magnesium salt, it was found that while the results were not entirely regular, the tendency was for ammonium salts to produce minus errors, the size of the error varying with the proportion of ammonium salts used, and that an excess of magnesia mixture tended to correct these errors.

> "These facts are quite in harmony with the hypothesis that the ammonium salt tends to produce an ammonium magnesium phosphate richer in ammonia and phosphoric acid and poorer in magnesia than the normal salt NH_4MgPO_4; for, though the production of such a salt in presence of an excess of the soluble phosphate compels the combination of a definite amount of magnesium with more than the normal amounts of phosphoric acid and ammonia (as was the case in the former series of experiments), when the supply of the soluble phosphate is limited the amount of magnesium associated with it must fall below the normal (as is the case in the present series of experiments). Moreover, the behavior of the precipitant is quite in accord with the hypothesis; for, though the influence of an excess of the soluble phosphate would naturally tend (as was observed) in the same direction as that of the ammonium salt and free ammonia, viz, to the production of the phosphate deficient in magnesium, the tendency of an excess of the magnesium salt must obviously be to increase the amount of magnesium in the phosphate. The hypothesis fits the facts, therefore, on both sides; and, if precipitation is practically complete (as was shown to be the case throughout), the argument for the existence of an ammonium magnesium phosphate—poorer than the normal salt in magnesium—possibly the salt $(NH_4)_4Mg(PO_4)_2$—seems to be strong."

In discussing the practical application of these results, attention is called to a method of determining magnesia proposed by Wolcott Gibbs,[1] in which the solution of magnesium salt is boiled with microcosmic salt, and ammonia added after cooling. In this method, which the authors consider very accurate, as well as in that of precipitation in the cold followed in the above investigations, it is recommended to use faintly ammoniacal solutions and wash water.

> "Our experiments go to show that good results may be expected when the solution of the phosphate, containing a moderate excess of the magnesium salt and not more than 5 to 10 per cent of ammonium chlorid, is precipitated by making it slightly ammoniacal, the precipitate being washed in slightly ammoniacal wash water. In general, however, and especially when more ammonium chlorid than this proportion, or more magnesium salt than twice the amount theoretically necessary is present, it is safer to decant the supernatant liquid from the precipitate (through the filter to be used subsequently to hold the phosphate), to dissolve the precipitate in a little hydrochloric acid and reprecipitate by dilute ammonia, washing with faintly ammoniacal wash water."

---

[1] Amer. Jour. Sci., 3. ser., 5 (1873), p. 114.

The magnesia mixture used in these experiments "was prepared by dissolving 55 gm. of magnesium chlorid in as little water as possible and filtering, mixing with this solution 28 gm. of ammonium chlorid purified by treating it in strong solution with bromin water and a slight excess of ammonia, filtering, diluting to 1 liter, and, after standing for some hours, filtering again."

The solubility of Thomas slag in citric acid solutions, E. HOTTER (*Jahrb. Pom. Landes Vers. u. Samen Control Sta., Graz, 5 (1897), pp. 29-32*).—Comparisons of the solubility of various samples of Thomas slag in Wagner's ammonium citrate; 1.25, 1.4, 2, and 4 per cent citric acid; and 1, 5, and 10 per cent acetic acid are reported. The 1.25 per cent citric acid solution gave results which agreed closely with those obtained by the Wagner method. The solubility increased with the strength of the citric acid solution used, a 4 per cent solution dissolving nearly the total amount of phosphoric acid present. The solubility in 10 per cent acetic acid was nearly the same as in Wagner's ammonium citrate. In the author's opinion it is a matter of indifference, therefore, whether the solubility of slag is determined by the Wagner or Passon method, or by the use of solutions of other organic acids. He prefers, however, a solution of citric acid not stronger than 4 per cent. The method proposed is as follows: Place 5 gm. of the slag in a one-half liter flask and fill to the mark with citric acid. Shake continuously for 30 minutes, allow to stand one-half hour, and filter rapidly. To 15 cc. of the filtrate add 50 cc. of Maercker's solution and 20 cc. of magnesia mixture, and stir vigorously for 30 minutes.

The estimation of potash, E. W. BELL (*Chem. News, 79 (1899), No. 2052, pp. 135, 136*).—The following method is proposed:

"In the case of manures, carefully boil 5 or 10 gm. of the sample with about 150 cc. of water with or without the addition of a little hydrochloric acid. Add ammonia in sufficient quantity to produce a slight alkalinity; then, without filtering, add a considerable excess of barium carbonate (usually about double the weight of manure taken) and continue the boiling for half an hour. Filter the mixture, wash the precipitate, and make up the filtrate and washings to 500 cc.

"Evaporate from 50 to 100 cc. of the solution to dryness with the addition of a small quantity of ammonium oxalate, ignite gently, treat with hot water, and filter, evaporate the filtrate with hydrochloric acid and platinum chlorid, and complete the determination in the usual way.

"In the case of soils, either the hydrochloric solution of the soil may be used (if K_2O soluble in HCl is required), and after being rendered alkaline by means of ammonia, treated with barium carbonate, etc., as above, or the soil may be moistened with strong sulphuric acid, gently ignited, and the residue, after boiling with water, treated with barium carbonate, the boiling continued, filtered, and a portion of the filtrate then evaporated directly with hydrochloric acid and platinum chlorid, without any previous addition of ammonium oxalate and ignition.

"For the estimation of potash in vegetable substances, the organic matter should be moistened with sulphuric acid, ignited, and treated in a similar manner to soil."

The method gave very satisfactory results on fertilizer mixtures of known and unknown composition.

Estimation of the perchlorate in Chile saltpeter, C. AHRENS and P. HETT (*Ztschr. Öffentl. Chem., 4 (1898), p. 445; abs. in Chem. News, 79 (1899), No. 2050, p. 110*).—The following method is recommended as sufficiently rapid and accurate for commercial purposes:

"Twenty grams of the well-powdered substance is placed in a platinum crucible and moistened with 2 or 3 cc. of a cold saturated solution of carbonate of soda; add 1 gm. of binoxid of manganese free from chlorin and evaporate to dryness. The mass is brought to fusing point, and the crucible, which must be well covered, is kept at red heat for 15 minutes. The product of this fusion is, after cooling, dissolved in 100 cc. of boiling water, the solution is cooled and made up to 250 cc.; of this when filtered 50 cc. is taken (equal to 4 gm. of the sample), acidulate with 10 or 15 cc. of nitric acid of 1.2 density, then add a 1 per cent solution of permanganate of potash until the red color lasts for at least a minute. Then add ferrous sulphate and titrate the solution by Volhard's method.

"The chlorin is also determined in 4 gm. of the sample by Volhard's method. From the difference between the number of cubic centimeters of decinormal silver solution employed after fusion and the number obtained before fusion we calculate the chlorin which exists in the saltpeter in the state of perchlorate.

"The addition of carbonate of soda before fusion is simply to prevent the partial volatilization of the hydrochloric acid. The addition of the binoxid of manganese facilitates the decomposition of the perchlorate; and finally the treatment with permanganate has for its object the elimination of the nitrous acid, and the transformation into iodate, of the small quantity of iodin which is present in the sample in the state of iodid."

A simple method for determining combined carbon dioxid, especially that in the form of calcium carbonate, in the soil, A. STUTZER and R. HARTLEB (*Mitt. Landw. Inst. Breslau, 1899, No. 1, pp. 101-105*).—The method proposed is as follows: Ammonium chlorid, 5 gm. to each 0.5 gm. of calcium carbonate present, is mixed with soil in an Erlenmeyer flask of Jena glass; the mixture is covered with 200 cc. of distilled water and boiled for 45 minutes, the distillate being collected in standard sulphuric acid. By this process the carbonates of calcium, etc., are converted into ammonium carbonate, which is carried over in the distillate and may thus be determined by titration. When iron carbonate is present, its influence upon the results may be destroyed by previously boiling the soil with water before adding the ammonium chlorid. Iron oxids were found to have no effect upon the results.

Determination of humus in soil, C. ASCHMAN and H. FABER (*Chem. Ztg., 23 (1899), No. 7, p. 61; abs. in Analyst, 24 (1899), No. 277, pp. 103, 104*).—Boil 25 gm. of the air-dry, finely sifted soil for 1 hour in a water bath with 100 cc. of sodium hydroxid (50 gm. per liter). For complete extraction of the humus acids it is necessary to decant the solution and repeat the digestion several times. Make the volume to 510 cc. (10 cc. being allowed for the volume of the soil), mix carefully, and allow to stand until the solution has become perfectly clear. To 5 cc. of this solution diluted with 100 cc. of water, add potassium permanganate solution (0.32 gm. per liter) gradually until no color appears when the solution is boiled for some time. After 5 minutes add 10 cc. of oxalic acid (0.63 gm. per liter) and carefully run in the permanganate solution until the end reaction is obtained.

A correction is made for the permanganate solution reduced by the oxalic acid used, which is determined by a preliminary test, as follows: To 5 cc. of the permanganate add 10 cc. of sulphuric acid (1:5), dilute to 100 cc., and boil for 5 minutes. Add 10 cc. of the oxalic acid and titrate.

Methods for the determination of color and the relation of the color to the character of the water, F. S. Hollis (*Jour. New England Water Works Assoc., 13, pp. 94–111; abs. in Tech. Quart., 12 (1899), No. 1, Rev. Chem., p. 14*).—"The author shows by a series of analyses, extending over a year, that in an unpolluted surface water the variations in oxygen consumed, loss on ignition, and albuminoid ammonia, in general, follow the changes in color. Among the methods for the determination of color are described the Tidy colorimeter, the Nessler scale of Leeds, the method based on a comparison of the natural waters with the Lovibond tintometer (erroneously spelled Lovi*bard*), the platinum scale of Hazen, and the special form of colorimeter used at the experimental filter station of the Boston waterworks. A table is given for the conversion of color readings from the Nessler and natural water standard to the platinum standard."

The examination of butter, A. Zega (*Chem. Ztg., 23 (1899), No. 29, p. 312, figs. 5*).—One cubic centimeter of the melted and filtered fat is shaken with 20 cc. of a mixture of 6 parts ether, 4 parts alcohol, and 1 part glacial acetic acid, in a tightly closed cylinder, and this cylinder is then allowed to stand in water at 15 to 18° C. With pure butter the liquid remains clear, and only after standing from 1 to 1½ hours will small crystals form. With oleomargarine, however, the crystals will form in from 1 to 2 minutes and will settle as a precipitate, while with mixtures of butter and oleomargarine in varying proportions the little crystals form in varying lengths of time. These crystals can be readily distinguished under the microscope. Illustrations show the several forms of crystals.—J. T. ANDERSON.

The constituents of the seeds of Picea excelsa and the cleavage products of the proteids, N. Rongger (*Landw. Vers. Stat., 51 (1898), No. 2–3, pp. 89–116*).—The seeds of this spruce were studied qualitatively with reference to the different classes of constituents, and were submitted to quantitative analysis. The composition is given as follows:

Composition of seeds of European spruce.

	Per cent.
Albuminoids	15.89
Nuclein and other undigestible nitrogenous compounds	3.23
Glycerids (and free fatty acids)	35.13
Cholesterin, less than	.06
Lecithin	.12
Water-soluble nitrogen-free extract (carbohydrates, organic acids, etc.)	5.43
Water-soluble nitrogen-free extract	7.00

A study of the cleavage products of the protein showed that about one-third of the protein was in the form of organic bases, and that of this a large proportion was arginin.

A compendium of toxicology, L. LEWIN (*Lehrbuch der Toxikologie. Vienna and Leipsic: Urban & Schwarzenberg, 1897, 2. rev. ed., pp. 509, pl. 1, figs. 7*).—This volume consists of a general treatise on the subject of poisons, and discusses under various headings, inorganic poisons, organic poisons, poisonous plants, poisonous animals, and poisons due to metabolic processes.

Analysis of superphosphates, M. ZECCHINI (*Staz. Sper. Agr. Ital., 31 (1898), No. 1-2, pp. 165-178*).—This is mainly an account of comparative tests of the Petermann and Martinotti modification (see below) of the Italian official or modified Appiani[1] methods.

The determination of phosphoric anhydrid soluble in water and citrate, F. MARTINOTTI (*Staz. Sper. Agr. Ital., 31 (1898), No. 1-2, pp. 160-164*).—The method proposed is as follows: Add about 100 cc. of distilled water to 5 gm. of substance in a 250 cc. flask. Neutralize with soda solution, add 100 cc. of neutral ammonium citrate, make volume to 250 cc., and shake in a rotary apparatus for 1 hour. To 50 cc. of the filtered extract thus obtained, add a few drops of nitric acid and heat for about 10 minutes in a water bath to convert metaphosphates into orthophosphates. Cool and add 100 cc. of water, 25 cc. of ammonia (0.92 sp. gr.), and 50 cc. of magnesia mixture. Stir for some time and allow to stand 5 to 6 hours before filtering.

Methods of soil analysis adopted by the agricultural experiment stations and laboratories of France (*Méthodes d'analyse des terres du comité consultatif des stations agronomiques et des laboratoires agricoles. Paris, pp. 45*).

On the analysis of nitrites, G. LUNGE (*Ztschr. Angew. Chem., 1899, No. 16, p. 369*).

Determination of nitrates and ammonia in water, F. X. MOERK (*Amer. Jour. Pharm., 71 (1899), p. 157; abs. in Chem. Ztg., 23 (1899), No. 36, Repert., p. 129*).

A volumetric method for determining boric acid, L. C. JONES (*Ztschr. Anorgan. Chem., 20 (1899), No. 3, pp. 212-220*).

The surface tensions of aqueous solutions of alkaline chlorids, C. E. LINEBARGER (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 411-415, figs. 2*).

A new and simple method of distinguishing butter and margarin (*Abs. in Jour. Hyg., 24 (1899), No. 1182, p. 160*).—The spots left from the evaporation of drops of ethereal solutions of these substances are said to furnish differential characters.

Artificial and natural indigo (*Jour. Franklin Inst., 147 (1899), No. 5, p. 403*).

On the reducing and invert sugars of maize stalks, C. ISTRATI and G. OETTINGER (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 17, pp. 1040-1043*).

On the rotary power of sugar, E. MASCART and H. BÉNARD (*Ann. Chim. et Phys., 7. ser., 17 (1899), May, pp. 125-144*).

On the standardized saccharimeter, B. WEINSTEIN (*Ztschr. Angew. Chem., 1899, No. 16, pp. 369, 370*).

Some new laboratory apparatus, M. KAEHLER and MARTINI (*Ztschr. Angew. Chem., 1899, No. 16, p. 372, figs. 3*).—Distillation apparatus and a weighing tube are described.

BOTANY.

The poisonous plants in New Jersey, B. D. HALSTED (*New Jersey Stas. Bul. 135, pp. 28, figs. 10*).—The author considers the poisonous plants under the heads of those poisonous to man and animals when eaten, and those poisonous by contact. Among those poisonous to man when eaten are mentioned the water hemlock, poison hemlock, wild parsnip, thorn apples, black nightshade, bitter-sweet, poke root, lobelias, false hellebore, and bouncing Bet. A number of poisonous fruits, seeds, and flowers are enumerated, and an extensive list is given of plants whose underground parts are more or less poisonous. Among the flowerless plants mentioned as poisonous are *Amanita muscaria, A. phalloides*, and *A. verna.*

---

[1] Staz. Sper. Agr. Ital., 28 (1895), p. 817.

Of the plants poisonous to live stock, the author mentions false hellebore, narrow and broad leaved laurels, *Leucothœ* spp., staggerbush, rattlebox, wild cherry, corn cockle, cocklebur, water hemlock, green potatoes, sneezeweed, ergot, etc.

Among the plants poisonous to the touch are mentioned the poison ivy, poison sumac, various euphorbias, and lady's slipper. An extensive list is also given of plants that are considered somewhat poisonous.

Classification of fruits, L. NICOTRA (*Bul. Soc. Bot. Ital., 1898, pp. 115–122, 204–212; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 2, pp. 172, 173*).—The author suggests certain changes in the terms at present applied to the different kinds of fruits. He proposes the term holocarp for an entire fruit resulting from a number of carpels, the product of each carpel being called a mericarp. Depending on the degree of concrescence of the carpels, a holocarp may be an apocarp or a syncarp, but these two forms pass into one another. According to the arrangement of the carpels in a spiral or in a whorl, a holocarp may be helicocarpic or actinocarpic, and according to the position of the placentæ, it is pleurospermic or antispermic. A caryopsis is said to differ but slightly from an achene. The author regards the follicle as probably a primordial carpological type from which are derived, in various directions, the legume, the single-seeded indehiscent achene, the silique, and the various forms of capsule.

Experiments in the autumn coloring of plants, E. OVERTON (*Nature, 59* (*1899*), *No. 1526, p. 296*).—While engaged on some osmotic experiments, the author observed that newly-formed leaves of *Hydrocharis morsus-ranæ*, which had been placed several days previous in a weak solution of cane sugar, assumed a rich reddish-brown color, although otherwise perfectly normal. Further experiments showed that the culture of these plants in solutions of cane sugar, grape sugar, and fructose constantly had this effect on the coloring of those leaves which were developed during the time the specimens were in the solutions, and that leaves which were fully developed before the commencement of the experiments gradually assumed the same reddish-brown hue. Salt solutions and solutions of organic compounds other than carbohydrates had no such effect on these plants, and even among the sugars galactose was without effect. Lactose acts only after a long period, the effect obtained being slight and is probably due to hydrolysis. The color in these leaves is said to be due to the appearance of red cell sap in the pallisade cells and those cells lining the air chambers of the leaf.

Lidforss[1] and the author independently found that during the winter leaves are entirely devoid of starch, but contain large quantities of sugar. The remarkable coincidence of the appearance of red cell sap with the increase of sugar in autumn and its disappearance in spring formed a starting point for a considerable number of experiments on the formation of red pigment of leaves.

From these experiments the author concludes that the red coloring matter of green plants is probably in the nature of a glucosid, in most cases a union of tannin compounds with sugar. The chief physical factors in their production are sunshine, which augments assimilation in the production of sugar while accelerating the chemical process which leads to the formation of pigment, and a low temperature, which prevents the conversion of sugar into starch. In other words, the red autumnal tints are in a great measure the direct result of the autumnal climatic conditions. The author states that it is possible in many plants to produce red autumnal tints at any time of the year by feeding them with glucose. Generally speaking, this artificial production of red cell sap is possible only where the natural reddening of the leaf has its seat in the mesophyll cells. In cases where the coloration is in the epidermis, all experiments with glucose were unsuccessful.

Among the plants which were found especially favorable for experiment the author mentions *Lilium martagon*, *L. candidum*, *L. umbelliferum*, *Ilex aquifolium*, and numerous succulent and water plants, such as *Saxifraga crassifolium*, *Hydrocharis morus-ranæ*, and different species of Utricularia.

A full account of these experiments has since appeared in the *Jahrbücher für Wissenschaftliche Botanik, 33 (1899), No. 2, pp. 171-231.*

Observations on stomata, F. DARWIN (*Proc. Roy. Soc. London, 63 (1898), No. 400, pp. 413-417*).—The author reports on a series of observations conducted with a form of hygroscope to determine the opening and closing of stomata. The principle of the hygroscope used is based upon the fact that in adult leaves transpiration is stomatal rather than cuticular. The index of the hygroscope is made of shavings of pressed and heated horn; and the instrument was insensitive to cuticular transpiration, so that any movements of the index must depend on transpiration through the stomata. The hygroscope is said to show the gradual closure of stomata that occurs when a plucked leaf withers. Contrary to the general statement that marsh and aquatic plants do not close their stomata under these circumstances, the author found that there was a partial closing in aquatic plants, although it was much less marked than in the case of terrestrial ones. Another interesting fact noted in the withering of leaves is that in many cases the closing of the stomata is preceded by a temporary opening, which may occur almost simultaneously with the severing of the leaf from the plant.

A series of experiments was conducted to ascertain the comparative effect of moist and dry air, in which it was found that the stomata closed before there were any visible signs of flaccidity in the leaf. When leaves were exposed to air dried by sulphuric acid the closing was preceded by a remarkably long opening of the stomata.

---

[1] Bot. Centbl., 68 (1896), p. 33.

Experiments with gases and vapors showed that chloroform and ether as well as pure carbon dioxid slowly close the stomata.

The fact that stomata are wide open in sunshine is said to be well known, but the difference between bright and somewhat diffused light is not so well known, nor is the fact that in dark, stormy weather the stomata may remain nearly closed during the day, even in summer.

The effect of differences in illumination is well shown by the investigation of a number of leaves which have stomata on both their surfaces. In these the stomata on the illuminated surfaces are much wider open than on the less brightly illuminated sides, and when the plant is reversed in position the stomata rapidly accommodate themselves to the change in illumination. One of the most interesting facts brought out in the experiments is in regard to the effect of artificial darkness. It is more effectual in producing closure in the afternoon than in the morning; and conversely, illumination opens closed stomata more readily in the morning than later in the day. These facts taken together with other observations tend to show a certain amount of inherent periodicity in the nocturnal closure of stomata.

The question as to whether or not the majority of plants close their stomata at night was investigated and the author concludes that in terrestrial plants, excluding nyctitropic plants, the great majority show some closure at night. On the other hand, the hygroscope shows widely opened stomata on most aquatic plants. The author partially agrees with Stahl in that nyctitropic plants are remarkable for not closing their stomata at night.

Since the hygroscope gives numerical readings it is possible to represent graphically the daily opening and closing of stomata. The curve begins to leave zero with the morning light, rises rapidly at first and afterwards more slowly. In some cases it remains almost horizontal until a rapid fall begins in the evening. In every case there is a slow rise to the highest point, which occurs between 11 a. m. and 3 p. m. The hygroscope generally sinks to zero within an hour after sunset.

The effect of heat has not been fully investigated, but enough has been done, the author states, to confirm previous observations, which show that heat opens stomata. In regard to the visible spectrum the author finds that red rays are decidedly most efficient in opening the stomata, but he is not able to find any evidence of a secondary maximum in the blue.

The biology of the noctural closure is briefly discussed, and it is suggested that the gaseous interchange of assimilation may require widely open stomata, whereas respiration may be carried on with comparatively closed apertures. If this be true, the stomata might to a great extent be closed at night and an economy in the use of water effected without detriment to metabolism. Observations show that as long as the stomata are open the transpiring leaf is considerably cooler than the dry bulb thermometer, but at night it has almost the temperature of the air. In this way there is undoubtedly a considerable saving of heat, but whether it is sufficient to be of practical importance to the plant the author is unable to state. The mechanism of the stomata is briefly described, and the author suggests that there is a necessity for further studies on this, especially from the point of view of irritability.

Stopped stomata, T. WULFF (*Oesterr. Bot. Ztschr., 48 (1898), pp. 201–208, 252–258, 298–307, pl. 1; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, p. 175*).—The author finds the closing of stomata by a layer of wax, which has heretofore been chiefly observed in the conifers, to be a widely spread phenomenon, the evident object being the reduction of transpiration. The transpiration of conifers as compared with that of angiosperms is about in the proportion of 1:6, and is largely due to this cause. When the stomata are not closed on the outside, the same result is obtained through a partial closing of communication between the pore and the internal air chamber by deposits of round or angular granules of wax. These appear to be formed from the guard-cells or from the epidermal cells contiguous to them. While hindering transpiration to a great extent, this layer of wax is said not to interfere with the diffusion of carbon dioxid. In all succulent plants examined, the stomata were entirely free from wax, but the phenomenon was found very common among the grasses.

Healing tissue in plants, M. J. MASSART (*Mem. Acad. Roy. Belgique, 1898, pp. 68, figs. 57; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 1, pp. 15, 16*).—The various modes in which wounds are healed in plants are described in detail Among the algæ and fungi the methods are comparatively simple, although many do not seem to have the power of repairing injuries. This applies in general also to the mosses and ferns. Among phanerogams there are two chief processes which take place in the adjacent tissue. There is an elongation of the meristematic cells toward the wound, together with the formation of numerous walls parallel to the surface and the formation of cork. It is said that a direct division of the nucleus always takes place in the phello gen of a wound. The spread of the irritation caused by a wound is very slow, since dead elements, such as vessels and fibers, do not conduct the stimulus. The author believes that a chemical process underlies the propagation of the irritation. The formation of cork over a wound is promoted by the drying up of the surface of the wound.

Mucilaginous epiderm of leaves, O. KRUCH (*Ann. Inst. Bot. [Rome], 6, pp. 191–271, pls. 2; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 1, p. 16*).—The presence of a mucilaginous epiderm in dicotyledons is said to be of quite common occurrence, frequent examples occurring in the order of Rosaceæ. It takes the form of a mucilaginous layer on the inner or on both the inner and outer walls of epidermal cells. The formation of mucilage seems to have a direct connection with assimilation, since it occurs only in cells which are in direct contact with assimilating cells. It never takes place on the lateral walls of epidermal cells, and when the epiderm consists of several layers it is confined to the inner walls of the lowermost layer. The property of secreting mucilage does not belong to all epidermal cells, but only to certain ones which are variously distributed.

In the Rosaceæ the mucilage always takes the form of a secondary thickening of the wall separated from the protoplasm by a layer of cellulose. The author regards the mucilage layer as a reservoir of water to protect the surface against excessive transpiration.

The winter condition of the reserve food substances in the stems of certain deciduous trees, E. M. WILCOX (*Amer. Jour. Sci., 4. ser., 6 (1898), No. 31, pp. 69–74*).—Investigations have been undertaken to determine more definitely some of the essential physiological processes involved in the dormant period of woody plants. Stated briefly, the problem is to determine what are the conditions in which the reserve food substances are stored in the twigs during the dormant period; what, if any, changes they undergo during this period, and how these changes affect the renewal of activity by the buds at the beginning of the subsequent season of growth.

The author points out that the phenomena of renewal of activity by buds does not essentially differ from that of germination of seeds, and states that both phenomena may well be classed under one head, the germination of dormant organs.

The work of a number of investigators on this subject is briefly reviewed, and a report is made of the studies so far conducted, which have been largely confined to the question of starch formation and distribution and its relation to the growth of the tree. Some 25 or more species of deciduous plants have been studied, and the details of collection and preparation of material are given at considerable length.

In this preliminary paper the facts observed in a study of *Liriodendron tulipifera* and *Pyrus malus* are given in detail, and with slight modification the results will hold good for the other species examined. The author finds that there is a general movement of starch from the more peripheral and exposed regions to the more deep-seated and protected regions of the stems during the winter, and a return again in the spring to the cortex and the regions of growth.

Further studies are to follow on the condition of starch and other substances throughout the entire year. Two essential questions are being studied in connection with this subject—the determination of the behavior of leucoplastids in the starch-bearing cells in the stems of deciduous trees during the period of dormancy, and the part which the intercommunicating threads of protoplasm play in the transmission of starch.

Experiments on the transpiration of plants, A. PAGNOUL (*Bul. Sta. Agron. Pas de Calais, 1898, pp. 10–15, fig. 1*).—Experiments are reported in which fescue grass was grown from March 30 to June 21 under almost identical circumstances as to conditions, the only difference being that one pot was filled with a poor clay soil without fertilizer, and the other with a rich calcareous soil to which dried blood and nitrate of potash were added. The same degree of saturation of soil was constantly maintained. The grass was cut May 2, 27, and June 21, weighed and analyzed. The results obtained are tabulated. It appears that during the first period, 33 days, the plants in the poor soil transpired 1,190 gm. of water per gram of dry weight, as compared with a transpiration of 555 gm. in the rich soil. In the second period the figures were 1,053 and 581 gm. of water per gram of dry weight, and for the last period 1,084 and 585 gm., respectively. The nitrogen content of the product of each pot was determined, and it was found that for each gram of nitrogen in the product of the poor soil 46 kg. of water was transpired, while in the rich soil 1 gm. of nitrogen was found for each kilogram of water given off.

Sap pressure, W. FIGDOR (*Oesterr. Bot. Ztschr., 18 (1898), No. 9, pp. 359, 360; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, p. 179*).—According to the author, the phenomena of sap pressure differ widely in temperate and tropical climates. In Java, where these investigations were conducted, there is always, in contrast to the prevalent conditions in temperate climates, a positive sap pressure which varies greatly in intensity in different plants. In one instance a pressure of more than 8 atmospheres was noted, and not infrequently pressures as great as three times those in temperate climates were recorded. The sap pressure in a given plant may vary greatly in the course of 24 hours, these variations being due not only to periodicity but also to external factors, such as transpiration.

Observations on the action of anesthetics on vegetable and animal protoplasm, J. B. FARMER and A. D. WALLER (*Proc. Roy. Soc. London, 63 (1898), No. 395, pp. 213–216, dgms. 3*).—The authors conducted a series of experiments to observe simultaneously and comparatively the effect of certain anesthetics on vegetable and animal protoplasm. Two gas chambers were arranged through which anesthetic and other vapors could be passed, the first containing a leaf of *Elodea canadensis*; the other the sciatic nerve of a frog. The movements of the chlorophyll bodies in the leaf cells were observed and measured by one of the authors, while the other watched the readings of the deflections of the galvanometer. The several series of experiments are reported, from which it appears that the action of carbon dioxid was to produce an initial slight acceleration, followed speedily by a complete cessation of movement. If the carbon dioxid apparatus was disconnected and air passed through the cells the protoplasm in a few minutes began to show signs of recovering. At first the movement was very slight. Later the movement was accelerated until the motion became more rapid than normal. This was followed by slowing down to the normal speed. The nerve showed itself under the conditions of this experiment somewhat less sensitive to carbon dioxid than the plant, and the latter was still less sensitive than the active plasmodium of a myxomycete.

Ether vapor passed over the plant for 2 minutes caused a speedy arrest of all movements and a quiescent condition which persisted for some minutes. Recovery then ensued and the normal rate of movement was slowly regained. If the ether vapor was insufficient to anesthetize the nerve protoplasm, circulation was unaffected. The action of chloroform proved to be far more deadly than that of ether, all movement being arrested in less than a minute, and in 2 minutes causing death of the cell. When a much more diluted vapor of chloroform was passed over the cell for 2 minutes recovery ultimately occurred. The action of ether and chloroform, especially the latter, was very marked in causing many of the chlorophyll granules, which had been previously almost restricted to the latter walls, to become dispersed throughout the cell.

On the influence of anesthetics on the formation of chlorophyll, E. C. TÉODORESCO and H. COUPIN (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 22, pp. 881–887*).—Experiments with wheat, vetch, white lupine, and buckwheat are reported in which series of plants were grown under bell jars, different amounts of ether and chloroform being added to the moist atmosphere.

The quantity of anesthetics used was not sufficient to destroy the plants, the object being to investigate their retarding influence on the plants. The different seedlings used in the experiment were etiolated, having been grown in the dark, and after being placed in the bell jars were exposed to sunlight. It was found that the anesthetics were able for some time to prevent the production of chlorophyll in etiolated plants after being placed in the sunlight. If the amount of anesthetic was considerably reduced, the production of chlorophyll would be somewhat retarded, but would take place slowly. It was further found that the amount of the same anesthetic which, without killing the plant, produced a maximum effect on one plant varied within narrow limits on others.

Chlorophyll assimilation of Limodorum abortivum, M. E. GRIFFON (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 23, pp. 973–976; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, pp. 178, 179*).—This terrestrial orchid is regarded as intermediate between those which have green leaves and which also possess a mycorrhiza and the nonchlorophyllous saprophytic species. Although this plant contains an abundance of chlorophyll, the chloroleucites are masked by a great quantity of a violet pigment in the stem, leaves, and all parts of the plant, and as a consequence it has but little power of decomposing carbon dioxid directly. On this account the respiration is said to be considerably in excess of the assimilation.

Action of gases on the currents of protoplasm and on cell division, P. SAMASSA (*Verhandl. Naturhist. Ver., Heidelberg, 6 (1898), No. 1; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, p. 169*).—From experiments conducted with the staminal hairs of Tradescantia, pure oxygen was found not to accelerate the circulation of the protoplasm, while hydrogen and carbon dioxid caused its complete suspension. When no oxygen is present, the division of the nucleus does not take place. No cyclosis of the protoplasm is exhibited in the terminal cells of the hairs while dividing.

Variation in Indian corn when brought from New York to Texas, H. NESS (*Trans. Texas Acad. Sci., 2 (1898), No. 2, pp. 73-78*).—In 1896 two varieties of sweet corn were planted at Cornell University, Ithaca, New York, and at College Station, Texas, and comparisons made at the end of the growing seasons. The same experiment was repeated the next season, 14 varieties of corn being planted in the two different places, and kernels from the same ears used in each case. A marked difference was noted in the height of the stalks, length and width of leaves, number of suckers, and number of ears produced. At the Texas Station there was a very great tendency on the part of all varieties of sweet corn to produce grains without the characteristic wrinkling.

The measurements of the different varieties are given in tabular form, from which it appears that in nearly every case the stalks of the Texas-grown corn were about one-fourth shorter than those grown in New York, the leaves were narrower and shorter, there were a greater number of suckers, and the ears were somewhat larger and more numerous.

In accounting for these differences, the author states that the variation could not be attributed to differences in temperature, soil, moisture, or rainfall, since they were practically the same for the growing period in the two places; but he thinks the difference is due to intensity of light, which is much greater in Texas than New York. He concludes that the main cause of the decrease in the size of stalks and leaves, and increase in the number of ears of Indian corn when brought from northern to southern latitudes, is the increased intensity in the light, and perhaps also the relatively greater increase of the more highly refrangible rays of light.

Grasses, E. A. SMYTH (*Virginia Sta. Bul. 81, pp. 101-114, figs. 6*).—Popular descriptions are given of the principal characteristics of grasses, nature of their flowers, and the relationships of the better known grasses which are found in the State.

Statistical summary of spontaneous hybrids in the flora of Europe, E. G. CAMUS (*Statistique sommaire des faits d'hybridité constatés dans l'etendue de la flore Européenne, 1897, pp. 12*).—A catalogue of hybrids.

Plants reputed poisonous to stock, F. M. BAILEY (*Agr. Jour. Queensland, 4 (1899), No. 4, p. 285, pl. 1*).—Describes *Pratia erecta*, a lobeliaceous plant reputed as very poisonous to sheep.

Notes on the botany of cotton. Varieties of cotton grown in Egypt and the climatic conditions which affect them, G. P. FOADEN (*Jour. Khedivial Agr. Soc. and*

School Agr., 1 (1899), No. 2, pp. 49–67).—General notes are given on the botany of the varieties of cotton grown in Egypt, and of the varieties most in cultivation. The American sea island (*Gossypium barbadense*) seems to have been the original.

Contributions to the life history of the genus Gnetum, J. LOTSY (*Ann. Jard. Bot. Buitenzorg, 16 (1899), pt. 1, pp. 46–114, pls. 10*).

Conspectus of the genus Lilium, F. A. WAUGH (*Bot. Gaz., 27 (1899), Nos. 4, pp. 235–254; 5, pp. 340–360, figs. 14*).—A revision is given of the wild and cultivated species of this genus, 64 species being recognized.

Revision of the genera Montanoa, Perymenium, and Zaluzania, B. L. ROBINSON and J. M. GREENMAN (*Proc. Amer. Acad. Arts and Sci., 34 (1899), No. 20, pp. 507–534*).

Synopsis of the genus Verbesina, with an analytical key to the species, B. L. ROBINSON and J. M. GREENMAN (*Proc. Amer. Acad. Arts and Sci., 34 (1899), No. 20, pp. 534–566*)

On the variation in Picea excelsa, C. SCHRÖTER (*Ueber die Vielgestaltigkeit der Fichte (Picea excelsa). Zurich: Fäsi & Beer, 1898, pp. 130, pl. 1, figs. 37*).

Poisonous toadstools, B. D. HALSTED (*Amer. Gard., 20 (1899), No. 231, pp. 380, 381, figs. 2*).—Notes on *Amanita muscaria, A. phalloides,* and *A. verna.*

Poisoning due to mushrooms and means to be adopted against it, G. ARCANGELI (*Atti R. Accad. Econ. Agr. Georg. Firenze, 4. ser., 21 (1898), pp. 25; abs. in Bot. Centbl., 78 (1899), No. 5, pp. 132, 133*).—Notes are given of *Amanita phalloides, A. pantherina, A. muscaria, Armillaria tumescens, Boletus luridus, B. satanus,* etc., and suggests antidotes as far as known.

Plant anatomy from the standpoint of classification, C. GUFFROY (*Bul. Soc. Bot. France, 45 (1898), Nos. 6–8, pp. 337–341*).

The dehiscence of the nutmeg fruit, J. M. JANSE (*Ann. Jard. Bot. Buitenzorg, 16 (1899), pt. 1, pp. 17–45, pl. 1*).

The relation of plant physiology to the other sciences, J. WIESNER (*Die Beziehungen der Pflanzenphysiologie zu den anderen Wissenschaften. Vienna: A. Hölder, 1898*).

Notes on the chemical physiology of the trunks of trees, H. J. J. VANDEVELDE (*Bot. Jaarb. Kruid. Genotsch. Dodonæa, Ghent, 10 (1899), pp. 14, pls. 3*).

On the physiological importance of furfuroids in the plant, J. STOKLASA (*Bot. Centbl., 78 (1899), Nos. 6, pp. 161–170; 7, pp. 193–203*).

Phytochemical notes, P. VAN ROMBURGH (*Ann. Jard. Bot. Buitenzorg, 16 (1899), pt. 1, pp. 1–16*).—Preliminary notes are given on the occurrence of acetone, methyl salicylate, methyl alcohol, and hydrocyanic acid in a number of plants, and of methyl cinnamate in *Alpinia malaccensis.*

Investigations concerning the occurrence of red cell sap in plants, E. OVERTON (*Jahrb. Wiss. Bot., 33 (1899), No. 2, pp. 171–231*).—See E. S. R., 11, p. 113.

Selective absorption of mineral elements by plants, M. E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 23, pp. 970–973; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, pp. 179, 180*).—It is stated that the author by growing very young plants in dilute mineral solutions was able to determine their selective power in the absorption of certain mineral elements. It was found among other things that the presence of potassium will greatly lower and even reduce to zero the absorption of sodium.

Nitrogen assimilation (*Agr. Dept. Univ. Col., Nottingham [and] Midland Dairy Inst., Kingston, 1898, pp. 4, pl. 1*).—Contains and account of experiments in sand cultures on beans and clover.

Can the agriculturist profitably use Alinit as a fertilizer? KLOEPFER (*Ztschr. Landw. Ver. Rheinpreussen, n. ser., 16 (1899), No. 15, p. 133*).—From data collected from various sources in which Alinit had been applied to more than 6,000 morgen, the author concludes it is impracticable to use it as a fertilizer.

On the influence of fungi on the form and characters of plants, T. MEEHAN (*Proc. Acad. Nat. Sci. Philadelphia, 1899, pt. 1, pp. 108–110*).—Notes the modification in Euphorbias and Hepatica by Æcidium so that specific characters were obliterated.

Spore formation in Dematium pullulans, F. WELEMINSKY (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 9, pp. 297-303, figs. 9*).

The action of some bacterial and animal toxins on plants, M. CONSIGLIO (*Arch. Ital. Biol., 29 (1898), No. 3*).

Effects of lightning on grapevines, L. RAVAZ and A. BONNET (*Ann. École Nat. Agr. Montpellier, 10 (1898), pp. 221-236, pls. 3, figs. 6*).

FERMENTATION—BACTERIOLOGY.

Influence of oxygen on fermentation, G. KORFF (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), Nos. 11, pp. 465-472; 12, pp. 501-507; 13, pp. 529-535; 14, pp. 561-569; 15-16, pp. 616-627; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 2, p. 182*).—Pure cultures of Saaz, Frohberg, and Logos yeasts were studied under different conditions of nutrition to ascertain the influence of oxygen on fermentation, fermentation energy, and reproductive power. The nutritive solutions used were of cane sugar or yeast water, and asparagin. The following general conclusions were reached:

Moderate aeration favors the reproductive energy and power of Saaz and Frohberg, but lessens that of the Logos yeast. The fermentation energy may be raised by moderate aeration in the Saaz and Logos or lessened in the Frohberg, and the fermenting power of Frohberg and Logos is increased by the same means, while in the case of Saaz moderate aeration is without influence. Oxygen increases the reproductive energy and also the reproductive power of the different yeasts, but diminishes the fermentation energy and power in every case. Hydrogen or the total deprivation of oxygen inhibits the reproductive energy of Saaz and Logos, and is without influence on Frohberg yeast. It also causes a reduction of reproductive power, and either reduces the fermentation energy, as in Saaz and Frohberg, or is without influence. The fermenting power of Frohberg and Logos is increased in hydrogen, but it has no effect on Saaz yeast.

Preparation of bacterial culture solutions in large quantities, A. THEOKTISTOV (*Selsk. Khoz. i Lyesov., 188 (1898), Feb., pp. 315-325*).—Experiments were made during 1897, with a view of devising a method of sterilizing liquid nutritive media, whereby the essential drawbacks of the present method of sterilization should be obviated. The method adopted is based on the joint action of volatile chemical substances and a single heating to 100° C. Carbon disulphid, ether, and chloroform were selected as the most suitable volatile substances for introduction into the substratum to kill the micro-organisms and their spores without changing the nutritive media, or at least but slightly, and which could easily be removed by heating to a temperature not exceeding that of boiling water. The experiments were made with 0.5 per cent aqueous solution of Merck's peptone and pure cultures of *Bacillus mesentericus vulgatus* in bouillon. The fluids to be sterilized were placed in flasks in quantities of 500 to 1,000 cc., and 0.5 to 4 cc. of the volatile chemical added. The fluids were allowed to stand from 18 to 24 hours at room temperature, after which the flasks were heated to boiling, which was continued 5 to 20 minutes after the odor of the chemical disappeared. On cooling in thermostats to 28 or 29° the liquids proved to be perfectly sterilized. In order to ascertain whether the carbon disulphid, ether, or chloroform have affected the composition of the nutritive medium, cultures were made which developed normally in the usual time. Where chloroform was used the liquid retained its normal appearance, while ether and carbon disulphid caused the liquid to appear somewhat darkened or clouded, but did not affect the growth of the cultures. It was found that 0.5 cc. of carbon disulphid or ether were sufficient for sterilizing 1 liter. In the case of chloroform, not less than 1 cc. was required, but on account of the expense the experiments with this volatile agent were not so exhaustive as in the other cases. The experiments were repeated on a larger scale, tin flasks containing 15 liters of the liquid being used with equal success.—P. FIREMAN.

Influence of metals on bouillon cultures of bacteria, B. ISACHENKO (*Selsk. Khoz. i Lyesov., 189 (1898), Apr., pp. 35–42*).—The solution of two questions was sought: The influence of metals on the virulence of bacteria and on their growth and general activity. For the experiments *Bacillus spermophilinus* was used. The following are the conclusions of the author: In cases where the bouillon cultures must be kept in a metallic vessel for more than one month only vessels of iron, tinned iron (or tinned lead) are admissible, the purity of the tinning, i. e., freedom from lead, being immaterial. Nickel-plated, zinc, or zinc-plated iron vessels are absolutely unsuitable for growing and transporting bacteria. Copper apparatus and vessels can be used only for keeping the culture of the sterilized bouillon during a very brief time.—P. FIREMAN.

The alcohol-producing enzym of the yeast plant, J. R. GREEN (*Ann. Bot., 12 (1898), No. 48, pp. 491–498*).—In a previous paper (E. S. R., 9, p. 923), the author reports the inability to find the enzym described by Buchner in yeasts which were in a resting stage. In the present paper a report is given of continued investigations on this subject, from which it appears that yeast cells when active are able to secrete an enzym which can be extracted by means which are described. This enzym, when extracted, is capable of fermenting sugar solutions under conditions which prevent the activity of the living yeast. All the conditions of such fermentation are readily observed, such as the diminution of the sugar, production of carbon dioxid, and the formation of alcohol. The enzym is easily decomposed, and is only secreted by the cell during actual fermentation by the yeast. It is quickly decomposed when this activity ceases, so that the resting yeast does not yield it. The high pressures which were employed by Buchner were found to be unnecessary for the extraction of the enzym, the author finding low pressures of 5 atmospheres to the square inch more active than those obtained by the use of hydraulic pressure.

The proteolytic enzym of Nepenthes, S. H. VINES (*Ann. Bot., 12 (1898), No. 48, pp. 545–555*).—In a previous paper (E. S. R., 9, p. 813), the author has called attention to the presence of an enzym in the pitchers of Nepenthes. He has followed up his investigations on this subject and states that the action of high temperatures and alkalis upon the enzym confirmed the statement made in the previous paper regarding its great stability. While the activity of the enzym may be diminished by exposure to high temperatures, or treatment with alkalies, it retains a sort of digesting power which can only be destroyed by relatively strong measures. It seems probable that the enzym is derived from a zymogen present in the gland cells. The presence of a true peptone among the products of digestion seems to indicate that it is a tryptic ferment mainly differing from trypsin of the pancreatic juice in requiring an acid medium for its digestive action.

Cellulose enzyms, F. C. NEWCOMBE (*Ann. Bot., 13 (1899), No. 49, pp. 49–81*).—The author reports a number of experiments conducted with extracts made from barley malt; *Aspergillus oryzæ*; cotyledons of *Phœnix dactylifera*, *Lupinus albus*, peas, and buckwheat; and the endosperm of *P. dactylifera*. The method of extracting these different enzyms is given, and their reaction upon starch and the cell walls is described. The author briefly summarizes the results of his work as follows:

"The enzym extracted from *A. oryzæ* attacks reserve cellulose with greater intensity than it attacks starch.

"The enzym from the cotyledons of seedlings of *L. albus* is very strongly cytohydrolytic but very feebly amylohydrolytic.

"The enzym from the cotyledons of seedlings of *P. dactylifera* is very strongly cytohydrolytic and very feebly amylohydrolytic, attacking starch a little more strongly than the extract of Lupinus does.

"The enzym from the endosperm of *P. dactylifera* is very strongly cytohydrolytic but amylohydrolytic to a little less degree than the extract of Lupinus and to a considerably less degree than the enzym from the cotyledons of Phœnix.

"The very dilute enzym of the malt of *Hordeum vulgare* as well as that of the other plants here considered attacks reserve cellulose; hence an enzym-solution need not be strong to act on cell walls.

"None of the 5 enzym extracts used in this work shows itself more than the other extracts peculiarly suited to the solution of any one kind of reserve cellulose here employed.

"With all the ferments the walls at first become hyaline, appear gradually more and more transparent, and finally melt wholly away in solution.

"The enzyms from *L. albus* and from *P. dactylifera* act on starch so feebly and on reserve cellulose so energetically that they are to be regarded as cytase as distinguished from diastase."

Investigations on the biochemic production of sorbose, G. BERTRAND (*Ann. Inst. Pasteur, 12 (1898), No. 6, pp. 385–399*).—The author concludes from his investigations that sorbose, the sugar which was discovered by Pelouze in 1852 under the name "sorbine," does not exist in the juice of the fruit of *Sorbus aucuparia* and allied species. On the other hand, it appears that it is produced by the oxidation of sorbite under the influence of bacteria analogous to or identical with *Bacterium xylinum*. In making cultures of these bacteria in a medium containing sorbite the transformation of sorbite into sorbose is easily effected, and in many cases as much as 80 per cent of the theoretical amount is obtained.

The principles of bacteriology, F. Heuppe, translated by E. O. Jordan (*London: Kegan Paul, Treubner, Trench & Co., 1899*).

Bacteria and yeasts in agricultural practice, M. Hoffmann (*Bakterien und Hefen in der Praxis des Landwirthschaftsbetriebes. Berlin: Paul Parey, 1899, pp. 118, figs. 19; rev. in Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 7, pp. 224, 225*).—According to the review the author, who has been at different times connected with the experiment stations of Tharand, Halle, Köslin, etc., has prepared a very practical work treating of the life history of these organisms and describes their action. Among those described are soil bacteria, bacteria of stable manure, of nitrogen assimilation, of wine and similar fermentations, of milk, silage, bread, sauerkraut, and of numerous infectious diseases of animals In the latter connection the use of various lymphs and cultures is explained at some length.

Fermentation and germ life, J. Nelson (*New Jersey Stas. Bul. 134, pp. 24, pls. 2*).—The general nature of ferments and fermentation is given, with descriptions of the various organisms which cause these changes. The distribution of the organisms is commented upon, and various methods suggested for the control of fermentation. In the plates, microscopic reproductions are given of a number of forms of bacteria and other vegetable organisms which are concerned more or less with the subject in hand.

METEOROLOGY—CLIMATOLOGY.

Proceedings of the Convention of Weather Bureau Officials, held at Omaha, Nebraska, October 13-14, 1898 (*U. S. Dept. Agr., Weather Bureau Bul. 24, pp. 181, pl. 1*).—Sixty-four officials of the Weather Bureau and 16 voluntary observers of the climate and crop sections were present at this convention. The topics discussed included the following: Relation between the Weather Bureau and the public, by F. J. Walz and G. N. Salisbury; Forecasts best calculated to aid maritime interests of the Great Lakes, method of reaching those interested, by H. J. Cox and N. B. Conger; Are the present warnings and displays by flag and lantern the best that can be devised for the Atlantic and Gulf coasts? by J. W. Smith and A. G. McAdie; Possibility of giving warnings of northers, cold waves, and heavy snows to stock-raising interests forty-eight hours in advance, by F. H. Brandenburg and E. J. Glass; Warnings of washouts, floods, cold waves, and heavy snowfalls for the benefit of transportation companies, by J. W. Smith and T. S. Outram; What classes are most benefited by the forecasts? Are they just what are needed? Are they properly disseminated and utilized? by J. R. Sage and H. C. Bate; Long range forecasts: Can they be made with sufficient precision to be of general utility? by H. A. Hazen, P. Connor, and B. S. Pague; Forecast distribution: Should the wording of the forecasts be confined to the vocabulary of the present logotype outfit? Is it advisable to extend the vocabulary of the logotype outfit? by F. P. Chaffee and G. M. Chappel; River and flood service, by R. J. Hyatt and L. M. Pindell; Should warning messages (Form 1043 C) be of some distinctive color to more readily attract attention? by S. W. Glenn and T. B. Jennings; Relation of the Weather Bureau to the Department of Agriculture, by E. B. Calvert; West Indian hurricane service, by W. L. Moore; Possibilities of the weather service on the Pacific Coast: Value of Mount Tamalpais observations, by W. H. Hammon and B. S. Pague; Some rain-producing processes, by E. B. Garriott; Relations with the press, commercial bodies, and scientific organizations—how promoted, by E. A. Beals and A. F. Sims; Meteorological statistics: How to improve them that they may meet the needs of the medical profession, hydraulic and sanitary engineers, promoters of irrigation projects, etc., and does the present monthly section report meet such needs? by E. W. McGann and W. M. Wilson; Some notes on agricultural meteorology, with special reference to the rainfall element, by C. E. Linney; Effect of forest clearing and cultivation upon (1) water supply and soil, (2) rainfall, (3) temperature, by W. M. Fulton and G. N. Salisbury; Is the weather map appreciated and understood by the masses? Would not the postal-card weather forecast prove a satisfactory substitute for the map, except where it is used for the purposes of study and instruction? by E. B. Calvert and T. F. Townsend; Primary work on meteorology for the use of schools, by P. Connor; Should not certain important Weather Bureau stations, the duties of which cover a wide range of work, be designated stations of instruction for newly appointed observers? by J. W. Smith and C. F. R. Wappenhaus; Climate and crop service weekly bulletins: Should remarks of correspondents be published as supplementary to general discussion? Should weekly reports of temperature and rainfall be telegraphed to section centers from selected voluntary stations? by A. E. Hackett and J. B. Marbury; Frost fighting, by A. G. McAdie; Aerial observations, by G. B. Wurtz, G. H. Noyes, and J. C. Piercy; Should not a book providing for a permanent record of meteorological observations for a prolonged period be furnished to the section centers for their use and for voluntary stations? by G. A. Loveland and J. W. Bauer; Atmospheric moisture and artificial heating, by W. M. Wilson; Should not a book be provided suitable for keeping record of the issue of instruments and flags to voluntary observers? by R. G. Allen and B. H. Bronson; Are changes in the present forms (1053 and 1054) for reporting weekly climate and crop conditions advisable? by C. E. Linney and A. J. Mitchell; Should compensation be allowed persons not in the employ of the Bureau while learning station duties to enable them to properly perform such duties in cases of emergency? by D. Cuthbertson and G. E. Franklin; Professor Marvin's weighing rain and snow gauge, by W. W. Carlisle; Interchange of standard climatic data, by A. G. McAdie; Studies of climate, by F. J. Walz; Voluntary stations: Their object and collateral functions, by A. J. Mitchell; Snow and ice measurements, by H. Volker; Benefits of the Weather Bureau to western Nebraska, by J. C. Piercy; Development of the daily weather map, by E. B. Calvert; Establishment and inspection of voluntary, river, and cotton-belt stations, by J. B. Marbury; Storm signals on the Great Lakes, by J. H. Cox; Can long-range weather forecasts be made with any degree of accuracy or profit? by A. B. Crane; The weather as a topic of conversation, by A. S. Brendle; Distribution of forecasts by mail, by P. F. Lyons; Utility of hygrometric observations, by A. Pennell and H. A. Hazen; Wind vanes, by C. P. Cronk; Forecasts of probable temperatures, by I. M. Cline; An official of the Weather Bureau: His duties and qualifications, by B. S. Pague.

The climate of the Congo (*Nature, 59 (1899), No. 1537, p. 564*).—This is a brief note on a work by A. Lancaster and E. Meuleman entitled *Le climat du Congo*, published in 1898. The temperature of this region is very uniform throughout the year, being as a rule about 86° F. in the afterntoon and 68° at night. The distinctive feature of the climate is the rainfall. The rainy season commences early in October and ends about the middle of May. The division into wet and dry seasons becomes less clearly defined as the distance from the sea increases and from the equator decreases. The rainfall is nowhere exceptional. Thunderstorms occur frequently in the interior—at all seasons in the equatorial region, only during the rainy season in the south and west.

On the photochemical climate of the Arctic regions, WIESNER (*Bot. Centbl., 75 (1898), No. 8, pp. 233-235*).—A brief résumé is given of a paper by the author, in which the results of his investigations on the climate of high latitudes are stated. It is claimed that at Tromso and Advent Bay the intensity of light is greater than at Vienna or Cairo for the same elevation of the sun and equally cloudy skies. At Advent Bay there was found little difference between the intensity of the light in the forenoon and afternoon. Usually the intensity of light in the afternoon has been found the greatest. During August the intensity of the light was 2.5 times that at Vienna when the sun was at the same elevation, namely, from November to February. The bearing this has upon plant growth is to be given in a subsequent paper.

Meteorological observations, J. E. OSTRANDER and A. C. MONAHAN (*Massachusetts Hatch Sta. Met. Buls. 121, 122, 123, pp. 4 each*).—The usual summaries of observations, with general notes on the weather during January, February, and March, 1899. The precipitation during February and March was considerably above the normal.

Meteorology, C. H. PETTEE (*New Hampshire Sta. Bul. 59, pp. 216-219*).—General notes on the weather and a monthly and annual summary (July, 1896-June, 1898) of observations on temperature, precipitation, cloudiness, and prevailing winds. The mean temperature for the year 1897-98 was 45.9° F., the precipitation 44.8 in. The year was characterized by a large but uniformly distributed precipitation.

Meteorological data and bloom notes, W. B. ALWOOD and H. L. PRICE (*Virginia Sta. Bul. 82, pp. 117-127, charts 2*).—This is a summary of observations made at the station since 1893 and comprises tabulated data for temperature, pressure, precipitation, cloudiness, and direction of the wind for each month, 1893-1898, and a record for the same years of the bloom periods of 2 varieties of pears, 3 of plums, 2 of cherries, and 1 each of apples, raspberries, blackberries, currants, and dwarf juneberries. The monthly precipitation and the maxima, minima, and mean temperatures are charted.

Meteorological summary for Laon, France, for the year ending November 30, 1898, L. GAILLOT (*Bul. Sta. Agron. Aisne, 1898, pp. 7-19*).

Observations on rainfall and temperature in the Department of Gironde, France, June, 1897, to May, 1898, G. FAYET (*Append. to Mem. Soc. Sci. Phys. et Nat. Bordeaux, 5. ser., vol. 4*).—The observations are tabulated and discussed in detail.

Observed variations in the velocity of the wind, F. HOUDAILLE and DESMOULINS (*Ann. École Nat. Agr. Montpellier, 10 (1897-98), pp. 48-56, pls. 2, fig. 1*).—Data for variations in velocity during the year are given and the amount of the force of the wind utilized by windmills is discussed. The work of the mill and pump used, measured by water raised, was 31,380,000 km. per 1 square meter of mill surface during an annual period of 31,536,000 seconds, the pump utilizing 0.7 of the force of the mill.

Researches on the movement of the winds of the southern Cévennes to the Mediterranean, F. Houdaille (*Ann. École Nat. Agr. Montpellier, 10 (1897–98), pp. 5–47, figs. 10*).

Climate and crop report, season of 1898, Alaska section, H. L. Ball (*U. S. Dept. Agr., Weather Bureau Doc. 188, pp. 7*).—Reprinted from Monthly Weather Review, 26 (1898), No. 12 (E. S. R., 10, p. 1018).

Frost: When to expect it and how to lessen the injury therefrom, W. H. Hammon (*U. S. Dept. Agr., Weather Bureau Bul. 23, pp. 37*).—This is a revised reprint of an earlier bulletin on this subject (E. S. R., 8, p. 109).

International cloud studies, 1896–97. Observations in Sweden (*Études internationales des nuages, 1896–97. Observations et mesures de la Suède. Upsala: Akad. Bokh., 2 v., pp. 29+103, pl. 1*).

On the cause of the blue color of the sky, W. Spring (*Bul. Acad. Roy. Sci. Belg., 3. ser., 36 (1898), p. 504; abs. in Naturw. Rundschau, 14 (1899), No. 15, p. 189*).

An elementary treatise on practical and agricultural meteorology (*Traité élémentaire de météorologie pratique et agricole, suivi de notions cosmographie. Chambéry: Perrin, pp. 64, figs. 5*).

AIR—WATER—SOILS.

Moisture of soil in relation to the crops under cultivation and to the climatic conditions, T. Lokot (*Selsk. Khoz. i Lyesov., 191 (1898), Nov., pp. 305–347; Dec., pp. 517–582*).—This article is based upon data obtained in the Poltava Experiment Field during the last 3 or 4 years, almost 2,000 determinations of moisture being made annually. In view of the fact that in order to judge of the adequacy of the moisture of a soil as determined by analysis it is necessary to know the minimum of moisture which will supply the demand of plants for transpiration, the author tried to establish this minimum for the soil of the Poltava Experiment Field. This he assumes (for the present) to be double the maximum hygroscopicity of the soil, which was found to be 5 per cent.

During the 3 years, 1895–1897, the moisture was determined on the most important plats of the field under the following conditions: On fallow land which had been uncultivated for many years, on plats occupied by perennial grasses, on alfalfa fields in 5-course and 10-course rotations, on plats under maize as compared with plats under cereals and broad-leaved plants, on fallow fields, and on fields under winter and spring cereals. A record of meteorological conditions was kept at the same time. Samples for the estimation of moisture were taken at the following depths: 0 to 5.25, 5.25 to 10.5, 10.5 to 15.75, 15.75 to 21, 21 to 28, 28 to 35, 35 to 42, 42 to 49, 49 to 56, 56 to 63, and 63 to 70 in.

Determinations were made for every plat from 3 to 5 times during the growing period. The mean results were found to vary as follows:

Moisture content of soils under different conditions.

	Per cent.
On fallow land, in the steppe	13.01
In the forest	13.62
On plowed plats	16.04
On plats covered with sod	13.85
Under gramineous plants	12.69
Under papilionaceous plants	12.33
In 5 course rotation:	
Alfalfa, plowing 7 in. deep	14.32
Alfalfa, plowing 14 in. deep	14.36
Corn, plowing 7 in. deep	15.75
Corn, plowing 14 in. deep	15.53
Corn, fertilized plats	15.83
Corn unfertilized plats	15.31
Alfalfa, plowing 14 in. deep	13.68
Alfalfa plowing 7 in. deep	13.63

Spring crop field, under oats	16.18
First 3-course rotation:	
Black fallow	16.81
Early fallow	16.82
Middle fallow	15.99
Late fallow	15.17

—P. FIREMAN.

Second report on the work in studying the fertility of soils, S. BOGDANOV (*Selsk. Khoz. i Lyesov., 191 (1898), Nov., pp. 387–414; Dec., pp. 499–516*).—In an earlier article the author described investigations regarding the fertility of soils carried out by him and his associates in the agricultural laboratory of the Kiev University, the principal conclusions from which were that it is possible to determine, by chemical analysis, the amounts of nitrogen and phosphoric acid assimilable by oats in a soil. The assimilable nitrogen was determined as follows: The soil, containing about 50 per cent of the available moisture which it was capable of holding, was kept for 48 hours in a thermostat at 30° C., and the nitrogen as ammonia (and in related forms) and as nitric acid was determined. Seventy-five per cent of this nitrogen was assumed to be assimilable by oats in the following vegetation period under favorable circumstances. For the determination of the phosphoric acid assimilable by oats the soil was digested with a 2 per cent acetic acid solution in the ratio of 1 part of the soil to 4 parts of the acid during 24 hours, and all the phosphoric acid extracted was assumed to be assimilable by oats in the vegetation period immediately following.

These methods were based on experiments carried out prior to 1896 with a number of soils on which oats were cultivated with and without fertilizers. In 1896 and 1897 the conclusions were confirmed by the results of a series of experiments on other soils. The tests were made in zinc pots, according to Wagner's method, though with some modifications.

With a view to testing the applicability of the results obtained by this method with one crop to others, experiments were made with barley, millet, peas, and white mustard on the same soils on which oats had been cultivated before. It was found that as regards nitrogen and phosphoric acid the results with oats gave correct indications of the requirements of other plants. The author is inclined to think that with a given soil fertility, various plants develop differently in correspondence with the peculiarities of their morphological and anatomical structure, chemical composition, etc., but not because they do not avail themselves in the same way of the fertility of the soil.

Further experiments which extended over 2 or 3 years showed that a laboratory investigation of the fertility of the soil furnished a basis for sound conclusions as to the yields for 2 to 3 years following.

For determining the available constituents of the soil the author recommends, as a result of his investigations, the use of an aqueous extract obtained by shaking 1 part of soil with 100 parts of water. Such an extract contains at least as much phosphoric acid in solution as is dissolved by a 2 per cent acetic acid solution (soil and acid in the ratio of 1:4) and also potash and lime, and apparently the other constituents, in sufficient quantities. The aqueous extracts were prepared by shaking the soil with water for 48 hours, and then filtering with suction through funnels closed with porous clay plates. A perfectly clear solution was thus obtained.—P. FIREMAN.

A rapid method for the determination of the amount of soluble mineral matter in a soil, T. H. MEANS (*Amer. Jour. Sci., 4. ser., 7 (1899), No. 40, pp. 261–266*).—This method, which has been worked out in the Division of Soils of this Department, "is practically a means of determining the specific electrical conductivity (or resistance) of the solution between the soil grains. When this is known, the amount of any salt which will produce this same conductivity may be calculated from published tables of the conductivity of salt solutions." The apparatus required and the method followed have already been described in bulletins of the Division of Soils (E. S. R., 9, p. 535; 10, p. 30). Directions for making salt determinations in soils are given in this article.

The method has been found to offer special advantages for the study of irrigated districts and alkali soils[1] since the apparatus necessary can readily be carried in the field and 2 men can examine from 60 to 100 samples of soil in a day.

Action of very dilute acid solutions on the phosphates of the soil, T. H. SCHLOESING, Jr. (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 16, pp. 1004–1007; abs. in Jour. Chem. Soc. [London], 76 (1899), No. 440, II, p. 449*).—In the author's experiments 10 to 20 gm. of 4 different soils were treated with 1 liter of water unacidulated or containing from 0 to over 20,000 mg. of nitric acid (N_2O_5). After rotation in a horizontal position for 10 hours, the acidity and phosphoric acid and iron contents of the solutions were determined. It was found that up to a certain point (100 to 200 mg. per liter) the amount of phosphoric acid dissolved varied with the concentration of the acid. Beyond this a further addition of acid did not decidedly increase the amount of phosphoric acid dissolved until the acid became quite concentrated (1 gm. per liter). The phosphates of calcium, magnesium, and the alkalis were dissolved out during the first stage, the extract containing only traces of iron. When the second stage was entered, however, the iron began to be freely dissolved. The soils which yielded the most phosphoric acid to the dilute acid (100 to 200 mg. N_2O_5 per liter) were those whose phosphoric acid proved most soluble in water.

---

[1] U. S. Dept. Agr., Division of Soils Bul. 14 (E. S. R., 10, p. 1026).

The daily heat exchange in the soil and the radiation of heat between the earth and the atmosphere, T. HOMÉN (*Der tägliche Wärmeumsatz in Boden und die Wärmestrahlung zwischen Himmel und Erde. Leipsic: Wilhelm Engelmann, 1897, pp. 147; noted in Phys. Rev., 8 (1899), No. 4, p. 251*).—This volume presents the results of researches at the University of Helsingfors upon solar radiation and the daily interchange of heat between the earth and the atmosphere.

The experiments, which ran through several summers, "included daily measurements and, for periods of many days, hourly measurements of the temperature of the upper layers of the earth's crust. Readings were taken at 10 different depths beneath the surface, varying from 1 to 70 cm., in sandy soil, in clay soil, beneath the vegetation of moorland and meadows, in granite rock, and in the waters of a small lake. Corresponding measurements were taken in the air at heights above the surface running to 10 meters. Determinations of the formation of dew with estimates of the amount of heat thus set free were likewise carried on, and measurements were made of the direct radiation from the sun, of that from the open heavens, and of the return radiation from the earth's surface." A special form of thermometer was used for the measurements of soil temperatures. For the measurements of radiation a modification of Ångstrom's instrument[1] was employed. The temperature readings are plotted on a large scale.

Contribution to the study of the forms and conditions under which the chlorin of the soil ordinarily enters plants, P. PICHARD (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 10, pp. 615-617; abs. in Rev. Sci., 4. ser., 11 (1899), No. 11, pp. 340*).—The investigations here recorded were undertaken to determine the forms and conditions under which the chlorin of the soil enters into growing tobacco. Five series of pot experiments were made with 2 varieties of tobacco on (1) sand charged with chlorids (0.5 to 2 gm. per kg.) receiving (a) organic fertilizers (b) nitrates; (2) artificial soils poor in potash and chlorin, fertilized as in (1); (3) artificial soils rich in potash, poor in chlorin, fertilized as in (1); (4) natural soils well supplied with potash and organic nitrogen, poor in chlorin, fertilized with nitrates; (5) same as (4) except kept in diffused light, the first 4 series of experiments being conducted in sunlight. Samples of tobacco grown under these conditions, as well as by planters on various kinds of soil containing from 0.28 to 0.7 gm. of chlorin per kilogram, were subjected to chemical analysis.

---

[1] See Phys. Rev., vol. 1, p. 365.

It was found that the chlorin content of the tobacco increased with the amount in the soil. Only the chlorids of potassium and sodium were found in appreciable amounts in the tobacco, the chlorid of potassium largely predominating. The amount of chlorin in the tobacco increased with the amount of potash in the soil. There was found as high as 11.23 per cent of potassium chlorid in the leaves of tobacco, the proportion in the stems being less and in the roots still smaller. On soils rich in chlorids tobacco appears to store up potassium chlorid in large quantities. Chlorid of sodium is taken up less readily by tobacco. In fact, it is not likely to appear in the plant unless it is present in the soil in large amounts. The most careful examination of the tobacco failed to detect the presence of any salt of sodium except the chlorid. The author suggests that in contact with the roots the potash replaces sodium in combination with chlorin, the potassium chlorid being taken up by the plant while the salts of sodium remain in the soil. It was observed in these investigations that a decrease in the amount of the nitrates of the soil was accompanied by an increase of the chlorin in the tobacco, and *vice versa.*

Is iodin present in the air? A. GAUTIER (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 11, pp. 643–649*).—Examinations of the air of Paris, of woodland, high mountains, and of the sea led to the conclusion that iodin derived from the decomposition of alkaline iodids is not present in the air in appreciable quantities. There was a certain amount of iodin present, especially in sea air, in the form of suspended organic matter.

Microscopy of drinking water, G. C. WHIPPLE (*New York: John Wiley & Sons, 1899, 1. ed., pp. 300, ill.*).

Microscopic water analysis, C. MEZ (*Mikroskopische Wassersanalyse. Berlin: Julius Springer, 1898.*

On the influence of electricity on the oxygen content of water, O. BERG and K. KNAUTHE (*Naturw. Rundschau, 13 (1899), Nos. 51, pp. 661–664; 52, pp. 675–677*).—Under the influence of electricity the oxygen consumption in water is accelerated. This is shown in the increased activity of electrolytic processes, such as the fixing of the nitrogen of the air.

On the industrial sterilization of potable waters by means of ozone, MARMIER and ABRAHAM (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 17, pp. 1034, 1035; Rev. Sci. [Paris], 4. ser., 11 (1899), No. 20, pp. 625–627*).

Some Nevada soils, N. E. WILSON (*Nevada Sta. Bul. 39, pp. 30*).—"This bulletin is intended as a forerunner of a more exhaustive work on the soils and irrigation waters of the State of Nevada. A general survey of the State, for this purpose, is under consideration and it is hoped it can be carried out in the near future." Chemical analysis of 26 samples of typical soils collected in different parts of the State are reported, and the origin, classification, and composition of soils in general are discussed.

Alkali lands, M. WHITNEY and T. H. MEANS (*U. S. Dept. Agr., Farmers' Bul. 88, pp. 23, fig. 1*).—This is essentially a summary of Bulletin 14 of the Division of Soils (E. S. R., 10, p. 1026), discussing conditions in the Yellowstone Valley, rainfall and seepage, how salt determinations are made, kinds of soils in the valley, salt content of the soils, and effect of underdrainage in removing the salts.

The soil, E. HOTTER (*Bodenkunde. Graz: Landes-Versuchsstation, 1899, pp. 56*).—An elementary treatise on the origin, formation, and properties of soils.

On soil management, A. ANSTADT (*Fühling's Landw. Ztg., 48 (1899), No. 8, pp. 297–300*).—This is a general discussion of the exhaustion of soils under different rotations. The general conclusion is reached that a record of the income and outgo of the fertility of the soil is not always a reliable guide in practice, since in many cases it is necessary to return more of the fertilizing constituents than the crops grown remove, in order to maintain and increase the productive capacity of the soil.

On the loss of plant food in cultivated soils E. WOLLNY (*Deut. Landw. Presse, 26 (1899), Nos. 34, p. 383; 36, p. 412; 37, pp. 424, 425*).

Contribution to the chemical study of the alluvial soils of Lodi, G. FASCETTI and F. GHIGI (*Staz. Sper. Agr. Ital., 32 (1899), No. 1, pp. 131–136*).

Minutes of the forty-first meeting of the Central Moor Commission, December 12–14, 1898 (*Protokoll der 41 Sitzung der Central-Moor-Commission. Berlin, 1899, pp. IV+216+38+8+31, pls. 10*).—Most of the experimental work referred to in this report has already been noted (E. S. R., 10, pp. 931, 1022).

The moor soils of Westphalia, G. HASELHOFF and H. BREME (*Die Haideböden Westfalens. Berlin, 1899, pp. 31, dgms. 3*).—This is the first part of this treatise and is devoted to the moors of Dörmen. It discusses the general properties, the mechanical and chemical composition, and the reclamation of these soils. A topographical map gives the location of the soils, and diagrams show the physical characteristics of the soils.

FERTILIZERS.

The action of organic nitrogen, particularly of barnyard manure, as a fertilizer, T. PFEIFFER, E. FRANKE, O. LEMMERMANN, and H. SCHILLBACH (*Landw. Vers. Stat., 51 (1899), No. 1–5, pp. 219–310*).—The work of other investigators, especially that of Maercker and Wagner, is reviewed at some length, and pot and field experiments by the authors during 3 years (1895–1897) are reported.

The soil used in both the pot and the field experiments was sandy and poor in nitrogen. In the pot experiments the crops grown were oats and mustard in 1895, carrots in 1896, and oats again in 1897; the fertilizers tested were nitrate of soda, sulphate of ammonia, ground horn, dried blood, meat and bone fertilizer, and barnyard manure without preservative and preserved with sulphuric acid and calcium carbonate. In the field experiments the rotation was potatoes, winter rye, mustard, and carrots; the fertilizers tested were nitrate of soda and barnyard manure. Fertilizers were not applied after the first year.

Ground horn, dried blood, and barnyard manure showed a higher fertilizing value in the pot experiments than was obtained by Wagner in similar experiments, as the following table shows:

Fertilizing value of different forms of organic nitrogen.

Fertilizer.	Effectiveness, taking nitrate of soda as 100.	
	In these experiments.	In Wagner's experiments.
	Per cent.	*Per cent.*
Ground horn	83–84	63
Dried blood	85	69
Barnyard manure withou preservative	46	
Barnyard manure preserved with sulphuric acid	56 }49	32
Barnyard manure preserved with calcium carbonate	45	

The after effect of the fertilizers was found to be considerable and was taken into account in estimating the fertilizing value of the different materials. The unpreserved manure, which showed an effectiveness of 46 per cent in the pot experiments, was found to have a fertilizing value of 92 to 93 per cent in the field experiments. This difference is believed to be due to the better aeration in the field than in the pots.

The after effects of the manures were not noticeable in the field after the second year.

Since in the field experiments the nitrogen of the manure was almost as effective as that of the nitrate of soda, even when applied at the rate of about 27 tons per acre, denitrification could not have gone on there to any marked extent. The poorer results in the pots may have been due to increased denitrification in the less thoroughly aerated soil.

Experiments on the treatment of manure with acid superphosphates, E. MARRE and L. BOYER (*Prog. Agr. et Vit. (Ed. L'Est), 20 (1899), No. 14, pp. 411–415*).—In these experiments the manure from 2 cows (from January 18 to March 8) was treated, morning and night, with 1 kg. of 14 to 16 per cent superphosphate, and that from 2 other cows with 1 kg. of the same superphosphate to which was added 100 gm. of sulphuric acid (53° Baumé). The manure received otherwise identical treatment, remaining in heaps until April 19. The two lots were then applied at the rate of 56,000 kg. per hectare to parallel plats of soil very rich in phosphoric acid and potash, on which potatoes were grown. The yield was decidedly less on the plat to which manure treated with acidulated superphosphate had been applied than on that receiving nonacidulated manure.

The manurial value of Nile mud, W. C. MACKENZIE (*Jour. Khed. Agr. Soc. and School Agr., 1 (1899), No. 3, pp. 99–101, figs. 2*).—"In Upper Egypt, where the basin system of irrigation is employed, the land receives yearly a deposit of Nile mud, which enriches the soil." From the amount and chemical composition of the sediment carried by the Nile water at different seasons the fertilizing value of this mud is computed. A comparison of the fertilizing matter supplied by the irrigating water with the fertilizer requirements of different crops indicates that—

> "Nile mud does not supply a sufficient amount of nitrogen for the use of 'nitrogen consuming' crops, but the growth of berseem [leguminous plants] may, in part at least, supply this deficiency.
>
> "Nile mud supplies sufficient quantities of phosphoric acid and potash for the growth of fair crops of cotton, wheat, barley, maize, beans, and potatoes, but does not do so for sugar cane, berseem, and berseem hagazi [alfalfa], though if the two latter crops are consumed by cattle on the land they may be left out of consideration."

Liming, C. W. BURKETT (*New Hampshire Sta. Bul. 59, pp. 178–182*).—Lime (1 ton per acre) was applied to an old meadow in connection with commercial fertilizers. The increase due to the liming is shown in the following table:

Increase in yield of hay due to liming, 1897–98.

	1897.	1898.	Average.
	Pounds.	*Pounds.*	*Pounds.*
Kainit and acid phosphate with lime	4,520	1,760	3,140
Kainit and acid phosphate without lime	3,480	1,600	2,540
Increase due to lime	1,040	160	600
Muriate of potash and acid phosphate with lime	4,440	2,080	3,260
Muriate of potash and acid phosphate without lime	3,360	1,440	2,400
Increase due to lime	1,080	640	860
Muriate of potash, acid phosphate, and nitrate of soda, with lime	4,280	2,520	3,400
Muriate of potash, acid phosphate, and nitrate of soda, without lime	3,800	2,520	3,160
Increase due to lime	480	....	240

"From these results it is evident that the lime has been more effective in the first season's growth."

In an experiment of the same kind on corn for silage the increase due to liming was 4,640 lbs. per acre, the total yield with lime being 16,820 lbs. per acre.

Tests by Wheeler's method (E. S. R., 9, p. 640) of the reaction of the soil of the different fields of the college farm are reported. Most of the soils were found to be acid.

Thomas slag vs. redondite as a fertilizer, C. W. BURKETT (*New Hampshire Sta. Bul. 59, pp. 189, 190*).—In 1897 and 1898 comparative tests of Thomas slag (160 lbs. per acre), raw redondite (80 lbs. per acre), and roasted redondite (40 lbs. per acre) were made on plats of grass which had received nitrate of soda, 80 lbs., and kainit, 400 lbs. per acre. Barley was used as a nurse crop, and was cut in September, 1897. The yields of barley were as follows: On the Thomas slag plat, 1,312 lbs. per acre; raw redondite plat, 1,520 lbs., and roasted redondite plat, 1,424 lbs. The yields of hay in 1898 were on the Thomas slag plat, 3,704 lbs.; raw redondite plat, 4,320 lbs., and roasted redondite plat, 3,248 lbs. per acre.

"In each year, as is shown in the data, the raw redondite gave the greatest yield. Of the other two, the roasted redondite exceeded the Thomas slag by 112 lbs. per acre in the first year, while in the present season it was reversed, the Thomas slag yielding 456 lbs. per acre more than the other. From this experiment, therefore, their values are in the following order: Raw redondite, first; Thomas slag, second, and roasted redondite, third."

The fertilizing value of oil cakes, L. MALPEAUX (*Ann. Agron., 25 (1899), No. 3, pp. 111–126; abs. in Jour. Chem. Soc. [London], 76 (1899), No. 439, II, p. 378*).—This is an account of a continuation of previous field experiments supplemented by pot experiments. The results were very variable. As in previous experiments, sesame cake proved most effective, followed in the order named, by poppy, peanut, camelina, colza, castor bean, cotton seed, and palm cakes. This order may be changed by further experiments. For spring application the more rapidly decomposing poppy, sesame, and castor-bean cakes are recommended. They should be applied as early as possible.

Manurial requirements of crops, W. P. BROOKS (*Massachusetts Hatch Sta. Bul. 58, pp. 3-12*).—This is a brief summary of results and conclusions based upon experiments on twentieth-acre plats with various fertilizing materials, begun in 1889, a more complete account of which is to be given in a later bulletin. "The conclusions presented are based upon some 30 such experiments with corn, some 6 with oats, 12 with grass and clover, and 1 each with rye, soy beans, turnips, and cabbages," made at the station and in most cases also at other points in the State.

The experiments show in general that—

"The widest differences in plant-food requirements exist between crops cultivated upon the same soil; corn, clovers, rye, and soy beans being benefited mostly by potash; grasses and oats, by nitrogen; and mustard, cabbages, and Swedish turnips by phosphoric acid.

"The experiments indicate the desirability of changes in the composition of the complete 'special' fertilizers offered in our markets. For most crops these fertilizers contain too much phosphoric acid. For oats and grass they contain too little nitrogen.

"It is believed that for none of our crops, except those of the mustard family, is the application of phosphates to supplement farm manure called for."

Formulas for fertilizers for different crops are given.

Notes on the proper handling of barnyard manure, C. WELLINGTON (*Massachusetts Hatch Sta. Bul. 58, pp. 13-16*).—A general discussion, which is summed up as follows:

"Of the three common conditions of barnyard manure, half-rotted manure is the most valuable, and well-rotted manure the least, because of their relative amounts of nitrates.

"Manure should be kept packed away from the air as tightly as possible, and if rotted should be plowed under just before planting, otherwise several months before that time.

"The more litter used in the manure, the greater liability to loss of nitrogen.

"The use of bedding material free from decomposable organic matter is a means of protection against loss of nitrogen."

Commercial fertilizers (*Kentucky Sta. Bul. 79, pp. 159-197*).—Analyses and valuations are reported of 38 samples of fertilizers analyzed under the old fertilizer law and 67 samples inspected under the new law (E. S. R., 10, p. 336), with notes on valuation and selection of fertilizers, and extracts from the fertilizer law of the State.

Fertilizer inspection, C. D. WOODS (*Maine Sta. Bul. 50, pp. 8*).—Tabulated analyses of 142 manufacturers' samples of fertilizers licensed before March 8, 1899, with a summary of the chief provisions of the State fertilizer law.

Analyses of fertilizers, C. A. GOESSMAN (*Massachusetts Hatch Sta. Bul. 59, pp. 14*).—This bulletin gives a schedule of trade values of fertilizing materials in 1899 and analyses of 106 samples of fertilizing materials, including mixed fertilizers, wood ashes, limekiln ashes, marl, muriate of potash, sulphate of potash and magnesia, nitrate of soda, dried blood, meat and bone, fine ground bone, acid phosphate, bone ash, liquid fertilizer, plant food in tablet form, velvet beans, tobacco dust, damaged grain, water extract of dry forest leaves, and cotton-seed meal.

The inspection of fertilizers in 1898, F. W. MORSE (*New Hampshire Sta. Bul. 61, pp. 28*).—Analyses of 64 brands of fertilizers inspected in cooperation with the State board of agriculture are reported.

Analyses of licensed commercial fertilizers, 1899, F. W. WOLL and A. VIVIAN (*Wisconsin Sta. Bul. 73, pp. 10*).—The bulletin includes explanations of terms, notes on valuation, analyses of 5 samples of fertilizers, and the text of the fertilizer law of Wisconsin.

Sale of commercial or artificial fertilizers in South Australia, W. L. SUMMERS (*Jour. Agr. and Ind., South Australia, 2 (1899), No. 6, pp. 499, 500*).—The provisions of the Fertilizers Act Amendment Act of 1898 and the Fertilizers Act of 1894 are noted.

Fertilizers, E. HOTTER (*Düngerslehre. Graz: Landes-Versuchsstation, 1898, pp. 89*).—A brief general treatise on the nature, management, and use of manures and fertilizers.

Experiments in fertilizing irrigated meadows, M. ZECCHINI and R. NUVOLI (*Staz. Sper. Agr. Ital., 32 (1899), No. 1, pp. 15–32*).

The use of lees and marc of grapes as fertilizers, E. CHUARD (*Chron. Agr. Canton Vaud, 12 (1899), No. 9, pp. 209–211*).

The situation of the nitrate of soda industry of Chile, MAIZIÈRES (*L'Engrais, 14 (1899), Nos. 17, pp. 395–397; 18, pp. 420, 421*).

A study of the assimilability of the fertilizing constituents in various types of arable soils in the Department of Aisne, France, L. GAILLOT (*Bul. Sta. Agron. Aisne, 1898, pp. 30–41*).—An account is given of experiments on sugar beets with different combinations of fertilizers on 7 typical soils in earthenware pots holding 100 kg. of soil.

FIELD CROPS.

Fertilizer, culture, and variety experiments on cotton, R. J. REDDING (*Georgia Sta. Bul. 43, pp. 253–288*).—This is in continuation of work previously reported (E. S. R., 10, p. 139). Among 30 varieties of cotton African "Limbless," Lee Improved, Christopher Improved, Hawkins Prolific, Nancy Hanks, Russell Big Boll, Texas Oak, and Mascot, in the order given, rank first in the value of lint and seed produced. Russell Big Boll produced the largest yield of seed, Texas Oak the largest percentage of lint, and Mascot with King Improved ranked first in earliness. From the results of 5 years' work it is concluded that large bolls, large seed, and a high percentage of lint are closely connected with a high value of the total product.

The seed of an early and a late variety of equal productiveness mixed and planted together gave a better yield than when each variety was grown separately. The object of the experiment was to determine whether the ripening season could be lengthened and thus the capacity of the soil utilized to a fuller extent.

This season planting cotton 1 ft. apart in rows 4 ft. apart gave the best results. The average results for 8 years are also in favor of this distance. Varying the distance between plants in the row and the intervals between rows confirm the results of previous years (E. S. R., 10, p. 139).

Cotton-seed meal as a source of nitrogen for cotton was a little more effective than dried blood, but slightly inferior to nitrate of soda. Plats which received all the fertilizer application before planting gave an average yield of 1,407 lbs. of seed cotton per acre, while those on which one-tenth of the application had been applied in the furrow at the time of planting yielded on an average 1,389 lbs. per acre. The results from the general fertilizer tests were inconclusive.

Popular notes on the work of the station, rotation of crops, and the application of fertilizers are appended.

Experiments with cotton, 1898, J. F. DUGGAR (*Alabama College Sta. Bul. 101, pp. 19*).—These experiments comprise variety, fertilizer, and culture tests. Similar work has been previously reported (E. S. R., 10, p. 37).

Of 14 varieties of cotton tested, 9 yielded over 300 lbs. of lint per acre. The most prolific varieties were Russell Big Boll, Deering, Peterkin, and Smith Improved, which yielded 382, 341, 339, and 339 lbs. of lint per acre, respectively. Texas Oak produced the largest percentage of lint and Smith Improved stood first in earliness.

In the fertilizer test cotton-seed meal, acid phosphate, and kainit at the rate of 200, 240, and 200 lbs. per acre, respectively, were applied singly and in different combinations. The results show an average increase of 206 lbs. per acre in the yield of seed cotton with cotton-seed meal, 168 lbs. with acid phosphate, and 230 lbs. with kainit. This experiment was conducted on a gray sandy soil, and all fertilizers yielded a profit. Applying all the fertilizer in the center furrow gave better results than applying two-thirds or all of it in the two listing furrows. A comparison of rotten cotton seed, cotton-seed meal, and nitrate of soda gave inconclusive results.

An experiment was made with potash fertilizers to determine their effectiveness in decreasing the black rust of cotton. It was shown that the use of 50 lbs. of muriate of potash and 200 lbs. of kainit per acre, supplying equal quantities of potash, were equally effective. One hundred pounds of kainit per acre reduced the amount of rust, but the application of 60 lbs. was less effective in causing the plants to retain their leaves.

Subsoiling late in February failed to increase the yield.

Cooperative fertilizer experiments with cotton in 1898, J. F. DUGGAR (*Alabama College Sta. Bul. 102, pp. 23–94*).—These experiments are in continuation of work formerly reported (E. S. R., 10, p. 431). Of the soil tests made this season in 41 localities of the State, 30 gave conclusive results, and these are discussed at some length and tabulated in detail. The inconclusive experiments are considered briefly. The fertilizer applications were the same as the year before, namely, 200 lbs. of cotton-seed meal, 240 lbs. of acid phosphate, and 100 or 200 lbs. of kainit, applied singly, in twos, and all three together.

Acid phosphate was found effective on a greater number of soils than the other fertilizing materials when applied alone. As in the previous year, the application of 200 lbs. of cotton-seed meal, 240 lbs. of acid phosphate, and 100 lbs. of kainit per acre gave the best financial results in the greater number of localities. The two complete fertilizer applications increased the yield of seed cotton 392 and 435 lbs. per acre, the application containing 200 lbs. of kainit giving the smaller increase. Acid phosphate and cotton-seed meal applied together gave an average increase of 339 lbs. of seed cotton per acre, and the increase of other applications ranged from 113 to 287 lbs. per acre.

Conclusions as to the fertilizer requirements for cotton on different soils in various parts of the State are drawn from the results, and fertilizer applications are suggested.

Seeding grass lands with vs. without a nurse crop, F. W. RANE, (*New Hampshire Sta. Bul. 59, pp. 183–187, fig. 1*).—In the spring of 1897 a mixture of 5 lbs. of alsike clover, 7 lbs. of red clover, 5 lbs. of red top, and 12 lbs. of timothy per acre was sown with and without a nurse crop. Barley was used as the nurse crop and was sown at the rate of 3 pecks per acre. The first season the crop grown with barley gave the best returns, but when the yields of two seasons were taken together, the difference was not so marked. The excess in yield of hay for the two seasons, in favor of the crop grown with barley, was 3,662 lbs. The author believes that in general for New Hampshire conditions it is advisable to sow grass seed with a nurse crop. A similar experiment has been previously reported (E. S. R., 10, p. 429).

Field experiments, J. A. MURRAY and T. H. MIDDLETON (*Agr. Dept., Univ. Col. Wales, Aberystwyth, 1898, pp. 42*).—The experiments here reported were comparative tests with fertilizers, and the results are tabulated. From the results on grass land it is concluded that nitrogenous manures, when used alone, are detrimental to the fertility of the soil and the quality of the grass. An application of 3 cwt. of basic slag and 2 cwt. of nitrate of soda per acre is considered a profitable dressing. As compared with the application of 6 cwt. per acre, 10 cwt. of basic slag gave an increase in the yield of hay proportional to the extra quantity of fertilizer applied.

The chlorid and sulphate of calcium, potassium, and sodium were used in connection with superphosphate as fertilizers for mangel-wurzels. Calcium sulphate produced no effect, while the chlorid materially reduced the yield. The potash and sodium salts increased the yield. Sodium sulphate gave better yields than sodium chlorid. Asparagus plants were benefited by an application of sodium chlorid, and to a still greater extent by an application of sodium sulphate. Common salt proved injurious to grass when applied in quantities which were not harmful to mangel-wurzels.

The results of an experiment on the relation of certain fertilizers to the yield of meadow hay showed that on the average nitrate of soda slightly decreased the crop; that superphosphate of lime, on the average, yielded a profitable increase, and that the use of kainit gave large and profitable returns. In conjunction with nitrate of soda and in the absence of potash fertilizers, lime gave good results; but on the average it decreased the yield of hay. It is recommended to apply 2 cwt. of basic slag in the fall and 1 cwt. superphosphate and 4 cwt. of kainit in the spring as a fertilizer for meadows.

Basic slag as a fertilizer in hay farming, A. T. NEALE (*Delaware Sta. Bul. 43, pp. 19–24*).—This article is a discussion of the advantages of basic slag as a fertilizer and the obstacles in the way of its general introduction. The experimental work with basic slag at several experiment stations is briefly reviewed, and the results of experiments at the station are reported.

Grass was sown with rye in 1897 and the plats were fertilized with bone, acid phosphate, and basic slag, furnishing 72, 42, and 54 lbs. of phosphoric acid per 300 lbs., respectively. The results are given in the following table:

Yields of rye and hay fertilized with different forms of phosphoric acid.

Kind of fertilizer.	Amount applied per acre.	Yield of rye per acre in 1897.		Yield of hay per acre in 1898.
		Grain.	Straw.	
	Pounds.	*Bushels.*	*Pounds.*	*Pounds.*
Bone and acid phosphate	300	21.4	2,414	5 383
Acid phosphate	300	22.8	2,661	4,788
Basic slag	400	17.9	1,922	5,391
None		18.2	2,083	4,605
Basic slag	800	17.0	2,100	4,644
Ground bone	300	16.9	1,543	4,992
Basic slag and acid phosphate	300	20.4	2,213	5,171

It is concluded that the acid phosphate had been exhausted by the grain, while bone and slag still had a good effect on the succeeding hay crop.

Experiments with rape, W. GRASHOFF (*Jour. Landw., 47 (1899), No. 1, pp. 85–90*).—Experiments were made to determine the influence of soil and fertilization on the fat content of rape seed. The method of conducting the experiments is described, and the results are tabulated. The author concludes, from the results obtained, that the character of the soil and the fertilizer have a marked influence on the fat content. The difference of fat content of seed grown on diluvial sand and "kohlenkeuper" was 5 per cent. The soil of the "kohlenkeuper" division (upper division of the Triassic) produced the largest yields and the highest fat content in the seed. Fertilizing with phosphoric acid increased the fat content over 2 per cent. The nitrogen content and the fat content of the seed seemed to be in direct relation to each other. The seed produced on "kohlenkeuper" showed the highest fat content and the lowest nitrogen content, and the seed obtained from soil fertilized with nitrogenous fertilizers was richest in nitrogen and poorest in fat.

Sorghum in 1898, C. L. PENNY (*Delaware Sta. Bul. 44, pp. 16*).—This is in continuation of work formerly reported (E. S. R., 10, p. 345).

The experiments were cooperative, and the results with the several crops at different times during the season are tabulated in detail. The "Brix method" and "glucose method" for determining the available sugar are compared.

The varieties of cane grown were Amber, McLean, and Orange. The percentage of sugar in the juice of Amber cane ranged from 12.89 to 17 per cent, with an average of 15.41 per cent for seven different crops. Only one crop each of McLean and Orange were grown, and in these the percentage of sugar in the juice was 14.79 and 11.61 per cent, respectively.

The crop of Amber cane which gave the best yield of available sugar per acre contained the least available sugar per ton of cane, while a crop which was one of the lowest in available sugar per acre stood next to the highest in available sugar per ton. "It is evident enough that the stand of cane is of prime importance. A shortage in that can not be supplemented by any richness whatever in sugar content."

Comparing the stalks of the crop of the previous year from the seed of which this season's crop was grown, it is shown that while the selection was made on the basis of the weight of the parent stalk the stalks of this season are practically equal in weight, and that the percentage of solids and of sugar in the juice is lower than in the parent stalk.

A few experiments were made to study the effects of blading the cane. The stalks were bladed from 10 to 17 days before cutting, and the results obtained show an increase of approximately 15 per cent of sugar in the juice, 4 per cent in the purity, 7 per cent in the tonnage of cane per acre, and 34 per cent in the available sugar per acre.

Sugar-beet investigations in 1898, A. D. SELBY (*Ohio Sta. Bul. 99, pp. 77-122, fig. 1*).—These investigations are in continuation of the previous year's work (E. S. R., 10, p. 346). The bulletin contains the detailed results of cooperative sugar-beet experiments for 1898, and gives complete directions for the culture of sugar beets, short notes on diseases and insects attacking the sugar-beet, and tabular statements of the weather conditions for the growing season.

The results of analyses of 498 samples grown throughout the State show an average weight per beet of 22.7 oz., and an average sugar content in the beet of 11.4 per cent, with a purity of 77.9. The results are not as satisfactory as those of 1897, and it is believed that insect and fungus injuries caused the decline. The average results are in favor of the northern and northeastern parts of the State, in which the most favorable theoretical conditions prevail.

Conditions pertaining to beet-sugar factories are discussed and analyses of certain water and limestone supplies of the State are given in tables.

Sugar beets in South Dakota for the year 1898, J. H. SHEPARD and W. H. KNOX (*South Dakota Sta. Bul. 62, pp. 35–82, figs. 10, pls. 6*).—Twenty cooperative experiments in the culture of sugar beets were conducted in five different localities of the State to determine the tonnage of beets per acre that might be obtained and the cost of production. The bulletin contains meteorological data, directions for sugar-beet culture, and the reports on the results in the different localities.

Vilmorin and Kleinwanzlebener were the varieties grown in these tests. The average results for all experiments were as follows: Sugar in the juice, 18.44 per cent; purity, 88.91 per cent; yield per acre, 16.30 tons; cost of production per acre, $37.64. The percentage of sugar ranged from 16.40 to 21.20 per cent, the purity from 79.70 to 94 per cent, the yield per acre from 6.50 to 32.90 tons, and the cost per acre from $19.10 to $53.77. In six instances the yield per acre was less than 12 tons. The small yields were caused mainly by late planting and insect attacks.

Sugar-beet investigations in Wisconsin during 1898, F. W. WOLL (*Wisconsin Sta. Bul. 71, pp. 34, fig. 1*).—The investigations in sugar-beet culture were conducted in 1898 as in the previous year (E. S. R., 10, p. 39). This bulletin reports the results of analyses of beets grown by farmers in different parts of the State and considers the experiment in sugar-beet culture made at the station.

The samples analyzed numbered 253, and they were furnished by 121 farmers in 56 different counties. They were taken at two different periods, 151 at harvesting time and 102 about one month before. The early samples had an average sugar content in the juice of 14.84 per cent with a purity of 78.8 per cent, and the samples taken later contained 15.36 per cent sugar in the juice, with a purity of 78 per cent. The average weight of the beets in the samples was 1.4 lbs. The average yield per acre was estimated at 12.6 tons.

Sugar-beet experiments have been carried on in the State during 5 seasons since 1890, and the analyses of 2,537 samples obtained from this work, not including samples grown at the station, showed an average of 13.59 per cent of sugar in the juice, and an average coefficient of purity of 77.7. The average yield of beets per acre for the samples grown during the 5 seasons is given as 15 tons.

The use of lime as a fertilizer for beets produced an increase in the sugar content in 6 cases, and a decrease in 2 cases, while in 1 instance no difference was noticeable. The average results were in favor of liming.

The average cost of growing an acre of beets as reported by 36 growers was $28.80.

A test of 15 varieties was made at the station on 2 fields of different grades of fertility. The less fertile of the 2 fields was fertilized with 360 lbs. of sulphate of potash, 360 lbs. of dissolved bone, and 400 lbs. of nitrate of soda per acre. The unfertilized field yielded 19.8 tons and the fertilized field 17.5 tons of beets per acre, and in most cases the sugar content of the beets from the unfertilized field was the greater. Of the varieties tested by the station, French Very Rich, and Pitzschke

Elite gave the best results. Analyses showed that the sugar content of varieties grown by outside parties decreased in the following order: Kleinwanzleben, Zeringen, French Very Rich, Kleinwanzleben Improved, Vilmorin Improved, and Kleinwanzleben Nebraska.

Fertilizer experiments on marshy soil were continued. This season the soil was fertilized with 130 lbs. of potash, 65 lbs. of phosphoric acid, 56 lbs. of nitrogen, and 1 ton of lime per acre, applied in different combinations. The fertilizers were applied in the form of sulphate, muriate, and silicate of potash, double carbonate of magnesia and potash, superphosphate, and nitrate of soda. The yield obtained was 13.65 tons of beets and a little over 2 tons of sugar per acre. The richest beets contained 16 per cent of sugar and were grown on a plat fertilized with bone phosphate and muriate of potash. The plat which had received nitrate of soda, potassium sulphate, and bone phosphate produced beets with a sugar content of 15.9 per cent. On most of the plats the increase in tonnage and sugar was obtained at a cost below that of the fertilizers applied. The author concludes that with good culture and proper fertilization, beets with a sugar content of 4 per cent above the factory standard can be grown on soil that contains almost 20 per cent of organic matter.

Experiences and results in breeding new varieties of plants, O. PITSCH (*Deut. Landw. Presse, 26 (1899), Nos. 21, pp. 221, 222; 23, pp. 249, 250; 25, pp. 273, 274; 30, p. 335; 31, p. 350; 34, pp. 383, 384*).—Notes on the results of breeding new varieties of potatoes, wheat, and barley.

Report of the Cawnpore Experimental Farm for the Kharif and Rabi seasons of 1897–98, S. M. HADI (*Allahabad, 1898, pp. 34, map 1*).—This is a report of the crops grown at this farm in British India during the fall of 1897 and the spring of 1898. The experiments consisted of fertilizer, variety, culture, and implement tests.

The results obtained indicate that indigo refuse, especially when old, is a better fertilizer than green crops plowed under. American and other foreign varieties of cotton were found superior to the native varieties, but it is believed that exotic cottons are more apt to deteriorate than other varieties. American wheat and Canadian oats were grown with good success.

The development of the production of fodder beet seed, H. K. GUNTHER, (*Fühling's Landw. Ztg., 48 (1899), Nos. 10, pp. 394–396; 11, pp. 414–417*).—A popular article discussing the improvement of the field beet. Some historical data are given and a number of varieties described.

Coffee in Porto Rico, A. C. HANSARD (*Planting Opinion, 4 (1899), No. 16, pp. 295–297*).—This article describes in a popular way how coffee culture is carried on in Porto Rico.

Coffee in Queensland (*Planting Opinion, 4 (1899), No. 19, pp. 351, 352*).—A popular note on the cultivation of coffee.

Further experience in the culture of corn for grain, F. VON LOCHOW (*Mitt. Deut. Landw. Gesell., 14 (1899), No. 8, pp. 106–109*).—This is a report on a test of 44 varieties of corn, including many American varieties. The results and the descriptions of varieties are given in tabular form.

The story of the cotton plant, F. WILKINSON (*New York: D. Appleton & Co., 1899, pp. 191, figs. 38*).—This is one of The Library of Useful Stories published by this firm. The topics treated are origin, growth, and descriptions of the chief cultivated species; cotton-plant pests and other injurious agents; cultivation of cotton in different countries; the microscope and cotton fiber; plantation life, and the early cleaning processes, including picking, ginning, and baling; manipulation of cotton in opening, scutching, carding, drawing, and fly frames; early attempts at spinning, and early inventors; further developments by Arkwright and Crompton; the modern spinning mule; other processes in the spinning of cotton; and destination of the spun yarn.

Cowpeas, J. G. SMITH (*U. S. Dept. Agr., Farmers' Bul. 89, pp. 16, fig. 1*).—This publication is a popular bulletin discussing the value and use of the cowpea for soil renovation, forage, and silage. Complete notes are given on the cultivation and harvesting of the crop and the method of harvesting the seed. Varieties and the variations occurring when grown under different climatic conditions are described, and the feeding value of the crop is pointed out by comparison with that of other common forage crops.

Sowing crimson clover in different months, F. W. RANE (*New Hampshire Sta. Bul. 59, pp. 188, 189, fig. 1*).—Crimson clover was sown June 29, July 31, August 31, October 10, and November 7. The plants sown early attained a fair size, but only a few withstood the winter. A mixture of medium red and alsike clover is considered more valuable than crimson clover for that climate. Tests with crimson clover have been reported in a former bulletin (E. S. R., 8, p. 586).

Russian flaxseed in its relation to German flax culture (*Deut. Landw. Presse, 26 (1899), Nos. 32, pp. 360, 361; 33, p. 373*).—A popular article discussing at some length the kinds of flaxseed produced in various parts of Russia and their importance to flax culture in Germany.

Drilling grain (*Landw. Wchnbl. Schleswig-Holstein, 49 (1899), Nos. 15, pp. 277-280; 16, pp. 295-298*).—This article is a popular presentation of the subject, pointing out the advantages of the use of the drill. The opinions of several investigators on the subject are given.

How shall we prevent the lodging of grain? SÄUBERLICH (*Fühling's Landw. Ztg., 48 (1899), No. 9, pp. 336-342*).—This article discusses in a popular way how to fertilize, cultivate, and rotate the crops in order to prevent the lodging of grain.

Top-dressing grass lands, F. W. RANE (*New Hampshire Sta. Bul. 59, pp. 187, 188*).—An acre of grass land was dressed in the spring with 100 lbs. of nitrate of soda, 100 lbs. of dissolved boneblack, and 50 lbs. of muriate of potash, while another acre of grass land served as a check plat. The first season the fertilized plat yielded 910 lbs. and the second season 820 lbs. of hay more than the unfertilized plat.

Pastures and grasses suitable for making hay, P. H. MELL (*Alabama College Sta. Bul. 100, pp. 318, 319*).—A note is given on the preparation of land for the establishment of pastures, and the different pasture grasses recommended are briefly described.

Hop growing on irrigated lands, J. SHOMAKER (*Amer. Farm. Mag., 5 (1899), No. 5, pp. 353-356, figs. 4*).—A popular article on hop growing in the Yakima Valley, Washington.

Lime as a fertilizer for hops (*Sächs. Landw. Ztschr., n. ser., 21 (1899), No. 14, p. 155*).—A note giving the results of experiments made by S. Hannamann and L. Kourinsky at Postelberg, Austria. Hops were grown on a soil poor in lime. An application of 3,400 kg. of lime per hectare increased the crop 402.6 kg.

Cultivation of oats in the Rhine Province and the varieties best adapted to the region, OSTERSPEY (*Ztschr. Landw. Ver. Rheinpreussen, 16 (1899), No. 14, pp. 123-125*).—A popular discussion on the cultivation of oats, giving a comparison of 7 varieties tested for several years.

Extra early potatoes, W. E. HALL (*Gardening, 7 (1899), No. 157, pp. 202, 203*).—Uncut potato tubers were set in shallow boxes with the blossom ends up and three-fourths covered with sand. The boxes were placed in rather subdued light at a temperature of 50 to 60°. Twenty-seven days later the tubers were carefully removed from the sand and placed in the field in the same position which they had occupied in the box. This lot matured from 7 to 10 days earlier than another lot planted directly from the bin. The first lot was also several days earlier than a third lot similarly treated, with the exception that it was not put in sand.

Report on F. Heine's comparative variety tests with potatoes, in 1898, at Kloster Hadmersleben, K. KITTLAUSZ (*Deut. Landw. Presse, 26 (1899), No. 30, pp. 339–342*).—A report on the results of a comparative test with over 100 varieties of potatoes. The results are given in tables and discussed at some length.

Sugar cane grown in soils containing salts, H. WINTER (*Arch. Java Suikerind., 1898, July 1; abs. in Sugar Cane, 30 (1898), No. 350, pp. 482, 483*).—This article treats of the effect of salts in the soil on the composition of cane juice.

The influence of the arrowing of cane on its saccharine content, H. C. PRINSEN-GEERLIGS (*Sugar Cane, 30 (1898), Nos. 346, pp. 258, 259; 349, p. 395*).—From the experiments reported it appears that the process of arrowing or flowering of the cane only very slightly diminishes its saccharine content.

On some constituents of the sugar cane, M. RACIBORSKI (*Sugar Cane, 30 (1898), No. 350, pp. 474–478*).—This article is a discussion of a chemical study of sugar cane. It is concluded from the results that sugar cane contains a chemical substance having the property of oxidizing guaiacum, and which exercises the same function in connection with the respiration of plants as hæmoglobin and hæmocyanin in that of animals. The author proposes to name the substance "leptomin."

A review of the methods of purchasing cane, whether by test or otherwise, W. C. STUBBS (*Audubon Park, New Orleans, La., 1899, pp. 12*).—A paper read before the Louisiana Sugar Planters' Association, in which the equitable division of profits between the grower and the manufacturer, the method of predicating an output of sugar from an analysis of the cane, and the methods of sampling cane are discussed.

Experiments with sweet potatoes, G. W. CARVER (*Alabama Tuskegee Sta. Bul. 2, pp. 15, figs. 5*).—This bulletin reports on the results of fertilizer tests with sweet potatoes and gives general directions for the culture of the crop. On account of adverse conditions the experiments were not conclusive.

Tobacco culture in the German colony of New Guinea (*Deut. Landw. Presse, 26 (1899), No. 32, pp. 359, 360, figs. 8*).—A brief popular description of tobacco culture as it is carried on in the German colony of New Guinea.

HORTICULTURE.

Green corn under glass, F. W. RANE (*New Hampshire Sta. Bul. 60, pp. 16, figs. 7*).—The author believes he has demonstrated that the forcing of green corn, an industry as yet practically unknown, may be profitably undertaken.

The forcing house should have 3½ to 8 ft. clear space above the bed, according to the variety to be grown, and should be capable of maintaining a temperature of 75° or more during the day and not lower than 60°, or better 70°, at night. Shade is not necessary. Any fertile greenhouse soil may be used.

Much time may be gained by soaking the seed and planting in pots, taking care to transplant, however, before the plants become root bound. Experiments indicate that the rows should be 18 inches apart, and the plants 9 inches in the row. The only training found necessary was the removal of suckers. One-half the tassels may also be removed without injuriously interfering with pollination. More strength is thus thrown into the ear. In these experiments the crop was matured in about 88 days.

"By keeping a high temperature and devoting a whole house to corn, it is believed that this crop could be harvested in a much shorter period. It usually takes from 12 to 15 weeks to mature lettuce from seed. While, of course, corn requires more space in the house, it is readily seen that it can be grown with as quick results; also, were we able to produce 2 ears per plant, an ear of corn would represent the product from about the same space that a head of lettuce occupies."

The varieties tested were Early Minnesota, Crosby Early, White Cob, First of All, Early Fordhook, and Adams Extra Early. Notes are given on each.

"The varieties found to do very well were Crosby Early, First of All, and White Cob. The White Cob was the earliest, but Crosby Early was thought to be more desirable. Other varieties we believe well adapted to forcing are the following: Extra Early Beverly, Eastman Early, and Early Fordhook. From our experience with the above-named varieties, I believe we can depend upon almost any variety that is desirable out of doors to be equally valuable under glass. Moreover, if proper heat, moisture, and a rich soil be given, a crop will mature in the greenhouse in a shorter time than in the garden. In the forcing house, with the exception of light, we can have almost ideal conditions. With the use of the electric light, even the cloudy weather of winter can be overcome to a degree."

Until the corn is 6 weeks old, the space between the rows may be utilized for catch crops. Radish and Grand Rapids lettuce gave best results as such.

The only pests to contend with are rats and mice. These dig up the seed and rats also attack the maturer corn, eating the more succulent parts, especially the ears. They should be exterminated before planting the crop.

Forcing pole beans under glass, F. W. RANE (*New Hampshire Sta. Bul. 62, pp. 29–36, figs. 2*).—The author has forced pole beans under glass successfully. The greenhouse requirements and methods of procedure are about the same as in the case of green corn (p. 147). Plants were trained both on poles and string trellises. The latter method gave better results. The bean is self-fertile, hence does not need to be cross pollinated. The time from germination to maturity ranged from 54 to 62 days. Beans planted in hills, 18 in. apart each way, with 2 to 3 plants to the hill, bore well. Practically no trouble from insects or fungi attended the growing of the crop. Comparative trials were made with dwarf and pole beans under glass. The fruiting period was divided into 8 pickings. The larger part of the dwarf beans were gathered in the first 3 pickings. "The pole beans are much more productive than the dwarf varieties. Not only is this true in the first 3 pickings, but they continue to yield good returns for a much longer period. The time from germination to maturity is a trifle longer perhaps with pole beans than with the dwarf varieties."

Some peach notes, H. N. STARNES (*Georgia Sta. Bul. 42, pp. 207–220; 230–250d, figs. 5, pl. 1*).—The various operations of peach culture are reviewed in considerable detail, and descriptive notes are given on 95 varieties of peaches. The following fertilizer for bearing trees is recommended: Three pounds high-grade acid phosphate, 1 lb. muriate of potash, and 1 lb. cotton-seed meal.

Tests were made to determine the resistance of the foliage of the

Elberta peach to various strengths of standard insecticides and fungicides. The results indicate that normal Bordeaux mixture is liable to injure the foliage of this variety, but when diluted to ½ or ¾ normal strength it may be used with safety.

Tests were made to determine the relative resistance of different varieties to normal Bordeaux mixture. Varieties were found to differ greatly in this respect and extremes were widely separated. The 69 varieties tested are grouped as follows:

"*Varieties extremely resistant.*—Bishop, Clifton Cling, Crimson Beauty, Crosby, Florence, Josephine, Mamie Ross, Mountain Rose, Picquett Late, Plant Seedling, Sallie Worrell, Triumph, and Wallace.

"*Varieties quite resistant.*—Admiral Dewey, Albert Sidney, Carman, Champion, Crawford Early, Early Tillotson, Fleitas St. John, Halo Early, Husted No. 50, Husted No. 52, Husted No. 51, Husted Extra Early, Lady Ingold, Miss Lola, Muir, October Beauty, Pace, Reeve Favorite, R. E. Lee, and Spottswood.

"*Varieties moderately resistant.*—Globe, Hill Chili, Robert, Sneed, Sylphide.

"*Varieties easily affected.*—Alexander, Baldwin Late, Bokhara No. 3, Bustian October, Chinese Cling, Elberta, Emma, Heath Cling, Hoover Heath, Husted No. 53, Lonoke, Oldmixon Free, Susquehanna, Waddell, and Wheatland.

"*Varieties quite easily affected.*—Chinese Free, Connecticut, Crawford Late, Early Michigan, Indian Blood, Stonewall Jackson, and Stump the World.

"*Varieties extremely sensitive.*—Diamond, Henrietta, Oldmixon Cling, Old Newington Cling, Pallas, Salway, Smock, and Thurber."

A preliminary account is given of a fertilizer test made to observe, through a series of years, the effect of radically different fertilizers on peaches. The fertilizers used were acid phosphate, muriate of potash, kainit, and cotton-seed meal alone and in various mixtures. An application of 20 lbs. of kainit per tree proved fatal. The most promising mixture consisted of 4 lbs. of acid phosphate and 1 lb. of muriate of potash per tree.

Persimmons, R. L. WATTS (*Tennessee Sta. Bul. Vol. XI, No. 1, pp. 191–219, figs. 10*).—This bulletin is a horticultural treatise on the persimmon, both American and Japanese, in Tennessee. The distribution of each group in the United States, and the botanical characters are discussed, and the most important varieties of each enumerated and described.

The American persimmon.—The American persimmon is considered a promising fruit commercially. The very limited culture which it now receives is profitable, and the supply is not equal to the demand. These conditions have been an incentive during the last few years to the amelioration of the wild types. The species are very variable and offer inviting opportunities to the plant breeder.

"We should have earlier ripening varieties. A persimmon one-third larger in size than any thus far introduced would be a valuable acquisition. The numerous large seeds found in most persimmons are objectionable; and one purpose in creating new varieties should be to reduce the number of seeds. A seedless variety comparatively free from astringency, as large as some of the Japanese class and ripening before the advent of frost in most sections of the South, would be one of the most valuable fruits that have ever been introduced."

The various topics of soil, location, cultivation, and propagation are discussed in detail. A large supply of nitrogenous matter in the soil is not necessary for the best development of tree and fruit, but a liberal supply of phosphoric acid, and particularly potash, is essential to secure the best results. It is believed that excessive cultivation is one cause of premature dropping of fruit in the Japanese species.

The Japanese persimmon.—Historical notes are given on the Japanese persimmon in America. On its own roots and in its native habitat the tree is of medium size. It is considered probable that in this country when worked on the native persimmon it will attain to a much greater development.

Fruits of the Japanese persimmon vary greatly in size, shape, smoothness, color of skin, and flesh. With the color of the flesh are correlated several characters or qualities of fruit, as astringency, consistency, and number of seeds.

The culture of the Japanese persimmon is practically the same as that of the native species. Three methods are given for obtaining Japanese persimmons of home production: (1) Cleft grafting the root of the common persimmon in the nursery row. This is the best method when a number of trees are wanted for orchard planting. (2) Cleft grafting small wild trees of the common persimmon; and (3) top working old trees of the common persimmon.

The Japanese persimmon requires but little pruning. Thinning is, however, necessary, if a considerable quantity of the fruit does not fall prematurely, in order to secure larger and finer fruits, uniform annual crops, and to promote longevity. It is the belief of one large grower that in the South overbearing kills 60 per cent of all trees that die from various causes.

Notes on the chemistry of the persimmon, J. B. McBryde (*Tennessee Sta. Bul. Vol. XI, No. 1, pp. 220–223*).—Analyses were made of both wild and cultivated persimmons, the results of which are shown in the following table:

Composition of persimmons.

	Average weight of fruit.	Seed in fruit.	Sugar.		Total acid in pulp.	Proximate analysis of pulp.			
			In pulp.	In fruit.		Water.	Crude protein.	Fats and carbohydrates.	Crude ash.
	Gms.	*Per cent.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
No. 1. Hachiya	180.0	Seedless	16.83	16.83	0.13	71.77	0.93	26.42	0.88
No. 2. Tsuru	194.0	....do ...	15.67	15.67	.16	73.45	.74	25.16	.64
No. 3. Hiyakume	175.0	1.71	17.83	17.52	.13	70.17	1.10	27.58	1.15
No. 4. Yemor	150.0	Seedless	15.99	15.99	.10	76.26	.45	22.69	.60
No. 5. Japanese graft on native	103.0	... do ...	16.55	16.55	.11	75.00	.42	24.13	.45
No. 6. Wild	6.6	15.5	18.72	15.74	.26	66.78	.64	31.32	1.26
No. 7. Wild	8.9	17.5	23.50	18.19	.15	57.24	.58	41.34	.84
No. 8. Wild	9.2	16.3	23.48	19.35	.17	57.25	.48	40.99	1.28

In a comparison of these analyses with others already reported (E. S. R., 8, pp. 229, 701) it was found "that the wild fruit contains 1¼ per cent more sugar than the cultivated fruit, and, furthermore, that they contain nearly 13 per cent more dry matter. On the other hand, the cultivated fruit is higher in protein. While these figures are, no doubt, correct for the samples so far examined, it will not do to be too hasty in drawing conclusions. . . . The most striking thing shown by these analyses is the large proportion of sugar, which in this fruit is all in the form of glucoses. Thorough tests failed to show a trace of cane sugar."

Small fruits in 1898, E. S. GOFF (*Wisconsin Sta. Bul. 72, pp. 37, figs. 51*).—Notes are given on a considerable number of the newer varieties of strawberries, raspberries, blackberries, currants, and gooseberries, and many of them are figured. The Loganberry, golden mayberry, strawberry-raspberry (*Rubus sorbifolius*), and Japan wineberry (*R. phœnicolasius*) are reported on unfavorably. A comparative study of varieties of currants was made with regard to vigor of growth, productiveness, size of fruit, and percentage of waste in the manufacture of jelly.

An experiment was made of postponing spraying the currant for *Septoria ribis* until after the harvest, thus avoiding smearing the fruit. Sprayed bushes retained their foliage 4 to 6 weeks longer than those not sprayed. Notes are also given on the relative vigor of growth and resistance to Septoria and mildew of different varieties of gooseberries.

Of the varieties of fruits reported in this bulletin the following are considered the most desirable: *Strawberries*—Wm. Belt, Clyde, and Splendid; *raspberries*—for the table, Loudon; for canning, Columbian; *blackberries*—El Dorado; *currants*—Raby Castle; *gooseberries*—Downing.

Small fruits: Culture notes and comparison of varieties, W. J. GREEN (*Ohio Sta. Bul. 98, pp. 61-76*).—In an experiment in soil culture 1 plat of strawberries was hoed and a second was worked with a cultivator just enough to keep down the weeds; a third plat was cultivated at least twice a week when the weather permitted, and always as soon as possible after a fall of rain. Determinations of soil moisture showed that plat 3 held more moisture throughout the season, the excess at times amounting to the equivalent of ½ in. of rain. The rainfall throughout the season was abundant generally.

Varieties differed greatly in the benefit derived from frequent cultivation. Of 3 varieties tested Tennessee Prolific on plat 3 showed an increased yield of 68 per cent over plat 1, while Haverland showed only 10 per cent. The use of a plank clod-crusher in cultivation is recommended for at least half the time rather than a cultivator all the time.

Notes are given on a considerable number of varieties of small fruit.

Kainit as a fertilizer for the grape, J. FARCY (*Prog. Agr. et Vit. (Ed. L'Est), 20 (1899), pp. 348-350*).—Tests were made of kainit as a substitute for sulphate of potash in manuring grapes. Five plats of 100 vines each on light porous soil received the treatments and gave the yields shown in the following table:

Fertilizer experiment with grapes.

Plat.	Fertilizer.	Amount.		Yield.		Density of must.
		Per plat.	Per hectare.	Per plat.	Per hectare.	
		Kg.	*Kg.*	*Kg.*	*Kg.*	°*B.*
1	Kainit	30	900	146.5	4,395	10.50
2	Superphosphate	20	600	196.5	5,895	9.50
3	Check	....	....	165.5	4,965	10.50
4	Kainit Superphosphate	30 20	900 600	148.0	4,440	10.00
5	Kainit Superphosphate Nitrate of soda	30 20 10	900 600 300	165.0	4,950	10.00

The effect of the kainit was plainly detrimental. On plats 4 and 5 the action of the superphosphate, from the use of which the high yield of plat 2 was obtained, was paralyzed by the kainit. The kainit did not appear to have any adverse effect on the density of the must, however, while on the contrary the superphosphate did.

The ill effects of the kainit in this experiment were apparently due to the impurities mixed with the sulphate of potash, chief among which are the chlorids of sodium and magnesium, the latter especially being very injurious. Fortunately magnesium chlorid is very soluble and is not retained by the soil; hence ill effects resulting from the use of kainit may be avoided by applying it early the fall before, giving the winter rains opportunity to wash away the injurious constituent. If this precaution is observed, kainit may be used as a fertilizer for the grape on permeable soils.

Latest facts about grafted roses for winter forcing, A. B. Scott (*Amer. Florist, 11 (1899), No. 558, pp. 817, 818*).—American Beauty, Kaiserin Augusta Victoria, Perle des Jardins, Bride, Bridesmaid, and Liberty roses were grown on their own roots and also grafted on Manetti stocks. All except American Beauty and Perle des Jardins did much better as grafts. The author concludes from his experiments that grafted roses will make strong, vigorous plants much quicker than roses on their own roots. They also produce as many, if not more, flowers, and a larger proportion of the flowers are extra fine. The roots are comparatively free from disease, and thus far in transplanting grafted plants no evidence of eel worms has been discovered. Grafted roses are said to have more vitality than roses on their own roots.

Manetti is considered the most desirable of the different varieties of stocks.

Ringing roses to facilitate propagation by cuttings, Greiner (*Bul. Soc. Cent. Hort. Seine-Inférieure, 2. ser., 2 (1898), No. 6, pp. 380,* *381*).—The stem or branch of the rose is ringed the latter part of July or August, causing the formation of a callus before the cutting is removed in November. Cuttings thus treated strike root much more readily than ordinary cuttings, which can make roots only after having formed a callus. By this method the propagation of varieties which can not be propagated by cuttings except with great difficulty, is rendered simple. Several rings may be made on the same branch by observing the proper distance for cuttings.

Report of the department of horticulture, F. W. RANE (*New Hampshire Sta. Bul. 59, pp. 190–192*).—Notes on commercial fruit culture in New Hampshire in 1898. Short lists of apples, pears, plums, and cherries adapted to the State are given, as reported by growers.

Hybridization, J. H. WILSON (*Amer. Gard., 20 (1899), No. 233, pp. 415–417, figs. 6*).—An historical essay.

Hybridization, G. W. OLIVER (*Amer. Gard., 20 (1899), No. 232, pp. 397–400, figs. 4*).—An essay treating of the history, principles, purpose, and limits of hybridization and sterility of hybrids.

Commercial fruit culture in North America, Y. NYEMETZ (*Promuischlennoe Plodovodstvo va Syevernoi Amerikye. St. Petersburg: I. Kirschbaum, 1899, 2. ed., pp. 388, figs. 223*).—This book is a report of observations made during a journey through the United States. There is a chapter devoted to instruction in horticulture in the United States, and special chapters on the apple, pear, quince, peach, apricot, plum, cherry, grape, small fruits, and garden vegetables.

Some of the more common fungus and insect diseases are mentioned, and the American remedies for fighting them are described.

Types of fruit and their persistence under cultivation, J. CRAIG (*Gardening, 7 (1899), No. 162, pp. 278, 279, figs. 2*).—Especially illustrated by the Borsdorf apple, a variety that has been in cultivation for upward of 400 years. The variety is figured and notes are given on its history and synonymy.

Effect of grafting (*Country Gent., 64 (1899), No. 2416, p. 388; Nat. Nurseryman, 7 (1899), No. 5, p. 48*).—Reports specific cases of modification of height of plant, color and flavor of fruit, maturity, and adaptation to climate and soil, caused by different stocks.

The pruning book, L. H. BAILEY (*New York: The Macmillan Co., 1898, pp. 530, figs. 331*).—A monograph of the pruning and training of plants as applied to American conditions. This work is one of the Garden Craft Series. The first part of the work on fundamentals considers the rationale of pruning and training; the effect of pruning on the vitality of plants; the fruit bud and its position on the branch in various cultivated fruits; and wounds and their treatment. The principles of pruning are concisely stated in the form of twenty rules after the manner of the author's well-known fifteen rules for plant breeding.

The second part of the book on incidentals treats of the details of American horticultural practice. Specific remarks are made on the pruning of the principal cultivated trees and shrubs. Over one-fifth of the entire work is devoted to American grape training.

The root pruning of transplanted apple trees, N. O. BOOTH (*Gardening, 7 (1899) No. 157, pp. 201, 202*).—A criticism of the Stringfellow root pruning method. From tests made to determine to what length the roots of the apple tree should be cut for transplanting, it is concluded that "the injury caused by too close root pruning is one that the trees do not outgrow, if they do not die outright. The heroic pruning advised by our southern neighbor seems to be ill adapted to our conditions. The mortality among our trees is far too great."

At the end of two years' growth, medium rooted trees were considered quite as desirable as long rooted ones. In an experiment to determine the relative importance of the fibrous and larger roots, most of those transplanted trees from which all of the fibrous roots had been removed died. The percentage of trees that survived transplanting was directly proportional to the number of small roots saved. From an experiment in horizontal root pruning, it is concluded that its advantage, if any, is so slight as not to be overcome by the individual variation of the tree.

Root pruning as frost protection, O. C. BUTTERWICK (*Florida Agr., 26 (1899), No. 18, pp. 280, 281*).—As a result of experiments the author believes that pruning lateral feeding roots is advisable, particularly in damp or very rich soil.

Results of the late freeze in the South, W. F. MASSEY (*Florists' Exchange, 11 (1899), No. 18, p. 485*).

Seedsmen's catalogues, new and old, S. B. DICK (*Florists' Exchange, 11 (1899), No. 21, p. 566, figs. 3*).—Comparative notes on the seed industry in England in 1793 and 1899, based on seedsmen's catalogues of those years.

Forcing fruits and vegetables in France from the industrial and commercial points of view, J. M. BUISSON (*Jour. Soc. Nat. Hort. France, Congrès Hort. 1899, pp. 5-15, dgms. 3*).

Truck farming in Florida (*Florida Agr., 26 (1899), No. 20, p. 312*).—Brief notes on the culture of several vegetables. Celery is not banked but wrapped with Florida moss, giving much better results.

The culture of asparagus, J. F. C. DU PRE (*South Carolina Sta. Bul. 38, pp. 10-15*).—Popular notes. For planting, one-year old roots are preferred to older ones. A commercial grower's statement of his methods of culture is appended.

Forcing green corn under glass, F. W. RANE (*Amer. Gard., 20 (1899), No. 219, p. 163, fig. 1*).—The data of this article are contained in the author's bulletin on the same subject (p. 116).

Raising Bermuda onions (*Jour. Jamaica Agr. Soc., 3 (1899), No. 5, pp. 240-243*)

Cold storage onions (*Pacific Rural Press, 57 (1899), No. 21, p. 321*).—Experiments in California have shown that it is perfectly feasible to overcome the sprouting propensity of the onion by cold storage. The bulbs were kept all winter in fine condition.

Grafting of muskmelon (*Jardin, 1898, Dec. 20, p. 372; Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), Feb., pp. 112, 113*).—A French experimenter has attempted to graft the muskmelon (*Cucumis melo*) on Cucurbitaceæ, especially of different genera, making use of *Cucurbita perennis*, *Bryonia dioica*, and *Thladiantha dubia*, all of which have perennial, fleshy roots. Grafts on the first species lived and grew, but on the last two have not yet succeeded. The experiments are to be continued.

Cultivation of the vanilla bean in Mexico (*Sci. Amer. Sup., 47 (1899) No. 1221, p. 19580*).—Notes on location, culture, and profits of the business.

Edible mushrooms, H. H. LAMSON (*New Hampshire Sta. Bul. 59, pp. 193-199, figs. 3*).—The author describes in a popular manner the general characteristics of edible mushrooms, and quotes from a publication of this Department directions for guidance in collecting them. He assigns a high food value to mushrooms. (See U. S. Dept. Agr., Farmers' Bulletin 79.)

Michigan fruit list, L. R. TAFT (*Michigan Sta. Bul. 168, pp. 127-139*).—Popular hints are given on selection of trees, care of trees when received from the nursery, planting, and pruning. Lists of varieties of apples, pears, plums, peaches, cherries, grapes, currants, gooseberries, raspberries, blackberries, and strawberries adapted to different sections of the State are suggested for home use and marketing. Notes are given on the peculiar merits of a number of recommended varieties.

Care of orchards, W. M. MUNSON (*Maine Sta. Bul. 49, pp. 8, figs. 2*).—A popular article treating of renovation, grafting, fertilizing, culture, and spraying. A statement is made of the lines of orchard work now in progress at the station. In renovating old orchards that have never been plowed, hogs are recommended for stirring the soil and working in fertilizer.

The treatment of old fruit trees, G. HÖHN and F. K. STOCK (*Kronen-, Stamm- und Wurzelpflege; ein Beitrag zur Behandlung der älteren Obstbäume. Wiesbaden: R. Bechtold & Co., pp. 42, ill.*).—A practical work, treating of pruning, diseases, and fertilizers.

The failure of certain fruit trees to set fruit; its causes and methods of prevention, C. Grosdemange (*Jour. Soc. Nat. Hort. France, Congrès Hort. 1899, pp. 16-27*).—A summary presentation of the subject. The causes considered are frost, rain, fogs, diseases and insect enemies, condition of the soil, exposure, and difference in varieties.

Ben Davis apple, F. A. Waugh (*Gardening, 7 (1899), No. 162, p. 278*).—This variety as grown in New England is much inferior to the same variety as grown in the Mississippi Valley. It is believed that Spy and Fameuse varieties of apples are especially adapted to the Vermont climate.

Origin of the Wealthy apple (*Amer. Gard., 20 (1899), No. 232, p. 404*).

Notes on the banana and its products (*Jour. Jamaica Agr. Soc., 3 (1899), No. 5, pp. 253-256*).—Notes on the culture, yield, and marketing of bananas and the manufacture and chemical composition of banana meal.

California olive industry (*Sci. Amer., 80 (1899), No. 24, p. 389*).—Notes on the history and extent of the industry.

A covered orangery (*Pacific Rural Press, 57 (1899), No. 23, p. 353, fig. 1*).—Notes on an orchard of 17 acres in California covered with lath as a protection against frost. The cost was about $450 per acre.

Curing lemons, A. S. Gaylord (*Pacific Rural Press, 57 (1899), No. 21, p. 324, fig. 1*).

The influence of cold on pear trees (*Garden, 55 (1899), No. 1436, p. 360*).—List of 51 varieties of pears, grouped according to hardiness in France.

Renewing strawberry beds, J. Meehan (*Gardening, 7 (1899), No. 162, p. 279*).—In commercial culture the early removal system is believed to be the most profitable.

Grape culture in the Government of the Black Sea and in the region along the Kuma River, P. Stroyev (*Selsk. Khoz. i Lyesov., 192 (1899), Feb., pp. 331-352*).

Report of the viticultural exposition of São Paulo, 1897, Campos da Paz (*Viticulture; exposition viticole de S. Paul en 1897. Rio de Janeiro: Imprimerie nationale, 1898, pp. 51, pls. 8*).—A statement of the methods of culture employed, varieties planted, and status of the industry in Brazil in 1897.

Lawns, pastures, and hay, P. H. Mell (*Alabama College Sta. Bul. 100, pp. 311-318*).—Directions are given for establishing a good lawn. In the preparation of the land, which is fully described, care should be taken that there is no deficiency in lime. Those grasses should be selected that will best stand the heat of the southern sun and live through the dry season. Notes are given on 5 species and 1 variety of lawn grass well adapted to Alabama soils and climate. These are Bermuda, St. Lucie, carpet, Kentucky blue, and St. Augustine grasses. Late fall seeding is recommended.

Photographing flowers (*Gard. Chron., 3. ser., 25 (1899), No. 649, p. 356*).—Notes taken from the Boston Herald.

Notes on varieties of carnations, C. W. Ward (*Amer. Florist, 14 (1899), No. 565, p. 1066*).—Notes on the merits of 47 varieties by a commercial grower.

The pansy: Its names and its evolution, R. P. Brotherston (*Gard. Chron., 3. ser., 25 (1899), No. 646, pp. 306, 307*).—The etymology of the word itself is discussed and a number of the popular synonyms of the last 150 years are mentioned with bibliographical references. Notes are given on some of the varieties of the early years of this century, the number cultivated and methods of propagation at that time.

The introduction of the fancy pansy, R. Dean (*Gard. Chron., 3. ser., 25 (1899), No. 648, p. 343*).—Extensive historical notes.

Roses for grouping, F. Josst (*Wiener Illus. Gart. Ztg., 23 (1899), No. 5, pp. 147-150*).—Culture of roses for grouping and notes on numerous varieties.

Origin of the Maréchal Niel rose, H. Dauthenay (*Rev. Hort., 71 (1899), No. 10, pp. 223, 224*).

A new method of violet culture (*Amer. Florist, 14 (1899), No. 573, p. 1289, figs. 2*).—The results of experiments by Sonnenschmidt and Junge at Indianapolis, Indiana. The bottoms are chiseled off from 6 in. flower pots, leaving rims 3 in. deep. These are set 1 in. deep in the soil and contain the plants. Marie Louise violets thus treated made a healthier growth, produced more flowers, and made fewer runners than with the usual culture. The plants can be watered without wetting the foliage, thus materially lessening the danger of damping off and overwatering.

Violets trained in tree-like form, H. DAUTHENAY (*Rev. Hort., 71 (1899), No. 6, pp. 142–143, fig. 1*).—A French gardener has produced a new and distinct modification of the violet by separating a stolon from its root and planting and training it to a stake in an upright position. The stems of plants thus trained are long, slender and smooth, and produce very few buds. The terminal bud develops into a cluster of leaves and flowers. Such plants have attained to a height of 50 cm. This height does not depend on the age of the plant but on the length of the stolon when planted. Experience is necessary in order to obtain good results in the use of this method. Thus far but few flowers have been obtained on a single plant. All varieties of violets are not equally amenable to this treatment. The results of this experiment are believed to be rich in suggestion for the culturist, not only of the violet, but also of the strawberry and other stoloniferous plants.

The practical employment of steam at a low pressure for heating greenhouses, A. GUION (*Jour. Soc. Nat. Hort. France, Congrès Hort. 1899, pp. 62–67*).

SEEDS—WEEDS.

Twenty-first annual report of the Swiss Seed-Control Station at Zürich, F. G. STEBLER and E. THIELÉ (*Die Schweizer. Samen-Untersuchungs-Anstalt in Zürich. Einundzwanzigster Jahresbericht, 1898, pp. 35*).—This gives the report of the activity of the station from July 1, 1897, to June 30, 1898, and the administrative report for 1898. During this time 8,462 lots of seed were tested for 525 individuals and firms, the results of the tests being shown in tabular form. Of these, clover and grass seed comprised 76.3 per cent, the remainder being miscellaneous seeds. According to the report, 155 domestic and foreign seed dealers have availed themselves of the privileges of the station in testing and guaranteeing their seed, and, for the most part, the seeds examined were in excess of the guaranty.

The averages of purity, germinative ability, and intrinsic value of all seed tested at the station since 1876 are shown in tabular form. In the following table are shown the data for a number of the more common seeds:

Average results of seed testing in 1876–1899.

Kind of seed.	Number of samples tested.	Purity.	Germinative ability.	Kind of seed.	Number of samples tested.	Purity.	Germinative ability.
		Per ct.	*Per ct.*			*Per ct.*	*Per ct.*
Red clover	10,800	96.4	91	Wood meadow grass	533	80.8	68
White clover	1,457	94.9	79	Yellow oat grass	696	69.3	52
Alsike	1,682	96.0	80	Fiorin	1,006	72.3	83
Alfalfa	4,169	97.1	90	Sweet vernal grass	357	92.4	43
Esparcet	3,740	97.1	76	Velvet grass	601	71.3	49
Crimson clover	145	95.8	89	Reed canary grass	231	88.6	65
Hop clover	369	95.9	78	Seradella	181	95.8	71
Rye grass	4,055	76.9	75	Peas	119	96.4	93
English rye grass	8,656	95.7	81	Vetches	387	91.7	89
Italian rye grass	8,243	94.8	77	Hemp	416	97.8	83
Orchard grass	5,919	78.5	81	Flax	102	97.9	82
Timothy	1,805	98.1	92	Beets	488	97.6	141
Crested dog tail	1,217	90.2	71	Mangels	122	98.5	118
Meadow fox tail	1,757	78.4	62	English fodder beets	213	98.6	90
Tall meadow fescue	2,519	93.0	85	Pine (*Pinus sylvestris*)	3,756	93.1	65
Sheep fescue	1,788	76.1	69	Fir	1,864	95.3	69
Red fescue	223	72.4	57	Larch	1,437	86.6	46
Blue grass	1,824	86.7	61	White pine (*P. strobus*)	300	92.1	58
Rough meadow grass	534	87.2	70	Black pine (*P. nigra*)	427	97.3	66

Plat experiments are reported in which grasses and clovers of different origin were compared. Alfalfa from Utah seed was compared with alfalfa of Italian, Hungarian, and Provence origin, the Italian giving the best showing. It is claimed the American alfalfa was more subject to attacks of *Erysiphe martii* and *Pseudopezizza trifolii* than plants grown from European seed. In other experiments American timothy and orchard grass made the best showing.

Report of the Agricultural Seed-Control Station, Stockholm, for 1897–98, O. Stjernquist (*Redogörelse för Verksamheten vid Stockholms Läns Hushällningssällskaps Frökontrollanstalt 1897–98, pp. 21, figs. 5*).—This gives a report of the activity of the Seed-Control Station of the Agricultural Society of Stockholm for the year ending June 30, 1898. During the year 1,004 analyses were made and 245,443 kg. of seed were certified to. The details of the seed tests are given, and also the averages of the 10-year tests, ending with 1898, of the germination and purity of some 80 varieties of seed. Experiments are reported in which the effect of temperature on the vitality of wheat, rye, barley, and oats was tested. Different lots of seed were subjected to temperatures of dry heat varying from 50 to 90° C. for from 10 to 60 minutes, after which they were germinated with the following results:

Effect of temperature on germination.

Time of heating.	Temperatures.

Barley	98	97	98	98	90	12.5
Oats	81	88	97	98.5	98	70

These results are comparable with some figures given for similar experiments made in 1894, in which the seeds were subjected to temperatures ranging from 50 to 99° C. for periods of from 15 minutes to 4 hours.

Illustrated descriptions are given of a number of special forms of apparatus that have been found of superior excellence in seed testing.

Fifth annual report of the Pomological Experiment and Seed-Control Station at Gratz, E. HOLTER (*V. Jahresbericht über die Thätigkeit der Pomologischen Landes-Versuchs- und Samen-Control-Station in Gratz, 1898, pp. 34, figs. 4*).—In addition to the routine report for the year ending June 30, 1898, the report contains brief articles on a number of topics, among them investigations on Lower Styrian varieties of apples, the iron content of apples and pears, the filtration of fruit wine, the manufacture of effervescent wines, ash and other analyses of apples and pears, the composition of Admont turf, the fertilizer value of the municipal compost fertilizers of Gratz, citrate solubility of Thomas slag, and the report of the seed control for the year.

Concerning the duration of the germinative ability of the seed of various cultivated plants, F. TODARO (*Staz. Sper. Agr. Ital., 31 (1898), No. 6, pp. 525–563*).—The tests upon which this paper is based were begun in 1889 by Professor Cugini, and were continued for several years. In 1896 the author took up the work and tested all the available samples to ascertain what effect the age of the seed might have upon its germinative ability. The average viability of commercial seeds was ascertained as a preliminary to the subject. In the following table is shown the vitality of lots of the same samples of seed tested in different years, the data being derived from 506 samples of seed, on which 1,133 tests were made. The figures given are in most cases averages of a number of tests and the species shown are selected from a larger number. The results follow:

Nevada weeds. III, Nevada and other weed seeds, F. H. HILLMAN (*Nevada Sta. Bul. 38, pp. 131, figs. 12*).—Believing that comparative immunity from many of our worst weeds may be secured by preventing the sowing and subsequent tillage of their seeds along with those of more desirable plants, the author has given a study of more than 150 species of weed seeds. The most of these are figured in their natural size, and are also shown in enlarged form. The descriptions given are as untechnical as the nature of the subject will admit. In the introduction a discussion is given of seed in its popular sense, methods of distinguishing various kinds, and notes on distribution of weed seeds and the desirability of and the methods for examination of commercial seeds to determine the presence and character of weed seeds.

On the destruction of the oxeye daisy, F. W. RANE (*New Hampshire Sta. Bul. 59, pp. 176–178, fig. 1*).—During a period of several years the author has been endeavoring to overcome this pest. One method adopted was to cut the hay early and thus avoid the maturing of the seed. In order to ascertain how elastic this period might be, a number of heads of daisies were collected for study, and the results of the germination of the seeds are shown in tabular form. It appears that it takes at least 12 days for seed maturity of the daisy after it first blossoms, and by repeatedly cutting the weed before or during this period its extermination could be secured.

Report of the seed-control station of the Imperial Botanic Gardens, St. Petersburg, J. KLINGE (*St. Petersburg, 1898, pp. 10*).—A summary is given of the results of 20 years' work.

On the influence of the size of seed on germination, H. J. J. VANDEVELDE (*Bot. Jaarb. Kruid. Genotsch. Dodonæa, Ghent, 10 (1899), p. 109, pls. 6, figs. 2*).

Spraying wild mustard (*Hoard's Dairyman, 30 (1899), No. 16, p. 315*).—Notes on experiments in Great Britain and elsewhere in which spraying with strong solutions of iron sulphate successfully destroyed wild mustard.

On the destruction of Orobanche on clovers, A. LONAY (*Jour. Soc. Agr. Brabant-Hainaut, 1898, No. 38*).

Cuscuta monogyna on the grape, P. VIALA and G. BOYER (*Ann. École Nat. Agr. Montpellier, 10 (1897–98), pp. 279–304, pl. 1, figs. 32*).—A botanical study of this parasite of the grapevine. The seeds are said to retain their vitality for 2 or 3 years in the soil, and by care the plant can be exterminated from a vineyard in that time.

DISEASES OF PLANTS.

The asparagus rust in Massachusetts, G. E. STONE and R. E. SMITH (*Massachusetts Hatch Sta. Bul. 61, pp. 20, pls. 2*).—The authors briefly review the history of the introduction of asparagus into the State, and show by statistics the present extent of asparagus growing for market. The rust of asparagus (*Puccinia asparagi*) is said to have made its first conspicuous appearance in the summer of 1896, but there was no perceptible damage to the market crop of 1897 as a result of the rust occurring in the year previous. During the latter part of the season of 1897 the uredo form of the rust appeared in considerable abundance and caused serious injury to the asparagus crop.

The life history of the rust is given, the different stages being described separately. The authors believe the earlier stages of the rust may possibly be omitted. In 1897 the teleutospores were borne in very great abundance, and they apparently failed to affect the plant in the spring of 1898, so that neither the æcidial or uredo forms appeared in 1898. It is thought probable that the teleutospores which failed to affect the plants in the spring retained their vitality until late in the summer, when they produced the fall stage of the rust. It is thought possible, also, that the fungus may remain alive over the winter in the plant tissues, not producing spores again until autumn.

The economic importance of asparagus makes this disease a serious one, and estimates made at various places concerning the amount of asparagus cut in 1898 show that there was a depreciation of from 15 to 80 per cent, the average loss experienced being 20 to 25 per cent.

The cause of the severe outbreak of the asparagus rust is said to be probably due to conditions of the plant brought about by the excessive drought during 1895–96, followed by the excessive rains of 1897. The effect of the rust upon plants grown in different soils is noted, it being much more injurious on soils which are dry and sandy, having little water-holding capacity; where the soils were heavier and retained water to a greater extent the rust has caused no appreciable harm.

Comments are made upon the methods of controlling the rust, from which it appears that burning the affected tops and spraying with fungicides, such as potassium permanganate, Bordeaux mixture, and potassium sulphid, are of little or no avail. Cultivation and irrigation as means of controlling the rust are believed to be more efficient, and it is stated that in this manner vigorous plants may be secured which will resist the attacks of the disease.

From the knowledge of the occurrence of the rust in Europe and from observations made throughout the State, the authors believe that the outbreak of the asparagus rust is of a sporadic nature and not liable to cause much harm in the future provided attention is given to the production of vigorous plants.

The asparagus rust in South Carolina, A. P. ANDERSON (*South Carolina Sta. Bul. 38, pp. 1–10, figs. 5*).—The author reports the occurrence of the asparagus rust (*Puccinia asparagi*) at numerous places in South Carolina. According to one grower its presence has been noted since 1895, and in his experience it seems to vary but little in its attacks upon different varieties. The cause of the disease is described and suggestions made for its treatment. In addition to spraying with fungicides and burning, which are frequently recommended, it is suggested that heaping up the beds to destroy the spores and sprinkling the soils with lime or land plaster might prove beneficial.

Some diseases of wheat and oats, A. D. SELBY (*Ohio Sta. Bul. 97, pp. 31–43, figs. 4*).—On account of the prevalence of diseases in the vicinity of the station, considerable study has been made and experiments conducted relative to the nature and methods of prevention. In the region mentioned the smuts and rusts of wheat are said to be the more prevalent and destructive fungus diseases, while the scab, glume spots, and other parasitic diseases usually take a minor rank.

The cause and nature of the loose smut and the stinking smut of wheat are described at some length. The life history of the loose smut (*Ustilago tritici*) is given in some detail, and it is said to cause yearly losses amounting to nearly $100,000 within the State. Different varieties of wheat vary in their susceptibility to the disease, and by care in seed treatment it may be prevented. Seed free from smut being once secured may usually be employed for several years without further treatment.

The stinking smut of wheat is said to be due to two species of fungus (*Tilletia tritici* and *T. fœtens*) which are described in some detail. The statement made in Michigan Station Bulletin 87 (E. S. R., 4, p. 352) that these two species of stinking smut, which can only be separated by a microscopic investigation, produce different kinds of diseases, known as high and low smut, was investigated without discovering any constant difference. It is probable, however, that only one of the stinking smuts is common in the vicinity of the station. Recent experiments with copper sulphate and hot water have shown the practicability of holding in check this disease, which is said to cause a loss amounting to $250,000 per year.

While it is generally believed that smutted seed is the usual source of infection, it is sometimes claimed that land which has grown a smutted crop will afford conditions necessary to infest a subsequent crop. An investigation of this subject was made in which plats of untreated grain from the crops of 1894 and 1895 as well as treated grain from both these years were sown alongside one another with the result that no direct infection could be ascertained through means of the soil. It is also stated that the claim sometimes made that old seed may be sown without danger of smut is incorrect, an experiment being cited in which spores germinated after having been kept 8½ years in a herbarium.

The rusts of wheat are described at some length and considerable quotations given from Eriksson's publications relating to these diseases (E. S. R., 10, p. 316).

The wheat scab, which usually causes but little injury to the crop, may at times and upon different varieties seriously interfere with the crop production, losses of 10 per cent or more being not unusual. This disease, which is due to the fungus *Fusarium roseum*, is described. The fungus is said to be of the conidial form of *Gibberella saubinettii*, and experiments conducted by the author seem to justify this conclusion, although they do not fully prove it. The means of prevention of scab suggested are the burning of stubble when wheat is to follow a scabby crop.

A disease of wheat is described under the name of glume spot, in which dark spots become very conspicuous upon the glumes of certain varieties such as Velvet Chaff. The fungus appears to be referable to Septoria.

Experiments in the prevention of grain smuts and the treatment of unsmutted wheat seed, J. F. HICKMAN and A. D. SELBY (*Ohio Sta. Bul. 97, pp. 43-61*).—This gives the results of experiments conducted by the authors during 3 years subsequent to 1895. In the treatments for prevention of wheat diseases, water heated to various temperatures, copper sulphate, and potassium sulphid were compared. The efficiency of hot water and copper sulphate treatments was plainly shown. The effect of seed treatment upon smut-free grain was tested, with no apparent increase on the treated plats.

Further experiments on the prevention of oat smut (E. S. R., 8, p. 238) are reported. The efficiency of hot-water treatment and the relative efficiency of Ceres pulver and potassium sulphid, effect of shortening the time of immersion in hot water, and the use of formalin were tested. The results of the different tests are tabulated, from which it appears that there was little difference between 10 and 15 minutes' immersion of seed in hot water; the Ceres pulver and potassium sulphid treatments were less efficient than the others, and 5 minutes' soaking in water heated from 140 to 144° F. gave practically the same results as have been previously secured by treating the seed for 10 minutes at 133°. In conclusion the authors state that much, if not all, the loss occasioned by the diseases of wheat and oats may be prevented by the proper treatment of seed prior to sowing, and give directions for the different forms of treatment recommended.

Three important fungus diseases of the sugar beet, B. M. DUGGAR (*New York Cornell Sta. Bul. 163, pp. 337-363, figs. 15*).—On account of the recent interest in the production of sugar beets, attention has been directed to some of the diseases to which this crop is liable, and the author has made careful investigations of three which are more or less prevalent.

The root rot of beets (*Rhizoctonia betæ*) was first noticed early in 1898, and a few days later was found abundant at a second station. A visit to the latter place in August demonstrated that the disease was a matter of considerable practical importance, an examination of the field showing that probably one-third of the beets were affected. The first evidence of an attack is manifested in the blackening of the bases of the petioles, the outer leaves first, so that the stalks soon become unable to support the blades and the leaves fall to the ground. The disease soon attacks the crown and root proper, causing the infested parts to turn brown. If the conditions continue favorable for the disease, the whole top rots away and the beet gradually disappears. Ordinarily the trouble is carried throughout the entire field, but numerous small areas indicate that the fungus passes rapidly from plant to plant in a row.

The cause of this root rot of beets is due to the fungus Rhizoctonia, as was demonstrated by a series of inoculation experiments. In these experiments it was shown that the fungus readily produces root rot where the conditions are favorable, and that moist conditions are essential for the spread of the disease from plant to plant. The special characteristics of the fungus are described at some length and attention is called to the probable fact that the fungus causing this beet disease is also a cause of other types of plant disease. Among those mentioned as probably due to this same fungus are the sore shin of cotton, the damping off of lettuce, cabbage, radish, eggplant, etc., and probably a stem rot of carnations.

As a remedy for the prevention of this disease, it is recommended that 60 to 70 bu. of air-slaked lime per acre be applied to the soil in the autumn or at least before the ground is turned so that the lime could be well distributed.

The leaf spot of the beet (*Cercospora beticola*) is a disease of very wide distribution. It attacks not only the sugar beet but many of the garden varieties as well. Its occurrence may be noted by the appearance of small brown spots with reddish purple margins scattered irregularly over the leaves. The spots become ashen gray at the centers with the border as before, and they may become so numerous as to cover a large portion of the surface of the leaf. As the leaves begin to appear parched and dry they assume a nearly upright position and a badly infested field presents a very characteristic appearance.

The technical characters of the fungus are described, and as remedies the author states that Bordeaux mixture has proved most efficient. It is believed that by beginning the sprayings early, the leaf spot may be almost entirely prevented by the use of this fungicide. The theory that this disease may possibly be distributed through the medium of the seed is briefly considered, and as having a bearing upon this subject all seeds were treated before planting with hot water and copper sulphate solutions to test their effect upon the germination. In general, even a strong solution of copper sulphate gave slightly better results than where the seed was soaked in water. This may have been due, however, to the exclusion of bacteria by the copper solution.

The beet scab (*Oöspora scabies*) is figured and described. This disease is well known on account of its occurrence on potatoes and beets. The only remedial treatment is to avoid growing beets in any soil which for several years previous has produced scabby potatoes or beets. The bulletin concludes with a list of references to literature of beet diseases.

The root rot of sugar beets, J. STOKLASA (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), No. 17–18, pp. 687–691, figs. 2; abs. in Ztschr. Pflanzenkrank, 9 (1899), No. 1, pp. 50–51*).—*Pythium debaryanum*, *Phoma betæ*, and *Rhizoctonia violacea* were found in greater or less abundance in the tissues of all diseased beet seedlings. All varieties are not equally susceptible to these attacks, and it was found that soaking the beet seed in a weak solution of corrosive sublimate prior to sowing was efficient in preventing the disease to a great extent. By the nature of the seed bolls they are liable to be infested by a number of organisms such as bacteria, etc., which attack the albuminoids in the young plant, greatly weakening it.

A contribution to the knowledge of fruit rots, J. BEHRENS (*Centbl. Bakt. u. Par., 2. Abt., 4 (1898), Nos. 12, pp. 514-522; 13, pp. 547-553; 14, pp. 577-585; 15-16, pp. 635-644; 17-18, pp. 700-706; 19, pp. 739-716; 20, pp. 770-777*).—An extended study has been made of the fruit rots. The author states that *Penicillium glaucum* causes the rot of the fruit of apples, pears, grapes, and the outer shell of the walnut; *P. luteum* of apple; *Mucor stolonifer* of pears and tomatoes; *Botrytis vulgaris* of apples, pears, strawberries, currants, grapes, and walnuts, and *Oidium fructigenum* on apples, pears, plums, cherries, apricots, peaches, quinces, etc. The physiology of each fungus, the specialization of the different fungi, the changes in the fruit subsequent to the attack, and the susceptibility of the fungi to copper compounds are reported upon at length.

The form of injury produced by each of these fungi is described, and means suggested for the prevention of their attacks. In addition to attacking the fruit, *Botrytis vulgaris* was found to attack other parts of the plant, and the author claims it produces a poison which is destructive of the living protoplasm of the cell.

Peach-leaf curl and notes on the shot-hole effect of peaches and plums, B. M. DUGGAR (*New York Cornell Sta. Bul. 164, pp. 369-388, figs. 9*).—The peach-leaf curl (*Exoascus deformans*) was technically described in Bulletin 73 of this station (E. S. R., 6, p. 554) and in the present discussion only a general account of the life history of the fungus is included. The appearance of the disease, life history of the fungus, conditions affecting the abundance of leaf curl, and remedies are discussed at some length. The sporadic occurrence of the leaf curl is said to be rather remarkable. In many sections of the State there was but little of the disease in 1896 while in the same sections in 1897 there was an abundance of it, and in 1898 these regions were characterized by unusual injuries from this cause. Numerous attempts have been made specifically to define the conditions which encourage this disease, but sufficient is not yet known of the life history to warrant positive statements regarding them. Different varieties vary greatly in the degree of susceptibility to attacks of leaf curl. The earlier experiments made to determine the value of fungicides for prevention of leaf curl were unsatisfactory, for the fungicides themselves often injured the leaves, and also the best time for spraying was not known.

In 1896 an orchard of young trees was affected with leaf curl, and the following year the disease was so abundant as to cause almost entire defoliation, and there was every promise of an abundant reappearance of the disease in 1898. Spraying experiments with Bordeaux mixture, potassium sulphate, and ammoniacal copper carbonate were conducted in which applications were made at different periods. The results seemed to indicate that where Bordeaux mixture was used before the buds swelled, the foliage of the tree was very largely free from curl. It also appears that treatments subsequent to the early treatment of Bordeaux are very insignificant in preventing the disease, and that the early treatment is the one of importance for the protection of the foliage during the season. An experiment is reported in which winter applications of milk and lime, and lime and dextrin were made to 12 trees in the center of a block of about 4,000 trees. All the trees were considerably affected with leaf curl with the exception of the treated ones, which were almost absolutely free from it. In spraying for the prevention of this disease care must be taken, since fungicides are very liable to injure the foliage, and a weak Bordeaux mixture would probably give the best results.

Leaves of the plum and peach have been frequently noticed in which the shot-hole effect was very apparent even where the trees had been abundantly sprayed. The author's attention was called in 1897 to the abundance of the shot-hole effect on Japan plums which had been frequently sprayed, and the indications were that the injuries to the foliage were due to the chemical agents applied. In general, peaches, apricots, and plums of the native and domestica groups were free from this effect, but Japan plums generally indicated some injury. Experiments made with properly prepared Bordeaux mixture produced no injury whatever except on the Japan plum (Burbank), while improperly prepared Bordeaux mixture affected the peach and Japan plums to a marked extent. Careful examination of the leaves of these trees showed no indication of fungus, and it must be attributed to the improper application of the fungicides. The author states that after examining a number of plum orchards, he finds the Japan plums so free from shot-hole fungi that there is no necessity for spraying them for protection against this disease. Where the plum rot is bad, it would be necessary to spray, and it will be necessary to disregard the slight injury to foliage resulting from the use of properly made Bordeaux mixture.

Treatment of mildew on grapevines, G. B. MALLETT (*Gard. Chron., 3. ser., 25 (1899), No. 648, pp. 354, 355*).—The author reports the successful use of hot water for the destruction of grape mildew. In 1898 unsuccessful attempts were made to stamp out the mildew from vineries by the use of potassium sulphid and by dusting the vines with sulphur, etc., but the crop of that season was a total failure. Early in 1899 the vineries were thoroughly cleaned, new soil replaced in borders and walks, and the canes of the vines were painted with a strong mixture of sulphur and potassium sulphid with but little effect, as the mildew appeared in several places by the time the vines had reached the flowering stage. Acting upon a suggestion, the author thoroughly sprayed the vines with water heated to the boiling point, which was carried a distance of some 60 yards and quickly sprayed over the leaves. The vines were thoroughly soaked on two separate occasions, and special investigations showed not a trace of living mildew, but brown spots on the leaves were plentiful. These leaves were removed and no trace of the fungus has since been observed. There was no injury observed to leaf or flower, nor were the tender growing tips injured, although adventitious roots on some of the canes were blackened.

Subsequently vines of the White Tokay were sprayed with water as near the boiling point as possible, and a few days later a second application of the same kind was given, the vines coming through uninjured. In all, 4 varieties of grapes have been experimented upon in this way, and in every case the vines are said to be growing freely and the berries are unharmed.

In a subsequent issue (No. 650, p. 388) the experience of several others with hot water upon living plants is given. In one instance the writer had dipped plants, without injury to them, into water heated to 170° F. to rid them of mealy bugs. In another case the writer reports having sprayed grapevines with water in the method described above with identically similar results.

A copper fungicide containing permanganate of potash, C. TROUCHOT (*Prog. Agr. et Vit. [Ed. L'Est], 20 (1899), No. 8, pp. 211-213*).—The author describes the use and gives the formula for a fungicide which it is stated has been very successfully employed for the prevention of black rot of grapes. The fungicide is composed of copper sulphate 1.5 kg., copper carbonate 2.5 kg., and water 100 liters. This should give a slightly alkaline reaction, and to it is added 25 gms. permanganate of potash, dissolved in a liter of water. On account of the presence of permanganate of potash the author has given the name to the fungicide of "violet mixture." Its action is said to be equal to that of Bordeaux mixture, and in addition it is claimed to adhere to the foliage better.

A study of the fungus parasites of the cultivated Rosaceæ, E. OUVRAY (*Jour. Soc. Nat. Hort. France, Congrès Hort. 1899, pp. 47-61*).—The author briefly describes the fungi which attack the cherry, plum, peach, apricot, almond, apple, pear, quince, medlar, service tree, hawthorn, strawberry, raspberry, and rose. Suggestions are also given for combating the fungi, and great stress is laid upon the value of winter treatments and the more extensive use of iron sulphate solutions is suggested.

Botanical, chemical, and toxicological properties of fungus-infested grass seeds, J. HOCKHAUF (*Verhandl. K. K. Zool. Bot. Gesell. Wien, 19 (1899), No. 2-3, pp. 120-123*).—A brief summary is given of the different fungi known to exist in the grain of cereals, etc., with notes on their chemical and toxicological properties.

Concerning the attack of Phoma betæ upon beets, FRANK (*Ztschr. Ver. Deut. Zuckerind., 48 (1899), No. 511, pp. 711-717*).

Cacao pod disease, J. H. HART (*Bul. Bot. Dept. Trinidad, 3 (1899), No. 11, pp. 167, 168*).—A note is given of a fungus, probably one of the Peronosporeæ, that attacks cacao pods and causes some loss. The disease seems widespread but poorly understood, and for the present it is advised that diseased pods be destroyed and badly affected trees sprayed with copper sulphate solutions. It is stated that Bordeaux mixture, unless very dilute, injures foliage in hot climates.

Diseases of coffee, J. B. POMPEU (*Bol. Inst. Agr. São Paulo, 9 (1898), No. 3, pp. 329, 330*).

Leaf blight of currants, J. E. WEISS (*Prakt. Bl. Pflanzenschutz, 2 (1899), No. 3, p. 22*).—Notes are given on *Glœosporium ribis*.

Studies of black rot of grapes, L. RAVAZ and A. BONNET (*Ann. École Nat. Agr. Montpellier, 10 (1897–98), pp. 90–102, pls. 2*).—A report is given of studies on the life history of the black-rot fungus, the germination of the spores, penetration of the tissues, development of the mycelium in the tissues, and the period of incubation being reported upon. Concerning the latter, it is said to be rarely less than 10 or 11 days between the sowing of the spores and the appearance of the disease.

A disease of hops, P. NYPELS (*Ann. Soc. Belge Micros., 23 (1899), pp. 34–39, pl. 1*).—A brief description of a hop disease of uncertain origin is given.

Peach diseases, H. N. STARNES (*Georgia Sta. Bul. 42, pp. 220–225, figs. 3*).—Of the diseases popularly described those due to undetermined causes are peach yellows, peach rosette, gummosis, and crown gall. Of the fungus diseases, peach rot, scab, pustular spot, leaf curl, and peach rust are given, and suggestions offered for their control.

Injurious diseases of pear trees, J. E. WEISS (*Prakt. Bl. Pflanzenschutz, 2 (1899), No. 2, pp. 9–11, figs. 4*).

The peony disease, G. MASSEE (*Gard. Chron., 3. ser., 25 (1899), No. 649, p. 351*).—A destructive disease, due to *Sclerotinia pæonia*, is briefly described. The disease begins on the leaf stalk an inch or less below the surface of the ground. The first symptoms are the curling of the edges of the leaves. All such leaves should be removed at once and the plants sprayed at intervals of 4 days with ammoniacal copper carbonate. The fungus is said not to be perennial in the tissues of the host. Where the disease has existed for some time the soil around the crown of the plant should be removed and fresh soil mixed with quicklime put in its place.

A disease of phlox, P. NYPELS (*Ann. Soc. Belge Micros., 23 (1899), pp. 9–32, pl. 1*).—Describes a disease of phlox, which is said to be due to *Tylenchus devastatrix*. A list of 45 species of plants known to be attacked by this pest is appended.

Concerning a living fluid contagium as a cause of the mosaic disease of tobacco, M. W. BEIJERINCK (*Seperat. Verhandl. K. Akad. Wetensch. Amsterdam, 1898; abs. in Bot. Centbl., 78 (1899), No. 5, pp. 146–151*).—It is claimed that the cause of the mosaic disease of tobacco leaves is due to what is termed a living fluid contagium. The author claims to be able to isolate the poison and to induce disease with it by inoculation. It is also claimed that peach yellows and peach rosette may be due to the same cause.

Concerning the Æcidia occurring upon the Umbeliferæ, H. O. JUEL (*Ofvers. K. Svenska Vetensk. Akad. Förhandl., 1899, No. 1, pp. 5–20, figs. 4*).

Studies on plant galls, O. APPEL (*Ueber Phyto- und Zoomorphosen. Sepabdr. Schr. Phys. Oekon. Gesell. Königsberg, 39 (1899), pp. 58*).

Bacterial excrescences on Juniperus phœnicea, F. CAVARA (*Bul. Soc. Bot. Ital., 1898, No. 8, pp. 241–250*).

Plant diseases due to nematodes, T. PETERSEN (*Natur, 49 (1899), No. 2, pp. 19, 20*).

Winter treatment for plant diseases, J. E. WEISS (*Prakt. Bl. Pflanzenschutz, 2 (1899), No. 3, pp. 19–22*).

Combating mildews, NESSLER (*Wchnbl. Landw. Ver. Baden, 1899, No. 3, pp. 26, 27*).—Notes on Oidium.

Apple spraying in Nova Scotia, C. H. HOOPER (*Gard. Chron., 3. ser., 25 (1899), No. 650, pp. 373, 374*).—Notes are given on the successful use of potash solutions for clearing trees of moss and lichens, and on spraying with Paris green, copper sulphate, and Bordeaux mixture for the control of insects and fungi on apples.

Notes on experimental spraying, W. M. ORR (*Fruit Growers' Assoc. Ontario Rpt. 1898, pp. 69–77*).—Gives a detailed report of the experiments in spraying 30 apple orchards in 1898 The orchards were in many cases widely separated, and upon nearly every variety the results were decidedly in favor of the treatment. Bordeaux mixture, to which 4 oz. of Paris green to 40 gal. of water was added, was the fungicide used.

Sulphuring grapes, H. DAUTHENAY (*Rev. Hort., 71 (1899), No. 9, pp. 207, 208*).—The author claims that sulphur applied to grapevines in the sun is more efficient than upon shaded vines or during cloudy weather.

Concerning the value of Bordeaux mixture in preventing potato diseases and in increasing the crop (*Fühling's Landw. Ztg., 48 (1899), Nos. 4, pp. 142–148; 5, pp. 166–169*).

The effect of ethereal oils on fungi, T. BOKORNY (*Arch. Physiol. [Pflüger], 73 (1898), pp. 555–594; abs. in Bot. Centbl., 78 (1899), No. 5, pp. 133–136*).—The ethereal oils are reported as quite poisonous to fungi, oil of turpentine being antiseptic when used in the proportion of 1 : 50,000.

A new fungicide of great adhesiveness, J. F. FAVARD (*Rev. Hort., 71 (1899), No. 4, pp. 87, 88*).—A solution of copper sulphate, sodium carbonate, and water, to which resin is added, is described.

Investigations on the adherence of copper fungicides and the causes for variation in fungicides as formerly prepared, J. M. GUILLON and G. GOUIRAND (*Rev. Vit., 1898, No. 265, pp. 29–32*).

ENTOMOLOGY.

The economic status of insects as a class, L. O. HOWARD (*Science, n. ser., 9 (1899), No. 216, pp. 233–247*).—In an address as retiring president of the Biological Society of Washington the author reviewed the economic status of insects, dividing them into two groups, as follows: (1) Injurious insects—those which destroy crops and other valuable plant life; those destroying stored foods, dwellings, clothes, books, etc.; those injuring live stock and other useful animals; those annoying to man, and those acting as carriers of disease; and (2) beneficial insects—those which destroy injurious insects, destroyers of noxious plants, pollenizers of plants, scavengers, makers of soil, and those which serve as food for poultry, birds, fishes, etc. The beneficial insects are said to embrace 113 families, and the injurious 116 families, while those belonging to both classes or undetermined represent 71 families.

Report of consulting entomologist, R. S. MACDOUGALL (*Trans Roy. Scot. Arbor. Soc., 15 (1898), pt. 3, pp. 307–316*).—The author gives notes on *Goës tigrina*, which occurred in oak timber shipped to Great Britain from the United States. Economic and biological notes are given on the small brown pine weevil (*Pissodes notatus*). The insects are said to lay eggs for two seasons. The egg laying takes place from April until September. As a preventive measure against this beetle the author recommends allowing sickly or diseased trees to stand as places for the insects to deposit their eggs. These trees may then be destroyed.

A description and the life history of the *Sirex gigas* is given. Concerning *S. juvencus* the author relates the life history at considerable length. An ichneumon fly (*Rhyssa persuasoria*) was seen depositing its eggs in bark which contained the larvæ of sirex. As a remedy against this species the author suggests burning the felled trees and waste timber in infested forest areas.

The pear midge (*Diplosis pyrivora*) is reported as increasing in numbers and harmfulness in Great Britain. Notes are given by way of description of the appearance and habits of the insect, and the usual remedies are recommended.

The insect record for 1898, C. M. WEED (*New Hampshire Sta. Bul. 59, pp. 199–215, figs. 12*).—The author gives notes on the life history and damages resulting from the work of the forest tent caterpillar (*Clisiocampa disstria*) and the American tent caterpillar (*C. americana*). In the case of the latter insect, an efficient method of destroying the larvæ while in the tent was found to be the application of a small quantity of kerosene, being careful not to saturate the bark of the twigs. In one town in the State the school children were offered 10 cts. per hundred for the egg masses; 8,250 egg masses were collected at an expense of $8.25, which would seem an effective means of reducing the number of these caterpillars.

The antiopa butterfly (*Vanessa antiopa*) is reported as feeding in colonies on the elm trees and defoliating large branches. It is recommended that the branches infested with the caterpillars be cut off and the caterpillars crushed.

The fall webworm (*Hyphantria cunea*) was especially prevalent during the year. The branches upon which this larvæ are feeding should be removed from the tree and the larvæ crushed or burned. *Edema albifrons* caused considerable destruction to the leaves of various species of oak. The caterpillars were preyed upon extensively by the common ruffed grouse. Popular notes are given on the cecropia moth and on the luna moth.

The rose beetle (*Macrodactylus subspinosus*) committed depredations on young hydrangea shrubs. The most effective means of combating these insects seemed to be brushing them into a pail or pan containing water with a film of kerosene upon it.

Some experiments were made with regard to remedies for the cabbage worm (*Pieris rapæ*). One family is said to have been made ill by eating cabbage which had been sprayed with Paris green. Pyrethrum applied dry, either undiluted or thoroughly mixed with an equal quantity of flour, or applied as a decoction in the proportion of 1 oz. of pyrethrum to 1 gal. of boiling water, proved to be an efficient remedy and not dangerous to man.

The bean weevil (*Bruchus obtectus*) is said to have been especially injurious during the year. As a remedy it is recommended that the beans be inclosed in a tight vessel and fumigated with bisulphid of carbon.

Some pests likely to be disseminated from nurseries. The nursery inspection laws, H. GARMAN (*Kentucky Sta. Bul. 80, pp. 201–273, figs. 9*).—This bulletin contains a general account of spraying machinery and directions for making the standard insecticides. The author discusses a number of insects and fungus diseases which are likely to be introduced upon nursery stock and which are to be guarded against. Brief descriptions with recommendations as to the kind of treatment to be applied are given in each case.

The insects mentioned as especially injurious are: San José scale, woolly aphis, oyster-shell bark-louse, scurfy bark-louse, apple aphis, apple-leaf skeletonizer (*Canarsia hammondi*), apple-leaf crumpler (*Mineola indiginella*), apple-tree tent caterpillar, white-marked tussock moth, bagworm, cherry-tree aphis, black peach aphis, pear-leaf blister mite, and strawberry crown borer.

Of injurious fungus diseases the author mentions the following: Apple scab, apple-leaf rust, cherry leaf spot, currant-leaf spot, grape mildew, peach rosette, peach yellows, peach-fruit spot, pear blight, black knot, quince-leaf spot, raspberry anthracnose, and strawberry-leaf blight.

The law of Kentucky regarding inspection of nursery stock is reprinted, as well as forms of the various certificates.

Butterflies and moths injurious to our fruit-producing plants, O. LUGGER (*Minnesota Sta. Bul. 61, pp. 53-331, figs. 237, pls. 24*).—In the first 10 pages of the bulletin the author gives a brief account of the general and special anatomy of butterflies and moths, together with some details as to their classification, habits, life history, and metamorphosis. The remaining portion of the bulletin is occupied with economic and biological notes on about 170 species of butterflies and moths. The most of these species are figured, some in all their stages. The life history and the methods of artificial treatment which are most approved are mentioned in each case.

The bulletin constitutes a quite complete compendium of information on the subject of the common butterflies and moths which are known to attack fruit trees and fruit plants. An index is appended.

Two destructive orchard insects, V. H. LOWE (*New York State Sta. Bul. 152, pp. 277-301, pls. 3*).—*The apple-tree tent caterpillar*, pp. 277-297).—The bulletin contains a resume of the history of our knowledge concerning the apple-tree tent caterpillar, together with suggestions regarding its means of distribution, a list of its food plants, and technical descriptions of the egg, caterpillar, and adult. The caterpillars are said to molt 5 or, exceptionally, 6 times. Descriptions are given of the tent and the method and place of pupation.

Among the natural checks the author mentions cold weather and rain storms while the larvæ are just hatching, and a considerable number of species of birds were observed to feed upon them. Among predacious insects the author records *Calosoma scrutator*, *C. calidum*, and *Podisus spinosus*. Of the parasitic insects, *Telenomus clisiocampæ* attacks the eggs of the tent caterpillar, and the following species prey upon the larvæ: *Pimpla conquisitor*, *P. pedalis*, *P. annulipes*, *Theronia fulvescens*, *T. melanocephala*, *Spilocryptus* (*Cryptus*) *extrematis*, *Dibrachys baucheanus*, *Apanteles congregatus* var. *rufocoxalis*, and *Frontina frenchii*.

A bacterial disease is reported as having been especially prevalent during warm moist weather and to have destroyed numbers of the caterpillars. The author recommends the destruction of wild cherry trees and neglected apple trees and brush such as are fed upon by the caterpillars. Collecting the egg masses is also to be encouraged, and the caterpillars may be destroyed by spraying with arsenical poisons. Green arsenite at the rate of 1 lb. to 150 gal. of water was applied 3 times. The second application was usually sufficient to destroy nearly all the caterpillars. The arsenite of lime and Paris green were tried in a similar way and with equally good success. The caterpillars may readily be destroyed in their nests by saturating with kerosene and burning. A list of the more important publications concerning the tent caterpillar is appended to these remarks.

Spraying experiments against the spring cankerworm (pp. 298–301).—In the experiments against the spring cankerworm Paris green was used upon 1 plat which consisted of about 100 trees. The Paris green was applied 3 times at the strength of 1 lb. to 150 gal. of limewater. The first application was made as soon as the young caterpillars appeared, the second about a week later, and the third 4 days after the second. A second plat consisting of 14 trees was sprayed with green arsenite in the proportion of 1 lb. to 150 gal. of limewater. "Four days after the second application a very few live caterpillars could be found. The results were practically the same on the 2 plats."

In comparing these 3 arsenicals, the author remarks that the results were about the same with each. No damage was done to the foliage in any case, the effectiveness of all 3 poisons was about the same. Paris green is the more expensive of the 3. Arsenite of lime, which has the advantage that it can be made at home, costs about 3¾ cts. per barrel ready for use, while Paris green costs about 10 cts. per barrel of solution of proper strength and green arsenite about 5 cts. per barrel.

The potato-stalk weevil (*Trichobaris trinotata*), E. E. FAVILLE and P. J. PARROTT (*Kansas Sta. Bul. 82, pp. 12, figs. 15*).—The food plants of the stalk weevil besides the potato are *Solanum carolinense*, *S. rostratum*, *Xanthium canadense*, *Datura stramonium*, *Physalis longifolia*. The weevil is said to be more common in the last-named plant than in the potato. The various stages of the insect are figured and described. Egg laying commences the first of June; the larva hatches in about 10 days; the pupal stage lasts from 8 to 11 days, and there is but one brood per year. The adult passes the winter in the plant in which it has gone through with its transformations.

As remedies, therefore, the author recommends the destruction of all potato vines as soon as possible after the potatoes are dug, and also of the other food plants mentioned above. Spraying with Paris green or London purple is also quite successful. In small plats of potatoes the weevil may be captured by sweeping the vines with an insect net. The only parasite mentioned is *Sigalphus curculionis*.

Some comparative trials of insecticide pumps in relation to the treatment of tea blights, and experiments in the treatment of red spider, W. J. FLEET (*Indian Mus. Notes, 4 (1899), No. 3, pp. 113–117, pls. 2*).—The author used a number of patented dust blowers and spraying machines for the destruction of the red spider (*Tetranychus bioculatus*). A number of insecticides were used, and the best results were obtained with pure sulphur blown upon the bushes in the early morning before the dew was gone. The insecticide is cheap, easily applied, and very efficient.

Spray pumps and spraying, W. PADDOCK (*New York State Sta. Bul. 121, App., p. 8, figs. 2*).—The bulletin serves as a supplement to Bulletin 121 (E. S. R., 9, p. 262). It gives a description of the Kerowater machine for making a mechanical mixture of kerosene and water. The author calls attention to the advantages of a removable top to the spray barrel. Brief notes are given on the relative value of the copper sulphate solution, Paris green dissolved in ammonia, London purple, green arsenite, arsenite of lime, and the kerosene and water mechanical mixture. Injury to the leaves is said to result frequently from the use of the kerosene and water mechanical mixture as well as from the copper sulphate solution and Paris green dissolved in ammonia.

The State entomological department (*Meddel. K. Landtbr. Styr., 1898, No. 48, pp. 279–286, pl. 1, figs. 2*).—This is a brief report, accompanied with a photograph of the exterior and the plans of the interior of the entomological building and insectary.

Collecting insects, W. J. HOLLAND (*Pop. Sci., 33 (1899), No. 6, pp. 122, 123*).—Gives general directions and descriptions of apparatus.

Molting of insects as a means of defense, K. D'HERCULAIS (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 10, pp. 620–622*).—On account of the free casting off of the skin and lining of the trachea, it was found difficult to infect certain grasshoppers with fungus diseases.

Apiculture, J. PONS (*El Agricultor, 1 (1899), No. 3, pp. 6, 7*).

Bees and how to manage them, A. GALE (*Agr. Gaz. New South Wales, 10 (1899), Nos. 1, pp. 84–86; 2, pp. 194–196, pl. 1*).—Contains a detailed description of the Langstroth hive with direction for its use.

Demonstration of the sense of hearing in bees, SYLVIAC (*L'Apiculteur, 43 (1899), No. 5, pp. 204–206*).—Proved by the ordinary test of responding to the stimuli of various sounds.

Life in a winter bee cellar, G. E. WALSH (*Sci. Amer., 80 (1899), No. 23, p. 380*).—A plan for the management of bees in a winter cellar.

The Notre Dame beehive and wintering device, B. J. CHRYSOSTOM (*Amer. Bee Jour., 39 (1899), No. 24, pp. 369, 370*).—A description of the hive and records of temperatures taken at different times in the packing about the hives.

A second plan for ventilating bees, W. T. CRAWFORD (*Southland Queen, 5 (1899), No. 1, pp. 4–7*).—Details of a plan of construction of hives for the purpose of gaining the benefits of currents of air.

The advantages of preventing swarming by artificial means, R. PINCOT (*L'Apiculteur, 43 (1899), No. 5, pp. 198–202*).—Prevents the excessive production of drones and insures the collecting of a greater quantity of honey.

Comb honey, A. GALE (*Agr. Gaz. New South Wales, 10 (1899), No. 4, pp. 247–249, pls. 2*).—Gives directions as to arrangement of supers so as to get the most perfect comb honey.

Foul brood and its treatment, L. FORESTIER (*Rev. Internat. Apicult., 21 (1899), No. 5, pp. 92–98, fig. 1*).—The symptoms of the disease are described in detail. The remedies recommended are beta-naphthol and formic acid. The ordinary preventive measures are described.

Foul brood in Burgundy, F. Jules (*Rev. Internat. Apicult., 21 (1899), No. 4, pp. 68–74*).—A discussion of the predisposing causes of the disease, of the means of contagion, and of remedies to be applied.

On the properties of cocoons of the various silkworm races of Japan, J. Kawara (*Imp. Univ. Col. of Agr. [Tokyo] Bul., 3 (1898), No. 5, pp. 508–520*).—A report of an investigation of the ductility, strength, size, and other properties of silk thread from different races of cocoons.

A preliminary study of ticks, E. P. Niles (*Virginia Sta. Bul. 86, pp. 25–30, pls. 4*).—The bulletin contains technical descriptions and notes on the life history of the following species of ticks: The "Lone Star Tick" (*Amblyomma unipunctata*), the cattle tick (*Boophilus bovis*), the wood tick (*Dermacentor americanus*), the cattle tick of California (*D. occidentalis* and (*Ixodes ricinus*). All the species are figured as well as some of their anatomical details.

The systematic position of the Pulicidæ, R. Heymons (*Zool. Anz., 22 (1899), No. 588, pp. 223–240*).—From a detailed study of their anatomy and morphological relations, the author concludes that fleas should be considered an independent order, Siphonaptera.

Entomology, M. V. Slingerland (*Trans. New York State Agr. Soc., 1897, pp. 507–525*).—Brief notes on plant lice, pear psylla, apple-tree tent caterpillar, cankerworms, San José scale, and the quince curculio.

Insect pests, W. W. Froggatt (*Agr. Gaz. New South Wales, 10 (1899), No. 4, pp. 268–271, pls. 2*).—Notes on the fig-branch borer (*Hylesinus porcatus*) and the lucerne web moth (*Tortrix glaphyriana*).

The wood-boring insects of fruit trees, Schule (*Wchnbl. Landw. Ver. Baden, 1899, No. 5, pp. 50–52*).

Two apple pests and how to check them, F. H. Hall and V. H. Lowe (*New York State Sta. Bul. 152, popular ed., pp. 8, figs. 3*).—A popular summary of Bulletin 152 of the station (see p. 170).

Insect enemies of the peach, H. N. Starnes (*Georgia Sta. Bul. 42, pp. 225–229, figs. 7*).—Notes on nematode galls (*Heterodera radicicola*), peach borer (*Sannina exitiosa*), fruit-bark borer (*Scolytus rugulosus*), curculio (*Conotrachelus nenuphar*), and San José scale (*Aspidiotus perniciosus*).

Insect and fungus enemies of fruit trees and their remedies (*Agr. Gaz. New South Wales, 10 (1899), No. 1, pp. 26–31*).—A popular account of Phylloxera with suggestions as to remedies. Also contains a description of white rot, anthracnose, and sun scald.

The San José scale in Idaho, J. M. Aldrich (*Idaho Sta. Bul. 16, pp. 16, pls. 2, figs. 3*).—The bulletin contains a description of the scale and a popular account of its habits and life history. The insect has become established in Idaho at two points, Lewiston and Boise. The sulphur, lime, salt, and lye solution was applied with good success.

The San José scale (*Amer. Florist, 14 (1899), No. 574, pp. 1309–1311*).—Gives the opinions of a number of economic entomologists on the value of an inspector's certificate.

The San José scale, G. Staes (*Tijdschr. Plantenziekten, 4 (1898), No. 2, pp. 45–60, figs. 7*).—The author gives a description and illustration of the insect, together with an account of its life history and habits. Its parasites and other natural enemies are mentioned, and the chief remedies are discussed, among them fumigation and the various washes.

Asia as the home of the San José scale, K. Sajo (*Illus. Landw. Ztg., 96 (1898), No. 96, p. 967*).—Gives evidence for the belief that the San José scale originally came from Asia.

The home of the woolly aphis, J. JABLONOWSKI (*Rov. Lapok., 6 (1899), No. 2, pp. 27-36*).—The author gives evidence for the view that the woolly aphis is native to America.

Schizoneura lanigera on fruit trees (*Deut. Landw. Presse, 26 (1899), No. 41, p. 467, figs. 3*).—Figures and describes the insect with an account of the common insecticides.

The grass or harvest mite as a pest of field workers (*Deut. Landw. Presse, 25 (1898), No. 98, p. 1016*).—A popular account of the vexation caused by the presence of large numbers of this pest with mention of remedies to be used.

The red spider or spinning mite (Tetranychus telarius), G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 3, pp. 83-92, figs. 3*).—Contains a description of its method of attack upon plants with suggestions of a number of remedies, such as flowers of sulphur, liver of sulphur, kerosene emulsion, and lysol.

Biological observations on forest Hymenoptera, L. G. SEURAT (*Bul. Mus. Hist. Nat. [Paris], 1898, pp. 364-369*).—A longicorn beetle (*Callidium sanguineum*) which attacks the oak is preyed upon by the following hymenopterous parasites: *Doryctes gallicus, Helcon tardator*, and *Phytodictus corvinus*.

May beetles and white grubs, E. S. ZÜRN (*Fühling's Landw. Ztg., 48 (1899), No. 9, pp. 346-350*).—An account of the injuries caused by white grubs with a discussion of remedies. May beetles when cooked are said to be excellent food for cattle. The constituents of the body of the May beetle are tabulated from a chemical analysis.

Lepidopterological notes, O. J. LIE-PETTERSON (*Bergen Museum Aarbog, 1898, Afhand, No. 14, pp. 12*).—Gives notes on various butterflies.

Notes on butterflies with descriptions of new species, H. SKINNER (*Ent. News, 10 (1899), No. 5, pp. 111-113*).—New species of Pamphila are described with notes on their habits.

The orchid bug (Phytocoris militaris), G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 3, pp. 61-64, fig. 1*).—The insect is described and figured. Quassia chips are recommended as a remedy for preventing its injuries.

The orchid beetle (Xyleborus perforans), G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 4, pp. 93-97, figs. 3*).—The beetle is figured and an account is given of its injuries and of remedies to be recommended for use against it, among them being the burning of infested stems.

On the destruction of ground fleas, R. THIELE (*Ztschr. Pflanzenkrank., 8 (1898), No. 6, pp. 312-314*).—The remedies which were used against this insect were lime dust and tobacco dust with various sulphur preparations. A concentrated sugar and gum arabic solution was added to make the insecticides adhere.

The destruction of fruit pests, A. H. BENSON (*Queensland Agr. Jour., 4 (1899), No. 4, pp. 264-280, pls. 5*).—General directions are given for the preparation of the better known insecticides. For the convenience of horticulturists, insects are classified according to their habits, and an alphabetical list of fruit trees is arranged in parallel columns with the common diseases to which they are subject and the remedies to be applied.

The author gives a description of the method and apparatus for applying the gas treatment to living trees.

Cochylis and lantern traps, C. MESTRE (*Prog. Agr. et Vit. [Ed. L'Est], 20 (1899), No. 20, pp. 599-602*).—Notes on the use of the lantern trap and the cost of its operation.

Cyanid of potassium as an insecticide, H. DIXON (*Gard. Chron., 3. ser., 24 (1898), No. 625, pp. 432, 433*).—A brief discussion of its use and value for fumigation.

Insecticides and spraying calendar, S. T. MAYNARD (*Massachusetts Hatch Sta. Bul. 60, pp. 11*).—Gives directions regarding the choosing of spray pumps and nozzles and regarding the preparation of the following insecticides and fungicides: Paris green, arsenate of lead, kerosene emulsion, kerosene water, pyrethrum, hellebore, Bordeaux mixture, and copper sulphate solution.

A spraying calendar is appended to the bulletin and covers a number of the more common diseases of fruit and garden vegetables.

The rational destruction of insects attacking fruit trees, F. DECAUX (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), pp. 158–184, figs. 3*).—Notes on the use of insecticides and parasites for controlling injurious insects.

A practical and simple insect band for fruit trees, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 2, pp. 35–44, figs. 9*).—A description with figure of a tarred paper band to be used against various fruit enemies.

Experiment with benzolin, D. G. JONKSEN (*Ztschr. Pflanzenkrank., 9 (1899), No. 1, pp. 29*).—Benzolin was used for the destruction of phylloxera without success.

The timely plowing under of stubble fields and its influence upon certain diseases of cereals, J. R. BOS (*Tijdschr. Plantenziekten, 4 (1898), No. 5, pp. 135–146*).—Mentions the effect of plowing under stubble fields at the right time upon the grain aphis, Hessian fly, and frit fly.

FOODS—ANIMAL PRODUCTION.

The nutritive value of soldiers' bread, K. PANNWITZ (*Der nahrwerth des Soldatenbrotes. Inaug. Diss. Berlin, 1898, pp. 123*).—A large number of experiments with men are reported on the digestibility of army bread made from rye flour containing 15 per cent bran; bread from coarse decorticated rye flour containing 7.5 per cent bran; bread from decorticated rye flour containing 15 per cent bran; bread from finely ground decorticated and undecorticated rye flour containing different amounts of bran, from finely ground wheat, and from finely ground bran; pumpernickel; and bread made from rye soaked and crushed without grinding. The principal conclusions were that ordinary army bread may be improved by removing the outer covering of the grain, even if the resulting flour is not more finely ground than at present. If finer grinding is practiced there is a still further improvement possible, since by the use of finer sieves the percentage of bran may be diminished from 15 to 25 per cent. Removing the outer covering of the grain has less effect upon the digestibility than the fineness of grinding and the amount of bran. The more completely the bran is removed the better the flour. Even if finely ground, bran is not a satisfactory food for man. Coarse breads are not regarded as satisfactory for feeding large numbers of persons, especially soldiers.

Beef cattle and swine, T. SHAW (*Minnesota Sta. Bul. 60, pp. 54, figs. 4*).—Tests are reported (1) on the possibility of profitably fattening steers in Minnesota; (2) on fattening range steers; and (3) on raising pork.

Growing beef in Minnesota (pp. 1–20).—To test the truth of the belief that steers can not be profitably fattened on farms in Minnesota in competition with western ranges, the author fed 2 calves from birth until about 30 months old. The foods selected were such as could be secured on any farm, and the care and management such as could be easily given by farmers in general. The calves chosen were a cross of grade Shorthorn cows and Shorthorn bulls. They were dropped in the fall. When taken from the cows they were fed new milk and later skim milk, meal, hay, ground corn, sorghum silage, and roots, and were pastured during the summer months. The grain ration included bran, oats, corn, barley, wheat, and oil cake. These were all ground and fed in such combinations as seemed desirable. The hay consisted chiefly of clover with a little timothy. The feeding stuffs were valued at market prices which varied considerably during the experimental period. The food consumed by the steers until 1 year old, between 1 and 2 years old, and after reaching the age of 2 years, is recorded. At the close of the test they were slaughtered and judged by experts. One steer was valued at $4.75 and the other at $4.40 per 100 lbs. Including the value at birth, the entire cost of raising one steer was $45.17 and the other $40.21. When slaughtered, the weights, making allowance for a shrinkage of 3 per cent, were 1,392 and 1,280 lbs., respectively. The profit on the first steer was $20.95 and on the second, $16.11. "But little fat was laid on externally, and the percentage of internal fat was not high. The outcome in the carcasses was not far different." The meat of both carcasses was of a very superior quality. "Throughout the loin and rib cuts and also in other parts of the carcass the admixture of the fat and lean . . . was . . . perfect. Particles of fat of more or less size flecked the lean in all the best cuts."

The principal conclusions from the test follow:

> "Since the steers were sold for $37.06 above the cost of production, under the conditions stated, it is just to conclude that a good profit can be made from growing beef in Minnesota, even when grown on the intensive plan.
>
> "The method of growing meat thus is applicable to average farm conditions in the State, since the foods fed may all be produced on the farm, except the bran and oil cake. The quality of meat thus grown is of the very best, and should therefore command the highest price in the market.
>
> "In growing beef as in this experiment, the farmer can get much better values for the food products which he grows by feeding them at home than by selling them directly."

Fattening range steers in winter (pp. 21-38).—A test was made with 9 steers, the principal object being to compare results obtained from fattening on large and smaller quantities of grain and to "gather information as to the behavior of range steers while under full feed."

After a preliminary period of 9 days, the test proper began November 15, 1897, and covered 194 days. The steers, which were part of a lot purchased in Montana, were about 2 years old, and showed Shorthorn-Hereford and Aberdeen-Poll blood. They were divided into 3 lots of 3 each. It was the author's intention to feed lot 1 a light grain ration, lot 3 a heavy grain ration, and lot 2 an intermediate grain ration. The grain consisted of bran, barley, and corn in different proportions. It was not possible to complete the experiment on these lines, and the gains made by the individual steers are recorded.

The financial statement is based on bran at $7.50, oil cake at $22, mixed hay at $4, and corn silage at $1.25 per ton; barley at 18 cts., and corn at 22 cts. per bushel. The value of the steers at the beginning of the test was $2.69 per 100 lbs., and at the close $4.62½. The average weight at the beginning was 1,038, and at the close 1,317 lbs. The average daily consumption of meal per steer during the entire period of feeding was 12.19 lbs., the average daily consumption of food being 23.89 lbs., and the average cost of food per pound of gain was 5.92 cts. The net profit on feeding the 9 steers, deducting the freight, was $141.54. Some of the steers were very restless when tied in stalls, and the author believes that range steers are not very suitable for fattening in this way. The tests are discussed at some length and compared with earlier work of the station.

Feeding pigs of different grades (pp. 39–54).—In the author's opinion, it is desirable to breed pigs which shall have the characteristics of the so-called bacon hog; that is, the carcass shall not show an excessive amount of fat. In his opinion, such pigs may be secured by selection and by crossing.

A test, which began July 13, 1896, and covered 112 days, is reported with 6 first cross Yorkshire-Tamworth pigs and with 6 second cross pigs of the same breed. The special object of the test was to compare the relative merits of first and second crosses from Improved Yorkshire sires for fattening, and to compare corn and barley as foods for pigs. The pigs were divided into 4 lots of 3 each, lots 1 and 3 being made up of pigs of the first cross and lots 2 and 4 of pigs of the second cross. All the pigs were 108 days old when the test began. The test was divided into 3 periods of 28 days. In the first period, lots 1 and 2 were fed oats and corn 3:1; during the second period, the same foods in equal parts; and during the third period, in the proportion of 1:3. During the fourth period, corn only was fed. The rations fed lots 3 and 4 were similar except that barley was substituted for corn. The grain was fed ground and was soaked in water 6 or 12 hours before feeding. The pigs were given all they would eat up clean with a relish. They were given green food in season, either corn, second growth clover, rape, or cabbage.

The financial statement is based upon oats at 14 cts., barley at 16 cts., corn at 18 cts. per bushel, and green food at 75 cts. per ton. An allowance of 5 cts. per sack was made for grinding the grain. At the close of the test the pigs were sold for $3.15 per 100 lbs. The results, which are recorded in detail for the different lots and different periods, are summarized in the following table:

Results of feeding barley and corn to cross-bred pigs.

	Food consumed.				Weight at beginning.	Gain in weight.	Cost of food per pound of gain.	Profit.
	Oats.	Corn.	Barley.	Green food.				
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Cents.*	
Lot 1 (corn)	414	980	....	322	247	354	1 65	$5.68
Lot 2 (corn)	449.5	1,033.5	....	297	275	328	1 89	4.53
Lot 3 (barley)	570	....	808	267	247	279	1.83	4.04
Lot 4 (barley)	458	....	826	297	279	288	1.96	3.94

The conclusions are as follows:

"Because of the low relative gains made by the pigs in all the lots during the first period of feeding and because of the relative increase in the gains subsequently as the proportion of the oats fed was lessened, the conclusion would seem to be legitimate that a diet in which oats is a predominant factor is not the most suitable one than can be fed to pigs while being grown and fattened.

"[Owing to] the low consumption of food by the pigs to which barley was fed, the conclusion would seem to be legitimate that the free use of barley long continued in growing and fattening pigs tends to weaken the appetite at least to some extent.

"[On account of] the low gains made by pigs to which barley was fed, the conclusion would seem to be fair that a barley diet long continued is not quite so well fitted to make increase in weight as a corn diet, the other adjuncts being the same as in the experiment.

"Since the pigs of the first cross made somewhat better gains and on less food than those of the second cross this experiment favors the view that they were a little more easily kept.

"Because of the smallness of the difference in the relative gains of the animal of the two respective crosses, the experiment does not prove that one cross, as such, has any superiority over the other in capacity to make gains.

"With the prices of food and meat as in the experiment, 100 lbs. of pork may be produced at a cost of $1.83 and yielding a profit of $1.32."

The cost of raising calves, F. W. MORSE (*New Hampshire Sta. Bul. 58, pp. 157-166*).—To secure data in regard to the cost of raising a dairy cow, the amount and cost of food consumed by a number of calves from the time they were weaned until 16 months old were recorded, as well as statistics of the breed, ages, weights, and weekly gains. The records include statistics of 13 animals and cover all seasons of the year. The financial statement is based on the following prices per 100 lbs.: Milk $1, skim-milk 20 cts., flaxseed $3.25, middlings 80 cts., bran 70 cts., linseed meal $1.25, oats $1, oatena 65 cts., mixed grain (middlings, oat feed, and linseed meal 2:2:1) 90 cts., hay 50 cts., and green barley fodder 15 cts.

It was found that 8 calves under 5 weeks old made an average weekly gain of 7.6 lbs. at a cost of 40.6 cts.; from 5 to 9 weeks the average weekly gain was 9.1 lbs. and the cost 36.7 cts. The same number of calves from 9 to 13 weeks old made an average weekly gain of 11.8 lbs. at an average cost of 43.1 cts. Eight calves from 13 to 20 weeks old gained per week on an average 10 lbs. at a cost of 52.9 cts.; 6 calves from 4 to 8 months old made an average weekly gain of 11.1 lbs. at a cost of 63.7 cts.; 2 calves from 8 to 13 months old made an average weekly gain of 5.25 lbs. at a cost of 58.3 cts.; 4 heifers 13 to 16 months old made an average weekly gain of 6.12 lbs. at a cost of 65.1 cts. per week; 4 of the heifers were maintained on pasture from July 24 to October 26, 1897, and the total gain in weight of the 4 animals was 313 lbs.

The author discusses the results in detail, quoting the work of other stations:

"During the feeding periods . . . comparisons were made between cooked ground flaxseed and cooked middlings as a substitute for the fat in milk, and also between rations including the cooked food and those without it.

"[In one trial] the calves were between 5 and 8 months old and the middlings proved to be a satisfactory substitute for the ground flaxseed, the cost being less and the gain in weight large enough for the purpose, though a little smaller than on the flaxseed.

"The calves [in another trial] were also over 5 months old. The substitution of the dry grain lessened the cost, and the gain was sufficiently large, although smaller than in the previous period.

"These trials show that for calves at the age of those described there is no object in using anything but dry grain and hay along with the skim milk, unless the greatest possible amount of growth is desired.

"[The cost of rearing a calf dropped October 1 is calculated as follows:] For 5 months, or 21⅗ weeks, the cost according to our own data would be 44.2 cts. per week, or $9.57. For the next 3 months, or 13 weeks, our data would make the cost 63.7 cts. per week, or $8.28.

"The pasture season would now be at hand and continue for 5 months, and the cost would vary with the location. The figures that we have obtained for calves range between $1.50 and $2.50 for the season.

"The remaining 3 months would cost according to our data 65.1 cts. per week, or $8.46 for the 13 weeks. The total cost for the food consumed by the heifer during the 16 months would then be $28.81 and she would weigh from 600 to 700 lbs. . . .

"In conclusion . . . high-priced foods, viz, whole milk, flaxseed, linseed meal, and oats, will cause the cost of the weekly ration to increase out of proportion to the gain, if fed freely. Flaxseed can not be used with economy except in the earliest stages of growth, the first 2 or 3 months, and whole milk should be discontinued as soon as possible."

Fattening lambs and wethers in winter, T. SHAW (*Minnesota Sta. Bul. 59, pp. 511–560, figs. 3*).—A number of tests made during the winters of 1896–97 and 1897–98 on fattening lambs and wethers are reported. They include the following topics: Fattening home-grown lambs, potatoes and field roots as food factors in fattening lambs, and fattening range wethers.

Fattening home-grown lambs (pp. 511–526).—Two tests are reported. The first was made with 10 wethers bred from pure bred Dorset sires and common-grade dams. They were grown on the station farm and had been fed almost entirely on summer forage other than grass. They had grazed with their dams from May 1 until about November 1, neither receiving any grain the greater portion of the season. After a preliminary period of 14 days, the test proper began November 23, 1896, and covered 16 weeks. The lambs were fed a grain ration consisting of oats, bran, barley, and oil cake, 3:3:3:1, together with native hay of poor quality, and mangel-wurzels and carrots in about equal parts. The grain was fed unground and the hay uncut. They received all the hay and grain they would eat up clean, and what in the author's opinion was a liberal allowance of roots. They had access to a shed and yard with a southern exposure.

The financial statement is based on bran at $6.50, oil cake at $14, and native hay at $3 per ton; corn at 18 cts., barley at 16 cts., and oats at 14 cts. per bushel; and roots at 9 cts. per 100 lbs. The average weight of the lambs at the beginning of the preliminary period was 90 lbs., at the beginning of the experiment proper 93.2 lbs., and at the close 134.2 lbs. During the test proper the average amount of food consumed per lamb per day was 5.09 lbs. Shortly after the close of the test the lambs were sold and slaughtered. They were valued at $3.50 per 100 lbs. at the beginning of the test and were sold for $5.50 per 100 lbs. The total profit per lamb was $2.43. In the opinion of experts, the mutton was of high excellence. Notwithstanding its high finish, the proportion of lean to fat was unusually large and the blending or intermingling of fat and lean was very satisfactory.

The principal conclusions drawn from the test were that "it is possible to so fatten lambs that the finish will be of a high order without unduly loading them with fat."

"Such a diet [as given] is eminently adapted to the production of large gains, since during the experiment proper it produced monthly 11 lbs. of increase. Such a ration is also eminently adapted to sustaining the ratio of increase during a long feeding period, since the lambs gained about as much during the last part of the feeding period as during the first part. It is admirably adapted to the cheap production of mutton, since 100 lbs. of increase was made during the entire period of feeding at a cost of but $3.41. The growing of lambs on forage other than grass pastures leaves them in a fair condition for being successfully fattened."

The second test, which was made with 9 lambs (all wethers but one), began November 15, 1897, and covered a period of 112 days. The lambs were dropped at the station farm in the spring of 1897, and were what remained after the best had been sold or selected for breeding purposes. "They were not really culls, but they were under the average of well-grown farm lambs. Nearly all of them were from a Dorset sire and grade ewes."

The lambs were confined in a shed with a yard and were fed a grain ration consisting of oil cake, bran, barley, and oats, 1:2:3:4. In addition they were given clover and timothy hay, the former predominating, and during the last 70 days of the test sorghum silage in addition. The barley and oats were fed whole; the hay was uncut. The lambs were given silage in the evening only; all other foods twice a day. This lot was compared with range lambs fed in a similar way (E. S. R., 6, p. 576).

The financial statement is based on oil cake at $22, wheat bran at $7.50, hay at $4, and silage at $1.20 per ton; barley at 20 cts. and oats at 17 cts. per bushel.

The average weight of the lambs at the beginning of the test was 72.5 lbs.; the average gain per lamb, 34.9 lbs.; and the cost of a pound of gain 4.07 cts. Shortly after the close of the test the lambs were sold and slaughtered. They were valued at $3.41 per 100 lbs. at the beginning of the test and $5.50 at the close. The total profit per lamb was $1.83, or 28 cts. more than was obtained with the range lambs fed in a similar way. "The explanation is found in the greater weight of the home-bred lambs at the beginning of the experiment and the increase in value put upon the original weight by fattening the lambs. And this result is probably the most important fact to be emphasized in the bulletin."

Potatoes and field roots as food factors in fattening lambs (pp. 527–537).—The value of potatoes and roots for fattening lambs was tested with 36 lambs divided into 3 lots of 12 each. They were the culls of a carload purchased in Montana. After a preliminary period of 7 days the test proper began November 22, 1897, and closed February 28. All the lambs were fed a grain ration consisting of equal parts by weight of corn, barley, and oil cake, with uncut clover and timothy hay in addition, the clover predominating. In addition lot 1 was fed potatoes, lot 2 mangel-wurzels, and lot 3 sugar beets. The potatoes and roots were sliced and fed with the grain, which was unground. The lambs were fed twice a day. They were gradually led up to a full ration and were given all the grain they would eat up clean.

The financial statement is based on hay at $4 and oil cake at $22 per ton, corn at 22 cts., barley at 20 cts., potatoes at 20 cts., mangel-wurzels at 5 cts., and sugar beets at 5½ cts. per bushel. The lambs were valued at $3.34 per 100 lbs. at the beginning of the test, and were sold for $5 per 100 lbs. (shrunk weight) at the close.

The 3 lots consumed practically the same amounts of grain, hay, and roots. The principal results of the test are shown in the following table:

Results of feeding potatoes and roots to lambs.

	Average weight per lamb at beginning of preliminary period	Average weight per lamb at beginning of test proper.	Average gain per lamb.	Food consumed per lamb per day.	Cost of food per pound of gain.	Total profit per lamb.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Cents.*	
Lot 1, potatoes	49.6	50.6	32.9	3.52	4.94	$0.86
Lot 2, mangel-wurzels	49.8	50.8	30.6	3.52	4.20	1.07
Lot 3, sugar beets	49.6	50.6	34.6	3.57	3.78	1.24

The conclusions drawn from the test were the following:

"Lambs of but indifferent development may be fed at a substantial profit with food and meat at the values named in this experiment.

"In feeding lambs, potatoes compare favorably with mangel-wurzels and sugar beets in producing increase in weight, but they are more costly food than the roots named. Because of the greater cost of potatoes as compared with mangel-wurzels and sugar beets, they should not be grown as food for lambs where the latter can be grown successfully.

"Judging by the results obtained in this one experiment, sugar beets are a more valuable food for fattening lambs than either potatoes or mangel-wurzels."

Fattening range wethers (pp. 538–560).—Two tests are reported on fattening range wethers. The first began November 16, 1896, and covered 84 days. It was preceded by a preliminary period of 6 days, and was made with 20 wethers selected from a carload purchased in Montana. They were grades, Merino blood predominating, and were from 1 to 3 years old. They were given a grain ration of oil cake, bran, and corn, and oats, 1:2:3:4, and in addition native hay of unsatisfactory quality.

The financial statement is based on oil cake at $14, wheat bran at $6.50, and native hay at $3 per ton; corn at 18 cts. and oats at 14 cts. per bushel. The average weight of the wethers at the beginning of the test was 116.8 lbs., and at its close 140.3 lbs. They were valued at $3.37 per 100 lbs. at the beginning of the test and at $4 per 100 lbs. at the close. The average net profit per wether during the test was 36 cts.

The results obtained in feeding wethers were compared with those from feeding lambs. The greater profit in the case of the lambs in the author's opinion was due to the greater gains made by them, and also to a relatively greater advance in the value of the product. "If as much profit is to be made from feeding wethers as from feeding lambs, it would seem to be necessary to buy them at a considerably smaller price per 100 lbs."

The second test, which was preceded by a preliminary period of 6 days, began November 8 and covered 87 days, 20 wethers selected from a carload purchased in Montana being used. They were regarded as somewhat better than the average range wethers, though inferior to those raised on the farm. They were fed a grain ration consisting of oil cake, wheat bran, corn, and oats, 1:2:3:4, with clover and timothy hay, the former predominating. During the latter part of the test sorghum silage was also fed. The corn and barley were unground and the hay uncut. The wethers were fed all they would eat up clean. This lot was compared with the lambs described in a previous publication (E. S. R., 10, p. 576).

The financial statement is based on oil cake at $22, wheat bran at $7.50, hay at $4, and sorghum silage at $1.20 per ton; corn at 22 cts., barley at 20 cts., and oats at 17 cts. per bushel. The wethers were valued at $3.80 per 100 lbs. at the beginning of the test, and were sold for $4.50 per 100 lbs. shrunk weight. The average weight at the beginning of the test was 117 lbs. and at the close 150 lbs. The average amount of food consumed per day was 5.27 lbs.; and the cost of food per pound of gain 4.83 cts. The profit per head was $2.30. The principal conclusions follow:

> "When wethers and lambs are bought at the same price per pound and are fattened under similar conditions, the lambs are likely to bring considerably more profit. This increased profit is likely to arise first, from the greater relative advance at which the lambs will probably be sold, and second, from the greater relative gains which the lambs are likely to make on a given amount of food.
>
> "This profit may be expected to increase with the decrease in the difference between the weight of the wethers and lambs respectively at the time of purchase, because of the influence which weight at the beginning of an experiment exercises upon any advance made in mutton values."

Alfalfa hay for fattening hogs (*Kansas Sta. Press Bul. 25, p. 1*).—A test of the value of alfalfa hay for pigs is briefly reported. Forty pigs, weighing on an average about 125 lbs., were divided into 4 lots of 10 each. Lot 1 was fed dry Kafir-corn meal and alfalfa hay, lot 2 whole Kafir corn, lot 3 dry Kafir-corn meal, and lot 4 wet Kafir-corn meal. The alfalfa hay was of the best quality and carefully cured. It was fed dry in a large feeding trough. The pigs were confined in large pens with open sheds. The test began November 24, 1898, and covered 9 weeks. Lot 1 gained 90.9 lbs. or 10.88 lbs. per bushel of dry corn meal and 70.83 lbs. of alfalfa; lot 2 gained 59.4 lbs. or 8.56 lbs. per bushel of grain; lot 3 gained 52.4 lbs. or 7.48 lbs. per bushel of grain; and lot 4 gained 63.3 lbs. or 8.09 lbs. per bushel of grain.

"These results are not due to the feeding value of the alfalfa alone, but also to its influence in aiding the hogs to better digest the Kafir corn. The alfalfa hay also gave a variety to the ration, making it more appetizing and inducing the hogs to eat more grain. . . . The hay-fed hogs ate more grain and gained more for each bushel eaten.

"In a former experiment at this college pigs were pastured through the summer on alfalfa with a light feeding of corn. After deducting the probable gain from the corn, the gain per acre from the alfalfa pasture was 776 lbs. of pork.

"These facts indicate that to produce pork most cheaply the Kansas farmer must have alfalfa pasture in summer and alfalfa hay in winter."

Silage for horses, D. O. NOURSE (*Virginia Sta. Bul. 80, pp. 97, 98*).—In view of the scarcity of forage crops in some parts of Virginia, the author made a number of tests in which corn silage was fed to 2 horses and 6 mules. The animals were given small amounts of silage for some weeks before the test proper. After the preliminary period they were fed for 6 weeks all the silage they would eat, with hay and corn in addition. The amounts of food consumed and the weights of the animals are recorded. The silage was not as readily eaten by horses as by cattle and in the author's opinion horses, after becoming accustomed to silage, eat no more than they can easily assimilate.

Some trouble has been reported in feeding silage to horses. The author believes this may be attributed to feeding too large quantities at the start. In his own tests—

"There was no falling off in flesh and this though all the animals were constantly at work, except during stormy weather. They all made gains in weight, but those fed silage, corn, and hay, and the others fed corn and hay alone, gained about equally, so this fact amounted to nothing except an indication of good health. As a whole it would appear that silage would make good coarse fodder for horses when used in connection with hay or stover and grain, but that the animal should become accustomed to the food by degrees, and that this is as important as when changing from old to new corn, or from hay to grass."

Culinary encyclopedia, C. H. SENN (*London: Spottiswoode & Co., 1898, pp. 96*).—This is a revised and improved edition. The names of foods, utensils, condiments and beverages, and technical terms pertaining to them are defined.

Plain words about food, ELLEN A. RICHARDS (*Boston: Home Science Publishing Co., 1899, pp. 176; rev. in Amer. Kitchen Mag., 11 (1899), No. 31, p. 121*).

Diet in ancient times, J. MARCUSE (*Ztschr. Diätet. u. Phys. Ther., 2 (1898), No. 3, pp. 222–238*).—A historical study.

Researches on bread, E. PODA (*Abs. in Jour. Hyg., 24 (1899), No. 1177, p. 117*).—A study of the comparative value of wheat and rye bread.

Mushrooms as food, C. F. Langworthy (*Plant World, 2 (1899), No. 8, pp. 134–136*).—A popular summary of the subject pointing out the fact that mushrooms have very little food value, but are valuable as condiments.

On the value of sugar for the production of energy by man, Schumburg (*Ztschr. Diätet. u. Phys. Ther., 2 (1898), No. 3, pp. 185–188*).

The value of sugar as a nutrient, Chauveau (*Bul. Med., 1898, Mar. 23; abs. in Ztschr Diätet. u. Phys. Ther., 1 (1898), No. 4, pp. 259, 260*).

Effect of alcohol on metabolism in man, R. Rosemann (*Ztschr. Diätet. u. Phys. Ther., 1 (1898), No. 2, pp. 138–155*).

The function of water in metabolism and in the feeding of man, A. Dennig (*Ztschr. Diätet. u. Phys. Ther., 1 (1898), No. 4, pp. 281–299, dgms. 4; 2 (1898), No. 4, pp. 292–323, figs. 7*).—A number of experiments are reported in which the balance of income and outgo of nitrogen was determined.

Digestion and assimilation of nursing infants in health and disease, together with the rational method of feeding infants, L. de Jager (*Die Verdauung und Assimilation des gesunden und kranken Säuglings, nebst einer rationellen Methode zur Säuglingsarnährung. Berlin: Oscar Coblentz, 1898, pp. 43; abs. in Hyg. Rundschau, 9 (1899), No. 9, pp. 466, 467*).

The nutritive value of the food constituents for infants, A. Vanderpoel (*New York Med. Jour. 1898; abs. in Ztschr. Diätet. u. Phys. Ther., 2 (1898), No. 4, pp. 335, 336.*)

Food adulteration, Carmody (*Proc. Victoria Inst. Trinidad, 1899, pt. 3, pp. 197–212*).—A paper (with discussion) read before the Victoria Institute.

Boron food preservatives and their influence on the human organism (*London: Perkins, Bacon & Co., Ltd., pp. 63*).

Digestibility of protein preparations, Vis and G. Treupel (*München. Med. Wchnschr., 45 (1898), No. 9; abs. in Ztschr. Diätet. u. Phys. Ther., 1 (1898), No. 1, pp. 83, 84*).

Gains in body weight and the transformation of fat into glycogen, Bouchar (*Semaine Med. Paris, 18 (1898), Oct. 19: rev. in Ztschr. Diätet. u. Phys. Ther., 2 (1898), No. 3, pp. 246, 247*).

General animal production, L. Hoffmann (*Allgemeine Thierzucht. Stuttgart: E. Ulmer, pp. XVI + 547, figs. 25*).—The subtitle states this is a text-book and handbook for students, and for practical use.

Calculating the rations of animals, G. Martinet (*Fed. Soc. Agr. Suisse Romande, pp. 16*).—A general discussion of the subject.

A new system of pasturing sheep, T. Shaw (*Minneapolis, Minn.: Northrup, King & Co., 1898, pp. 17, figs. 9*).—On the basis of investigations carried on at the Minnesota Station the author advocates growing forage crops for sheep.

On the care of horses, F. Pogson (*Proc. Victoria Inst. Trinidad, 1899, pt. 3, pp. 274–284*).—A general article (with discussion) read before the Victoria Institute.

DAIRY FARMING—DAIRYING.

The effect of food on the quality of milk, E. O. Arenander (*Nord. Mejeri Tidn., 14 (1899), Nos. 6, pp. 76, 77; 7, p. 91*).—Analyses of about 2,000 samples of milk delivered at creameries in Norrland (Sweden) were made at the chemical plant-biological station at Luleå and published in the report of the station for 1897. The results show in a striking manner that the fat content of milk may be reduced 1 to 2 per cent below normal by scant feeding. During the period from January to May, Norrland cows are in general fed only a meager allowance of marsh hay or old stock hay, and hence are in a very poor condition when turned out on pasture in June. The results of the analyses published point clearly to three periods of feeding, namely, (1) pasture

(June to September), (2) ample stable feeding (October to December), and (3) scant stable feeding (January to May). The variations in the fat content of the milk during these periods are shown in the following table:

Fat content of milk as affected by quantity of food.

Period.	Variations in fat content.		
	Maximum.	Minimum.	Average.
	Per cent.	*Per cent*	*Per cent*
1 (June to September), pasturage	5.0–5.8	2.65–2.9	3.71–4.25
2 (October to December), ample stable feeding	4.1–4.2	2.30–2.9	3.32–3.52
3 (January to May), scant stable feeding	4.0–4.6	1.10–1.9	3 20–3.30

The average fat content for the year was 3.35 per cent. The author concludes that the fat content of milk can not be increased at will by increasing a normal ration, but on the other hand that it can be greatly decreased by scant and poor rations. If a change is made from a deficient to a normal ration the fat content of the milk will again be raised to the limit determined by the inherent qualities of the individual cow.

The high fat content of milk from cows on pasture is considered remarkable, and is attributed in part to the effect of the healthful summer climate of northern regions.—F. W. WOLL.

Do cows of mountain breeds yield milk richer in fat than those of other breeds? P. HELLSTRÖM (*Landtmannen, 10 (1899), Nos. 16, pp. 217–254; 17, pp. 268–272*).—While the mountain breed of northern Sweden produces considerably richer milk (0.2 to 0.9 per cent) during the summer months than cows in southern or middle Sweden, the average percentage of fat in the milk for the whole year is very nearly the same in both regions. It is shown, however, that all cows in the northern latitude behave similarly in this respect, irrespective of breed. The author concludes that the power of producing rich milk must be considered an individual rather than a race characteristic, and that since the pure Swedish mountain breed produces on the average less fat during the year than the common mixed breed, the latter is, on the whole, the more profitable breed.—F. W. WOLL.

State and municipal milk legislation, A. T. NEALE (*Delaware Sta. Bul. 43, pp. 15–19*).—The hardship which the milk inspector of Philadelphia works to the farmer is illustrated by several cases in which milk, containing over 3.6 per cent of fat and over 12.3 per cent of solids, was condemned as below the standard in solids-not-fat (9.5 per cent). This standard appears to be an arbitrary one adopted by the city inspector, who holds that milk below it has been watered, and uses it as "the factor by which the percentum of adulteration is determined."

The variations which may result between night's and morning's milk where the interval between milkings differs considerably, is shown by the record of a cow. If the farmer sells milk to the city retail trade, "it is absolutely essential that the intervals between daily milkings shall be as nearly equal in length as is possible, for by this means only can he obtain a daily output uniform in quality."

A discussion of farm dairy methods, G. H. TRUE (*Michigan Sta. Bul. 167, pp. 113–126, fig. 1*).—A popular discussion of different methods of creaming milk, handling cream, and packing and printing butter, in which various tests made at the station are noted.

A comparison of deep setting in standing water and in running water at the same temperature showed no difference in the efficiency of creaming. Milk was set in deep cans immediately after milking, a half hour after, and one hour after, the water in all cases being at the same temperature and the milk never above 36° F. The fat content of the skim milk in the three cases was 0.216, 0.25, and 0.26 per cent, respectively. Tests of two separators at different rates of speed are briefly reported. Two trials comparing setting in shallow pans, cold deep-setting, and separating by means of a hand separator showed a saving of from 8 to 20 per cent of butter in favor of the separator method, with but little difference between the other methods. Creaming by dilution was tested in a 2-weeks' trial of a can known as the Wheeler Cream Separator. The average loss of fat amounted to 0.7 per cent; the skim milk being diluted about ½ with water could not be fed to advantage, and the cream soured rapidly. With churns filled ¼, ½, and ¾ full, other conditions being uniform, the time required for churning cream averaged 34, 56, and 64 minutes, respectively. The loss of fat in the buttermilk was practically the same in each case.

A strange property of the fat globules of milk, H. ATWOOD (*West Virginia Farm Review, 7 (1899), No. 5, pp. 129–132*).—A number of churning experiments are reported with cream from deep setting which was cooled to different temperatures and either held there for some time or churned almost immediately. Where the cream was cooled too rapidly or was not held at the low temperature a sufficient time "the globules in the cream were still too soft for good results, and this explains the reason for the larger amount of fat left in the buttermilk and the shorter time required for churning." This result was verified in a number of other experiments.

"The hardness of the fat globules of milk at any particular time does not depend entirely upon the temperature of the globules at that time, but is influenced materially by the previous temperature of the globules. In other words, the hardness or softness of the fat globules changes more slowly than the change in temperature of the milk or cream when this change is somewhat rapid."

Construction of cheese-curing rooms for maintaining temperatures of 58 to 68° F., F. H. KING (*Wisconsin Sta. Bul. 70, pp. 29, figs. 13*).—Reference is made to the previous studies of the station on the effect of temperature on the ripening of cheese (E. S. R., 10, p. 787), and records are given of the temperature of the soil and ground water and of the air in Wisconsin. In papers read before the Wisconsin Cheese

Makers' Association in 1893 and 1897 the author called attention to the possibility of utilizing the lower temperature of the subsoil and of the ground water for the purpose of cooling curing rooms. Since that time a number of factories in the State have been equipped with subearth ducts, either horizontal or vertical. A number of these are described and records given of their operation and effectiveness. Experiments are briefly noted in using an air blast for drawing air from a well and cooling a lecture room in the university.

. Advantage may be taken of the night air for cooling curing rooms when the temperature is sufficiently low. For this purpose the air should be taken in through a wind funnel rising not less than 15 ft. above the ridge of the roof of the factory. The employment of horizontal or vertical subearth ducts is regarded as more satisfactory. The horizontal duct should be at least 12 ft. below the surface and at least 100 ft. long, being connected at its outer extremity with a vertical flue, terminating in a funnel about 50 ft. in height. The duct may be constructed of a single line of large tile, but the author recommends either 3 rows of 10-in. drain tile or 5 rows of 8-in. tile, the cost being about the same for both sizes. These may be placed side by side, or the ditch may be dug narrower and deeper and the tile placed one above the other. The flue may be made of plank, with an opening 12 in. square, or of galvanized iron tubing 12 in. in diameter. The latter is regarded as preferable, as it is essential that the flue should be perfectly tight.

In cooling by vertical subearth ducts, a well 25 to 30 ft. deep should be dug, where the water is sufficiently far below the surface, and the flue communicating with the funnel should extend to the bottom of the well, where it leads into a series of 13 lines of 6-in. drain tile or 5-in. galvanized iron conductor pipe, which communicates with the curing room. The earth is packed firmly between the pipes to facilitate the cooling. Where it is not practicable to go deeper than 15 or 20 ft. without striking water, sandy soil or fine sand may be filled in around the air flues, and this wet once a week or oftener with cold water from the well to assist in lowering the temperature. Where this is done, galvanized iron flues should be used in place of drain tile to avoid percolation of water.

The air may be cooled in a similar way by leading the pipes into a cistern 12 or 15 ft. deep, which is filled with water. In such case the flues should have a water-tight connection, with a drum at top and bottom to prevent the entrance of water. The water may be changed from time to time as is necessary to keep it sufficiently cool.

In all the above cases a wind funnel is depended upon to supply a sufficient current of air. It is suggested that where practicable a small blower might be used with advantage, at least when the wind is very light.

The efficiency of these methods for cooling curing rooms depends very largely on the proper construction of the curing room. The author gives detailed directions for the construction of wooden and masonry above-ground curing rooms and of underground curing rooms. Commenting upon the expense of the form of construction recommended, the author says:

> "It should be kept in mind that two important points must be secured if anything like full effectiveness of the subearth duct is desired; (1) the walls must be so tight that the pressure and suction of the wind on the building does not drive out the cool air and leave in its place the warm air of the outside, and (2) the walls must be a sufficiently poor conductor to permit a relatively small movement of air through the subearth duct to remove all of the heat which penetrates the walls. The curing room is perfect in construction only when its walls are so tight that no air can enter the room except through the subearth duct, or at another specially provided opening which is used only when the air from the duct is too cool or too damp."

Dairying in Denmark in 1898, B. Boggild (*Tidsskr. Landökon, 1899, No. 3, pp. 133–163*).

Facts for consideration by dairy farmers, G. S. Thomson (*Jour. Agr. and Ind., South Australia, 2 (1899), No. 9, pp. 738–741*).—Urges the sterilization of utensils and the use of tuberculin.

The conformation of the dairy cow, A. M. Soule (*Hoard's Dairyman, 30 (1899), No. 19, p. 376*).—A popular address delivered before the Rural Science Club of the University of Tennessee.

The evolution of a rational system of cattle feeding, W. H. Jordan (*Vermont Dairymen's Assoc. Rpt. 1898, pp. 69–88*).—A popular paper on feeding dairy cows.

Twelfth Annual Report of the Iowa Dairy Commissioner (*Iowa State Dairy Com. Rpt. 1898, pp. 80+38*).—Text of the dairy laws of Iowa and various statistics and discussions relating to the dairy interests of the State.

A grade dairy herd, C. D. Smith (*Michigan Sta. Bul. 166, pp. 103–112, figs. 3*).—A financial account for one year is given of a grade dairy herd of 29 cows purchased to represent the average cows of southern Michigan and given uniformly good care and feed. The average production of milk per cow for the year was 7,009 lbs., the largest yield being 10,310 lbs. The average production of fat was 259.91 lbs., estimated as equivalent to 304.89 lbs. of butter. The net profit from the herd, not including the manure, amounted to $277.58. Notes are given on the record of individual cows, including tabulated data on the total milk and butter production of each.

The college herd, C. W. Burkett (*New Hampshire Sta. Bul. 59, pp. 192, 193*).—Brief statistics are given on the milk production of the college herd for the year ending October 30, 1898.

> "The herd has been equivalent to 309 milch cows and 94 dry cows for one month, and has produced 173,011 lbs. of milk and 9,376.89 lbs of butter, making an average monthly yield per head for 403 cows, 429 lbs. of milk and 23.3 lbs of butter, or 5,148 lbs. of milk and 280 lbs. of butter for the year."

Uniformity in the composition of milk, how to maintain it, C. B. Lane (*Trans. New York State Agr. Soc. 1897, pp. 252–259*).

How can we improve the factory milk-test system? J. L. Hills (*Vermont Dairymen's Assoc. Rpt. 1898, pp. 34–51*).—A popular article.

Water content of butter, E. H. Farrington (*Breeders' Gaz., 35 (1899), No. 20, p. 597*).—From the results of an investigation comparing the appearance and water content of salted and unsalted butter the author explains the apparent dryness of foreign butter as due to the absence of salt or the presence of only a small quantity.

Second report of the periodical Finnish butter exhibitions in Hangö (*Helsingfors, Finland, 1899, pp. 24*).—Four hundred and fifty tubs of butter from 175 different creameries were exhibited and judged during the year. The average water content of the butter was 12.3 per cent., the maximum being 16 per cent and the minimum

9.2 per cent. Of the tubs exhibited 83 leaked 10 or more grams of brine during storage, the average amount being 181 gm. and the maximum 985 gm. Of the 175 creameries participating in the butter exhibitions, 28 manufactured over 350 tubs per year; 71 made 150 to 350 tubs, and 76 less than 150 tubs; 165 were separator creameries, 3 used both separator and the ice-creaming system, and 7 used the latter system only; 29 pasteurized all their cream or milk and 4 used pasteurization to some extent. Fifty-eight creameries used pure culture starters.—F. W. WOLL.

VETERINARY SCIENCE AND PRACTICE.

Veterinary studies, A. T. NEALE (*Delaware Sta. Bul. 43, pp. 4-15*).—Brief notes are given on rabies, tetanus, and Texas fever. Numerous tests have been made by the station in cooperation with private veterinarians, of tuberculin in dairy herds. The tuberculin is considered practically infallible. A number of vaccination experiments were tried upon cattle suffering from anthrax with good results. The station is attempting to secure sterilization of the waste which escapes into the water and causes anthrax in certain localities.

Cerebro spinal meningitis in horses has been studied by the station. The question has been investigated as to whether the bunt in wheat and certain aspergilli and other fungus diseases upon food plants may cause cerebro spinal meningitis. The station hopes to be able to verify or disprove the theory that *Diplococcus intracellularis* is the specific germ of the disease.

Brief notes are given on the remedies for swine diseases as well as the serum treatment of those affections.

The condition of bovine tuberculosis in Europe, H. W. CONN (*Connecticut Storrs Sta. Bul. 19, pp. 12*).—According to statistics gathered from slaughterhouse inspection and from tuberculin tests, tuberculosis is rapidly spreading in European countries. It is much more prevalent in the northern countries of Europe than in the southern, and in herds which are closely housed than in those which are allowed to range freely. Fifty per cent of the cattle of northern Germany and Denmark are estimated to be tuberculous, and the cattle which were imported into Kiel from Denmark during 1897 were tuberculous to the extent of 66 per cent.

The tuberculosis of man and that of animals seems to be slightly different. The disease is readily transmitted by contagion from one animal to another, but it is becoming more and more doubtful in the minds of most scientists whether it is ever transmitted from man to animals, and the danger of transmission from animals to man is considered much less than was formerly believed.

In order to combat the disease, it is necessary in the first place to discover every case of tuberculosis, and for this purpose the use of tuberculin is considered essential. All animals which respond to the tuberculin test should be separated from the healthy animals, and must be cared for by separate attendants in order to prevent the disease from again breaking out in the healthy herd. Strict measures of this sort have been adopted in Denmark and carried out for a number of years with very promising results.

Tetanus, C. McCulloch (*Virginia Sta. Bul. 85, pp. 13–22, figs. 2*).—Tetanus is invariably produced by the introduction of the tetanus bacillus into a wound. The bacillus is said to be especially common in the dust of old floors, stables, and gardens. A detailed description is given of the appearance of the tetanus bacillus and an account of its biology and behavior in the incubator and upon nutrient media. Tetanus is particularly common in the horse, mule, sheep, and pig; less so in cows, calves, and lambs. There are two forms, acute and subacute, of which the acute is much more common. Death may occur in from 5 to 8 days and recovery is rare before the third week.

In the sheep and pig the mortality is about 100 per cent; in the horse, 80; in the ox, 50. The only affections with which tetanus is liable to be confounded are strychnin poisoning and cerebro spinal meningitis.

As a preventive treatment, careful antiseptic washing of wounds is recommended, and, whenever the disease develops, the use of the tetanus antitoxin is strongly advised.

Canine distemper, C. McCulloch (*Virginia Sta. Bul. 87, pp. 33–41*).—Canine distemper is caused by a micro-organism and is contagious. It is found in the dog, cat, fox, wolf, hyena, monkey, and has been found in the human family. The symptoms are depression, conjunctivitis of the eye, constipation or a fetid diarrhea, and a catarrh of the nasal passages. In weak subjects cerebral symptoms predominate and are characterized by stupefaction. The temperature usually rises, sometimes to 104° F. The mortality is from 50 to 60 per cent, and the prognosis in young animals is generally unfavorable.

Treatment should be symptomatic, to relieve the symptoms as they develop. Calomel in 1-grain doses 3 times a day gives good results. For the eye, ½ to 1 per cent solution of sulphate of zinc, or ½ to 2 per cent solution of nitrate of silver acts well. For the nervous symptoms, a sedative, such as bromid of soda 2½ drams or chloral hydrate 2 drams, gives favorable results. For the reduction of the fever, 2 grains of acetanilid may be blown into the mouth every 2 hours until the temperature begins to drop.

Report of the Royal Veterinary College for 1898, J. McFadyean (*Jour. Roy. Agr. Soc. England, 3. ser., 10 (1899), pt. 1, pp. 112–155*).—The report contains an account of work done by the laboratory of the Royal Veterinary College for the year 1898 on the following diseases: Glanders, anthrax, tuberculosis, swine fever (hog cholera), the contagious origin of warts, and milk fever. Some success has been had with vaccination according to the method introduced by Pasteur for anthrax. Statistics are given for tuberculin tests upon 4,379 cows, of which 31.7 per cent reacted. It was shown that warts, such as occur on the inside of the lips and on the tongue of dogs, may be transmitted by inocula-

tion. Good success is reported with the use of injections of iodid of potassium into the udders of cows suffering from milk fever.

Dehorning, E. P. NILES (*Virginia Sta. Bul. 84, pp. 12, figs. 6*).—A brief history is given of the dehorning methods practiced in different parts of the United States. The saw and horn clipper are not recommended on account of the unnecessary pain caused, and of the liability to subsequent trouble in the healing of the wound. The author recommends the ordinary caustic potash treatment, which is to be applied to young calves a few days after birth. Horns up to an inch or two in length can be removed by this method.

The gape worm of fowls; the earthworm, its immediate host, H. D. WALKER (*Franklinville, N. Y., 1897, pp. 30, pl. 1*).—The author relates a number of experiments in which the disease known as the gapes was produced in chickens by feeding them earthworms (*Lumbricus terrestris*). Chickens which were prevented from eating earthworms did not acquire the disease in any case. The larvæ of the gape worm (*Syngamus trachealis*) were found in the earthworm, and artificial cultures of the larvæ were made in the serum of blood.

For the prevention of the gapes in chickens, the author recommends the destruction of earthworms where the chickens are allowed to run by means of common salt or lime or with ashes in the soil.

On the cause of epizootic-catarrhal fever of dogs, P. JESS (*Berlin. Tierärztl. Wchnschr., 1899, No. 19, pp. 227–230, figs 3*).—Gives a description of the germ, with an account of the experimental inoculation of guinea pigs.

Rabies in England, M. E. LECLAINCHE (*Rev. Vet. Toulouse, 24 (1899), No. 6, pp. 358–362*).—Discusses the question of the relative efficiency of central and local authorities in controlling this disease.

Gangrenous mammitis of the goat, P. LEBLANC (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 372–374*).—The cause was found to be a micrococcus.

Chronic arthritis of the stifle joint, CADIAC and MATRION (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 257–262*).

Lung-worm disease of goats caused by Strongylus capillaris. A clinical, pathological, anatomical, and zoological study, M. SCHLEGEL (*Arch. Wiss. u. Prakt. Thierh., 25 (1899), No. 3–4, pp. 137–171, pls. 4*).

Bots, or worms, in the head of sheep or goats, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 14 (1899), No. 10, pp. 667, 668*).

Lime and sulphur dip, A. G. DAVISON (*Agr. Jour. Cape Good Hope, 14 (1889), No. 10, pp. 644–651*).—From experiments the author considers this the most effective dip to be used against sheep-scab mite.

Easy method of dipping sheep, C. S. PLUMB (*Amer. Agr. (mid. ed.), 63 (1899), No. 24, p. 751*).—When the number of sheep to be dipped is small, a wagon box of double height was found to be a convenient place to allow the sheep to enter while dripping.

Saturnism in the horse, MOSSELMAN and HEBRANT (*Ann. Med. Vet., 48 (1899), pt. 1, pp. 13–21*).—An account of cases of lead poisoning in horses.

Diaphragmatic hernia in horses, PÉCUS (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 262–271*).—A detailed account of clinical symptoms and of the autopsy.

The colic of horses from a diagnostic, genetic, and therapeutic view. The causes, prevention, and cure by means of extensive irrigation with certain fluids, DREYMANN (*Berlin. Tierärztl. Wchnschr., 1899, No. 21, pp. 251–255*).—The author had best success with enemas of from 20 to 50 liters of lukewarm water.

American horses and worm diseases, DR. LIEBENER (*Fühling's Landw. Ztg., 47 (1898), No. 19, pp. 736–739*).

Observations on hog cholera, G. GEROSA and G. BILLITZ (*Clin. Vet., 22 (1899), No. 16, pp. 181–185*).—A differentiation of hog cholera and swine plague, together with a description of the pathological anatomy of the disease and the methods of producing immunity.

Azoturia, O. G. Noack (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 5, pp. 277-282*).—The disease is said to be caused by poisons which are liberated in the intestines. The treatment recommended is the giving of aloes, followed by a cholagogue and then bicarbonate of soda.

Directions for using Reindl's process for combating infectious abortion (*Ztschr. Landw. Kammer Sachsen, 1899, No. 2, pp. 43-47*).—The stalls are to be disinfected with ammoniacal soda in boiling water. The external parts of the animals are to be washed with the same soda solution.

Contagious vaginitis of the cow, Mathis (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 198-202*).—A clinical record of a number of cases, with suggestions for antiseptic treatment.

Contributions to the treatment of parturient apoplexy according to Schmidt, O. Schwarzkopf (*Berlin. Tierärztl. Wchnschr., 1899, Mar. 30, pp. 156-158*).—Critical test of the iodid of potash treatment, with results which indicated it to be a doubtful success.

A contribution to statistics on the treatment of parturient apoplexy with iodid of potash, C. Saass (*Berlin. Tierärztl. Wchnschr., 1899, Mar. 30, pp. 155, 156*).—Sixty cases were treated with iodid of potash and 45 were cured.

The icteroid bacillus and its toxin, J. B. de Lacerda and A. Ramos (*Arch. Méd. Expér. et Anat. Path., Paris, 11 (1899), No. 3, pp. 378-398*).—Experiments with virulent cultures on rabbits and dogs gave positive results. A serum prepared by Sanarelli was not effective in preventing the disease.

The action of strychnin and chloral on animals affected with tetanus, Roger (*Compt. Rend. Soc. Biol. Paris, 11. ser., 1 (1899), No. 17, pp. 392-395*).—Chloral was not effective in stopping the contractions of tetanus.

An experimental study of tetanus, J. Binot (*Compt. Rend. Soc. Biol. Paris, 11. ser., 1 (1899), No. 17, pp. 409, 410*).—The fatal dose of toxin is found to vary according to the place and method of injection.

Vaccination against the foot and mouth disease, W. Flatten (*Berlin. Tierärztl. Wchnschr., 1899, No. 2, pp. 15, 16*).—The injection of seraphthin serum into the jugular vein produced positive though not well marked effect.

Foot and mouth disease, L. Anderson (*Maanedsskr. Dyrlaeger, 10 (1899), No. 10-11, pp. 385-438*).—Contains a detailed account of outbreaks of the disease in a number of herds. Tabulated statistics of the herds are given showing the number of animals in the herds, the number of cases of foot and mouth disease, and the number of deaths.

Some further remarks on red water, or Texas fever, A. Edington (*Proc. Roy. Soc. [London], 65 (1899), No. 414, pp. 111-114*).—Gives evidence of the communicability of Texas fever through blood from animals which have long recovered or from animals which were inoculated months before their blood was used.

Texas fever, or red water, Koch (*Agr. Jour. Cape Good Hope, 14 (1899), No. 10, pp. 658-667*).—Record of experiments in conferring immunity and destroying ticks

Studies on the cattle plague, Nicolle and Adil-Bey (*Ann. Inst. Pasteur, 13 (1899), No. 4, pp. 319-336*).—An account of experimental inoculation with virus and the production of immunity with a record of the experiments and charts of curves of temperatures.

My experience with blackleg vaccine, M. V. Byers (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 4, pp. 219-221*).—Six hundred animals were vaccinated. The author prefers vaccination in the tail rather than in the ear or in the shoulder.

Rinderpest and tsetse, Koch (*Agr. Jour. Cape Good Hope, 14 (1899), No. 27, pp. 552-560, figs. 2*).—Inoculation with bile followed by virulent blood is reported as being a very successful means for combating rinderpest. The disease is said to be rapidly decreasing in South Africa.

The tsetse or surra disease is confined to cattle, horses, elephants, and dogs. The parasite is of the trypanosoma type and is carried from animal to animal by the tsetse fly.

Further investigations on immunity to splenic fever, G. SOBERNHEIM (*Ztschr. Hyg. u. Infectionskrank., 31 (1899), No. 1, pp. 89–132*).

Experiences in vaccination against splenic fever according to Pasteur, BARKOW (*Deut. Tierärzlt. Wchnschr., 7 (1899), No. 17, pp. 153, 154*).—Of 330 animals vaccinated, only 1 died.

Contribution to the treatment of actinomycosis with iodid of potash, REMY (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 19, pp. 169–172*).—A record of 8 cases of actinomycosis. Potassium iodid was used in all cases and was shown to be a specific even in advanced stages of this disease.

A bibliographical index of works published on the subject of tuberculosis in 1899 (*App. Rev. Tuberculose, Paris, 6 (1899), No. 1, pp. 12*).

Phagocytosis in the pigeon with reference to the tubercle bacillus of birds and of man. A contribution to the study of natural immunity, DEMBINSKI (*Ann. Inst. Pasteur, 13 (1899), No. 5, pp. 426–434*).—The phagocytic reaction in the pigeon varies, depending upon whether the bird has been inoculated with the bacillus of birds or of man. After being inoculated with the bacillus of birds phagocytosis is very active, and three stages can be distinguished—polynuclear, mixed, and mononuclear. After inoculation with the bacillus of man, polynuclear and mononuclear leucocytes appear at the same time.

Several cases of tuberculosis in cattle with accompanying meningitis, HAMOIR (*Ann. Méd. Vét., 48 (1899), pts. 2, pp. 75–88; 3, pp. 136–142; 4, pp. 190–199*).—Calls attention to the necessity of observing the nervous symptoms in this sort of tuberculosis. The disease is said to be accompanied frequently by meningitis of the spinal cord or of the brain, or both. The symptoms are unequivocal and characteristic.

Contribution to the question of the infectiousness of the milk of tuberculous cows and on the value of the tuberculin inoculation, L. RABINOWITSCH and W. KEMPNER (*Ztschr. Hyg. u. Infectionskrank., 31 (1899), No. 1, pp. 137–15.*).

Tuberculosis in a goat, P. SCHLATHÖLTER (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 20, pp. 179*).—The goat was reared on cow's milk.

A case of fœtal tuberculosis in a calf, M. P. RAVENEL (*Vet. Jour., 48 (1899), No. 288, pp. 417, 418*).

On tuberculous meat and milk, J. NIVEN (*Jour. Sanit. Inst., 19 (1898), No. 4, pp. 534–554*).—Recommends the creation of a veterinary public health service, greater facilities for inspection of outside cows, and prompt notification of disease.

On traumatism and tuberculosis, LANNELONGUE and ACHARD (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 18, pp. 1075–1078*).—The tubercle bacillus placed in wounds did not bring about an infection.

Tuberculosis and variola, P. A. LOP (*Rev. Tuberculose, Paris, 6 (1899), No. 1, pp. 28–44*).—Variola is shown to be a predisposing cause to tuberculosis. Variolous parents are apt to have tuberculous offspring.

Tuberculosis, N. ROUCHÉS (*Jour. Agricole [Paris], 10 (1899), No. 110, pp. 79–81*).—The disease is reported as being rare in the Department of Seine, only 5 out of every 100 cows responding to the test.

Tuberculous cattle (*Agr. Student, 5 (1899), No. 9, pp. 174, 175*).—A record of tuberculin tests with 13 cases, and notes on post-mortem conditions.

The application of the tuberculin test in cattle, OSTERTAG (*Mitt. Deut. Landw. Gesell., 1898, Feb. pp. 4*).—Recommends further and more stringent laws for the thorough suppression of tuberculosis.

Tuberculosis among cattle and means of combating it, O. E. STENSTRÖM (*Meddel. K. Landtbr. Styr., 1899, No. 54, pp. 40*).—A general account of the nature of tuberculosis; the means by which it is transmitted from animal to animal, or from animals to man, and *vice versa;* and directions for using the tuberculin test, together with a discussion of its value.

Tuberculosis and methods of fighting it, V. R. I. CROESEN (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 11 (1899), No. 131, pp. 89–94*).—Gives a discussion of the nature and symptoms of the disease. For controlling the disease, it is urged that all cattle be tested with tuberculin, that the healthy be strictly separated from the diseased, and that the usual precautions be taken to prevent contagion from one animal to another.

Tuberculin testing and combating tuberculosis among cattle, A. Eber (*Tuberkulinprobe und Tuberkulosebekämpfung beim Rinde. Berlin: Paul Parey, 1898, pp. 84*).—This work gives a discussion on the significance of bovine tuberculosis, the diagnostic value of tuberculin, the effects of tuberculin upon cattle, and the prevalence of tuberculosis among cattle according to the results gained from tuberculin tests.

Treatment of tuberculosis by subcutaneous injections of artificial serum in small doses, M. G. Morard (*Compt. Rend. Soc. Biol. Paris, 11. ser., 1 (1899), No. 15, pp. 335, 336*).—Saline serum injections in small doses checked the disease in about one-half the cases. The dose which operated most favorbly was one of from 2 to 3 cc. per day.

Tuberculin and its use, G. J. Bernier (*Rev. Facult. Agron. y Vet. La Plata, 4 (1898), No. 3, pp. 77-93, pl. 1*).—A discussion of the nature and value of tuberculin and directions for its use in making tests for tuberculosis.

Investigations with tuberculin (*Meddel. K. Landtbr. Styr., 1898, No. 48, pp. 258, 259*).—Notes on tuberculin tests with 13,768 animals.

Combating tuberculosis in domesticated animals, G. Regner (*Meddel. K. Landtbr. Styr., 1899, No. 55, pp. 29*).—A dialogue in the form of questions and answers concerning practical methods of recognizing tuberculosis and of applying the tuberculin test for separating diseased animals from healthy ones.

Tuberculosis in man and beast, H. Maxwell (*Nineteenth Century, 1898, Dec.; abs. in Rev. of Reviews, 1899, Jan., pp. 101, 102*).—The author calls attention to the dangers of infection from the milk of tuberculous cows.

Bacteriolytic enzyms as the cause of acquired immunity and the cure of infectious diseases by means of them, R. Emmerich and O. Löw (*Ztschr. Hyg. u. Infectionskrank., 31 (1899), No. 1, pp. 65*).—Enzyms are produced during the growth of bacteria, which check the growth of the latter. In several cases an enzym is produced which destroys the activity of other species of pathogenic bacteria as well as of that species which produced the enzym in question.

A contribution to the knowledge of the infectious diseases of animals and man which are caused by anærobic bacteria, E. von Hibler (*Centbl. Bakt. u. Par., 1. Abt., 25 (1899), No. 17, pp. 593-613*).—Gives biological notes on certain anærobic bacteria which are distinguished from the *Œdema bacillus* and the *Tetanus bacillus.*

Extracts from the report on the work of the Kharkof Bacteriological Station for 1898 (*Selsk. Khoz. i Lyesov., 192 (1899), Mar., pp. 553-556*).—Gives a brief account of the activity of the station along various bacteriological lines.

An experimental study on the effect of toxins and antitoxins introduced into the digestive canal of animals, G. Carriere (*Ann. Inst. Pasteur. 13 (1899), No. 5, pp. 435-443*).—Ptyalin had no effect on the activity of antitoxic serums. The artificial gastric juice did not change the antitoxic serum, but had a slight effect on antivenom serum. The bile of cattle had no modifying effect on the antitoxins which were studied. Pancreatin changed them very much, and even destroyed them. The intestinal micro-organisms also had a strong modifying effect upon them.

Notes on Bacillus anthracis similis, J. McFarland (*Centbl. Bakt. u. Par., 1. Abt., 24 (1898), p. 566; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 1, p. 72*).—An organism isolated from the pus of an abscess, the colonies of which were identical with *B. anthracis,* is described. It is a large bacillus with slightly rounded ends, and forms long filaments with transverse septa. In bouillon cultures 4 days old there were no spores, but in agar cultures 3 weeks old they were exceedingly abundant. In agar and gelatin cultures the organisms are similar to those of *B. anthracis.* The growth on the potato is luxuriant. On bouillon there forms a surface mycodern and a sediment from constantly precipitating bacillary masses. *B. anthracis similis* is said to be nonpathogenic to guinea pigs, mice, or rabbits.

Report of the bacteriological station of the Kazan Veterinary Institute for 1897 (*Kazan, 1898; rev. in Selsk. Khoz. i Lyesov., 191 (1898), Nov., p. 480*).

Twenty-fourth annual report of the government institution for the cultivation of vaccine virus in the government veterinary school at Utrecht, A. W. H. WIRTZ (*Vier en twintigstejaarverslag van de Rijksinrichting tot kweeking van koepokstof. Utrecht: J. Van Druten, 1897, pp. 32*).—The paper gives a record of a number of experiments made on the cultivation of vaccine virus in calves. Tables are given which show the effect upon the calves of the inoculation, and the method of obtaining a preparation of the vaccine from the calves is explained.

Annual report on the literature in the field of veterinary medicine, ELLENBERGER, SCHÜTZ, and BAUM (*Jahresbericht über die Leistungen auf dem Gebiete der Veterinär-Medicin. Berlin: August Hirschwald, 1898, pp. 240*).—A classified bibliography of books, pamphlets, and periodical articles on the subject of veterinary medicine in all its branches.

AGRICULTURAL ENGINEERING.

Proceedings of the seventh annual session of the National Irrigation Congress, held at Cheyenne, Wyoming, September 1-3, 1898 (*Cheyenne: Business Men's Club of Cheyenne, 1899, pp. 159, pls. 4*).—This report, compiled by R. C. Morris, contains discussions and papers on a variety of topics, including among others storage reservoirs, obstacles to settlement of the arid region, national legislation on the reclamation of arid lands, successes and failures in canal building, and other enterprises; the measurement of streams; what Congress is doing for irrigation; national forest reserves; cession of arid lands in connection with irrigation; sociological questions connected with irrigation; laws and regulations to promote the best use of water in time of scarcity; irrigation work of the agricultural experiment stations, etc.

The resolutions adopted contain the following, which is of especial interest to the Department and the experiment stations:

> "We cordially approve the beginning of an investigation of these problems by the Department of Agriculture. This Department can, by continuing and extending this work, do much to assist the creation of homes in what are now arid wastes, in augmenting our national wealth, and in promoting the prosperity and contentment of the farmers of this country, both in the East and West. . . .
>
> "We favor the creation, in the Department of Agriculture, of a Division of Irrigation, to carry out the work outlined above, and the making by Congress of liberal appropriations for its support.
>
> "We express our cordial appreciation of the value of irrigation investigations already made by several of the agricultural experiment stations within the arid States. The value of the results already secured warrants an extension of this work, and we recommend that the experiment stations of the arid States give increased attention to this class of problems and a liberal support to those engaged in these investigations."

Experiments with windmills, T. O. PERRY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 20, pp. 98, pls. 12, figs. 39*).—This is an account of dynamometric experiments carried out during the years 1882 and 1883 for the United States Wind Engine and Pump Company of Batavia, Illinois, with a detailed discussion of the results as applied to the construction of windmills of the highest efficiency. "As a result of these experiments radical changes and improvements were made in the windmills. As a matter of business policy the company did not desire that the results of these tests should be made known for some years. After the expiration of a certain time, however, the data have been placed at the disposal of the public through the kindness of the officers of the company and the efforts of Mr. Perry. Although as the result of this work great changes have been made in windmills, many of the suggestions made have not yet been put into practice and may serve as a foundation for further work along this line. The importance of the windmill as a means of utilizing the water resources of a part of the country is so great that all available information on the subject should be diffused and brought to the attention of persons who can make use of the facts."

An earlier paper of this series giving an account of experiments with windmills and discussing their value for irrigation has already been noted (E. S. R., 9, p. 796).

Operations at river stations, 1897 (*Water Supply and Irrig. Papers, U. S. Geol. Survey, Nos. 15, 16, pp. 200*).—Brief descriptions of the river stations at which work was carried on by the Division of Hydrography of the U. S. Geological Survey during 1897, together with tables of daily height.

Irrigation near Bakersfield, California, C. E. GRUNSKY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 17, pp. 91, pls. 11, figs. 21*).—"This paper is the first of three relating to San Joaquin Valley, the others being entitled, respectively, Irrigation near Fresno, California, and Irrigation near Merced, California. (See below.)

"In this, the first paper, some space has been devoted to a general description of San Joaquin Valley as a whole, and of the irrigation districts which have been organized within it, the history of these being briefly outlined. There is also added a description of the methods of irrigation commonly employed, as this has especial interest in connection with the more detailed statements regarding the individual canals and ditches. Following these more general matters, Kern River is taken up, its drainage basin discussed, and each of the numerous systems of water supply depending upon the river is described at some length. Then the creeks lying to the north, Poso and Deer, are described, as well as Tule River.

"Although a relatively high degree of development of irrigation has been reached in this part of the arid region, yet the results are far below the possibilities."

Irrigation near Fresno, California, C. E. GRUNSKY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 18, pp. 94, pls. 14, figs. 21*).—This paper, which is the second of a series of three devoted to irrigation in the San Joaquin Valley, "relates mainly to the irrigation systems deriving their water supply from Kaweah and Kings rivers and covering the agricultural lands on the east side of San Joaquin Valley between Visalia and Fresno."

Irrigation near Merced, California, C. E. GRUNSKY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 19, pp. 60, pls. 11, figs. 14*).—"This paper describes the irrigation systems deriving their water supply from San Joaquin, Chowchilla, Merced, Tuolumne, Stanislaus, and Mokelumne rivers."

Stream measurements in 1897, F. H. NEWELL (*Nineteenth An. Rpt. U. S. Geol. Survey, 1897–98, pt. 4, pp. 632, pls. 70, figs. 207*).—This is a detailed account of stream measurements in all parts of the United States, the main results of which have already been reported in Water Supply and Irrigation Papers 15 and 16 of the U. S. Geological Survey. (See above.) The methods pursued in these measurements are described, and some account is given of the character of the various river or drainage basins and of the present and prospective use of the different streams. The data "are given numerically by months, the daily changes being graphically expressed in diagrams."

Preliminary report of an investigation of rivers and deep ground waters of Ohio as sources of public water supply (*Cleveland: J. B. Savage Press, 1898, pp. 259*).—The investigations were made under the auspices of the State Board of Health.

State irrigating canals (*Montana Bureau Agr. Labor and Ind. Rpt. 1898, pp. 64–76*).

Tests of pumps and water lifts, O. P. HOOD (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 14, pp. 91, pl. 1, figs. 58*).—This is an account of tests made at the State Agricultural College, Manhattan, Kansas, of the efficiency of various pumps and water lifts and of the various sources of frictional loss, with a discussion of the results.

Steel tracks for wagon roads (*Amer. Agr.* (*mid. ed.*), *63* (*1899*), *No. 21, p. 670*).

Sprinkling roads with oil (*Country Gent., 64* (*1899*), *No. 2420, p. 465*).

STATISTICS—MISCELLANEOUS.

Tenth Annual Report of New Hampshire Station, 1898 (*New Hampshire Sta. Bul. 59, pp. 169–219*).—This contains a financial statement for the fiscal year ending June 30, 1898; a subject list of the publications issued by the station since its organization; and reports of the director, vice-director, agriculturist, horticulturist, bacteriologist, entomologist, and meteorologist, parts of which are noted elsewhere.

Eleventh Annual Report of Tennessee Station, 1898 (*Tennessee Sta. Rpt. 1898, pp. 5–17, 28*).—This contains a financial statement for the fiscal year ending June 30, 1898; reports of the secretary, chemist, horticulturist, botanist, entomologist, and librarian, setting forth the station work for the year, and a brief description of a new barn built at the station.

Report of Virginia Station for 1898 (*Virginia Sta. Rpt. 1898, pp. 12*).—This includes brief reports by the director and heads of departments on the station work for the year, and a financial statement for the fiscal year ending June 30, 1898.

Report of the Agricultural Department of Sweden for 1897 (*Meddel. K. Landtbr. Styr., 1898, No. 48, pp. 424*).—The report is made up of the annual reports on meteorology and crops in Sweden during 1897; reports of county agricultural societies, agricultural educational institutions, the various public agricultural functionaries, tuberculin investigations, the piscicultural and entomological institutes, the chemical and seed control stations, and the chemical plant biological station at Luleå.

According to the report of the chemical-control stations, 51,859 samples, of which 41,374 were dairy products, were examined at the 8 stations in operation during the year. The 18 seed control stations in operation during 1897 made 10,333 seed examinations, the average results of which are given.—F. W. WOLL.

Reports of the Ploty Agricultural Experiment Station (*Compt. Rend. Ann. Sta. Agron. Ploty, 1895, pp. 24; 1896, pp. 124, figs. 2, charts 3*).—This station was organized in 1894 by Prince Paul Troubetskoi. It is situated in the government of Podolia, southern Russia, on the chernozem soils, where the climate is entirely continental. The station is equipped with an agricultural laboratory, a meteorological station, and experimental fields.

These, the first two, reports record analyses of soils and water, experiments with fertilizers and methods of culture on various crops, experiments with grapes, and meteorological observations, especially as related to the growth of crops.

Agriculture in Denmark in connection with the general development of that country, N. A. KRUKOV (*St. Petersburg: Department of Agriculture of the Ministry of Agriculture and Imperial Domains, 1899, pp. XII + 327; rev. in Selsk. Khoz. i Lyesov., 192* (*1899*), *Mar., pp. 707, 708*).—According to the author the high degree of development of agriculture which Denmark has attained, in spite of the unfavorable natural conditions, is due, on the one hand, to the extensive development of mutual-aid associations of farmers, and, on the other, to Government measures, such as the maintenance of a considerable staff of specialists in various branches of agriculture, the financial assistance to the agricultural associations, etc. One of the essential features of all these measures is the support and the intellectual development of the small farmers, which constitute a large proportion of the Danish landowners.—P. FIREMAN.

Report of the Spalato (Dalmatia) Agricultural Chemical Experiment Station, 1894–1898, F. GVOZDENOVIĆ (*Ber. Thätigkeit Landwirth.-Chem. Versuchs. in Spalato, pp. 32; separate from Ztschr. Landw. Versuchw. Oesterr., 2 (1899), No. 3*).—This is a summary statement of the work of the station from its organization until December, 1898.

Third annual report of the Ploti Agricultural Experiment Station, in the government of Podolsk, 1897 (*Odessa, 1898, pp. 158; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Feb., pp. 473, 474*).

On horticultural stations, P. NÖVIK (*Tidsskr. Norske Landbr., 6 (1899), No. 4, pp. 145–173*).

The asylum farm of Bois de Cery (GAVILLET, BAUVERD, and GILLIÉRON-DUBOUX (*La Ferme de l'Asile du Bois de Cery. Lausanne: A. Borgeaud, 1899, pp. 68, pls. 10, figs. 21*).—A description of an asylum farm and its management. The farm is located near Lausanne, in Switzerland.

Fourth annual report of the superintendent of farmers' institutes of Ontario, 1897–98, F. W. HODSON (*pp. XIV, App., pp. 440*).—This includes a brief summary of the work of the year; a list of institute officers; data showing the membership of local farmers' institutes, meetings held, attendance, receipts and expenditures; a report of the women's institute at Saltfleet, including a financial statement and text of constitution and by-laws; and an appendix containing 141 selected papers read at different institutes during the year; a review of investigations conducted at various European and American experiment stations, and reports by the directors of Connecticut Storrs, North Dakota, Illinois, Kansas, Maine, Michigan, Massachusetts Hatch, New Jersey, Nebraska, Ohio, Rhode Island, and Washington stations. The report showed that during the year 658 meetings were held, 3,270 addresses delivered, and 126,094 persons attended the meetings.

Review of the Polish agricultural literature for 1897, F. LUBANSKI (*Selsk. Khoz. i Lyesov., 192 (1899), Mar., pp. 681–693*).

Suggestions to auxiliary clubs (*South Carolina Sta. Bul. 39, pp. 8*).—Brief popular suggestions for conducting experiments with fertilizers and for testing dairy cows.

Index to preceding bulletins (*Virginia Sta. Bul. 83, pp. 133–140*).—This is an index to Bulletins 1–82 of the station.

Trade of the Philippine Islands, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 14, pp. 160*).—A statistical review of the foreign trade of the Philippine Islands, showing the nature, quantity, and value of the principal imports and exports. The total imports in 1894 amounted to $14,250,717 and the exports to $16,541,842. The principal agricultural imports are wines, rice, wheat flour, and canned goods. The principal exports are manila hemp, sugar, copra or cocoanut kernels, leaf tobacco, and cigars and cigarettes. The quantity of manila hemp exported in 1897 was 112,786 tons, and of sugar 152,687,620 lbs., the two products amounting to more than 75 per cent of the total export valuation of the islands. During the years 1892 and 1893 manila hemp and sugar were sent chiefly to the United Kingdom and the United States, and tobacco and coffee to Spain. Detailed statistics are given on the trade of the Philippines by countries. Among the countries receiving imports from the islands the United Kingdom ranks first, the United States second, and Spain third for the period from 1887 to 1896. As regards exports to the Philippines, Spain, the United Kingdom, and Germany rank in the order mentioned for the years 1892 to 1896, inclusive.

NOTES.

Arkansas Station.—W. G. Vincenheller, a professional orchardist, and for the past six years State commissioner of agriculture, has been appointed pomologist and institute worker. The experimental work of the horticulturist will be with truck crops and small fruits.

Colorado College and Station.—The following new members have been appointed on the governing board: P. A. Amiss, of Pruden, and Harlan Thomas, of Denver, *vice* A. S. Benson and M. A. Leddy, retired; and Jesse Harris, of Fort Collins, *vice* J. J. Ryan, deceased. P. F. Sharp, of Pueblo, has been elected president of the board, *vice* A. L. Kellogg, and A. M. Hawley, secretary, *vice* J. E. Du Bois, deceased. The executive committee, which has charge of matters pertaining to the station, consists of the president of the board, P. F. Sharp, B. F. Rockafellow, of Canon City; J. L. Chatfield, of Gypsum; P. A. Amiss, and Jesse Harris. Henceforth the directorship of the station is to be separated from the presidency of the college. B. O. Aylesworth, of Denver, former president of Drake University, Iowa, has been elected president, and L. G. Carpenter, director.

Illinois Station.—The chemist of the station, C. G. Hopkins, has been granted leave of absence for a year, to be devoted chiefly to the study of agricultural chemistry in Germany. L. H. Smith, who has been associated with the department during the past four years, will be left in charge as assistant chemist.

Indiana Station.—A new piggery, designed especially for feeding purposes, has been erected. The first floor is of cement, and all partitions and woodwork, excepting a limited number of posts, are clear of the floor by about an inch and a half, so that the whole floor can be flushed with water and kept clean. Steel troughs for feeding are placed immediately over the gutter in front of the pens. Ample provision is made for storing different kinds of grain or feed in the second story. The building contains a small hospital room, bedroom for watchman, scales, stoves for heating water, etc., and is provided with ventilating chutes. It is not intended for housing the pigs at night except in special cases, and to meet such cases 4 special pens are connected directly with sleeping rooms. Ordinarily the pigs sleep in small houses placed in yards or fields adjoining the feeding house.

Iowa College and Station.—John J. Repp has been elected veterinarian of the station, *vice* M. Stalker. It has been decided to appoint an additional assistant in animal husbandry to meet the increased demands in that branch of the college and station work. The number of students in the four years' course in agriculture has reached 165, having more than doubled during the past year. Great need is felt of increased facilities for instruction and investigation.

Kansas Station.—The governing board and the station staff are at present constituted as follows: Board of regents—President, E. T. Fairchild, of Manhattan; vice-president, J. S. McDowell, of Smith Center; treasurer, W. T. Yoe, of Independence; William Hunter, of Blue Rapids; Mrs. Susan J. St. John, of Olathe; Carl Vrooman, of Parsons; J. M. Satterthwaite, of Douglass. Station staff—J. T. Willard, chemist and chairman of station council; A. S. Hitchcock, botanist; Paul Fischer, veterinarian; H. M. Cottrell, agriculturist; E. A. Popenoe, entomologist and horticulturist; Lorena E. Clemons, secretary; D. H. Otis, assistant in dairying; P. J. Parrott, assistant entomologist; R. W. Clothier, assistant chemist; J. M. Westgate, assistant botanist; R. B. Mitchell, assistant in veterinary department; Albert Dickens, assistant horticulturist; J. G. Haney, assistant in feeding and field work.

MINNESOTA STATION.—Thomas Wilson, of St. Paul, has been elected a member of the governing board of the station, *vice* M. R. Todd.

NEBRASKA STATION.—T. L. Lyon has been made acting director of the station, and William H. Tuck has been promoted to be laboratory assistant in animal pathology.

NEW HAMPSHIRE COLLEGE AND STATION.—At the last meeting of the board of trustees Frederick Symmes Johnston, of the Ohio State University, was elected assistant professor of agriculture and assistant agriculturist at the college and station, and will give special attention to the work in agronomy and soil physics.

NORTH CAROLINA COLLEGE AND STATION.—George T. Winston, formerly president of the universities of Texas and of North Carolina, has been elected president of the college and director of the station. W. A. Withers, who has been acting director of the station for the past two years, will in future devote his entire time to the chemical work of the college and station. B. Irby, who formerly held the chair of agriculture in the college, becomes professor of agriculture and agriculturist, succeeding F. E. Emery. C. W. Hyams, assistant botanist, has also been made assistant entomologist. Cooper Curtice has severed his connection with the station to accept the position of veterinarian to the State board of agriculture. On July 1, 1899, in accordance with the act of the general assembly, the State board of agriculture assumed direct supervision of the fertilizer control, and B. W. Kilgore, formerly of the Mississippi College, has been appointed State chemist in charge of this work. The members of what had been the fertilizer control division of the station, A. W. Blair, C. B. Williams, C. D. Harris, F. G. Kelly, W. G. Haywood, H. E. King, and Miss M. S. Birdsong, were transferred to the State board of agriculture. The executive work of the North Carolina commission for controlling crop pests has been assigned to the commissioner of agriculture instead of the director of the station. The station is not charged at present, therefore, with police work of any character.

NORTH DAKOTA COLLEGE AND STATION.—A combined sheep and pig frame barn, 36 by 48 ft., one and one-half stories, is about completed, as is also an addition to the mechanical building, 22 by 36 ft., for instruction in blacksmithing. A department of steam engineering has been established in connection with the mechanical course, intended more particularly to accommodate young men desirous of operating steam traction engines. Several additions have been made to the faculty of the college. C. H. Mallarian has been elected instructor in German, French, and philosophy; F. V. Warren, instructor in steam engineering and mathematics; Albert T. Mills, instructor in history and civil government; L. R. Waldron, assistant in the botanical laboratory, *vice* Merton Field, resigned, and R. A. Shattuck, accountant and instructor in bookkeeping, *vice* P. W. Farnham.

OHIO STATION.—Luther M. Strong, of Kenton, has been appointed a member of the board of control, *vice* S. H. Ellis, whose fourth term of continuous service on this board has expired.

OKLAHOMA STATION.—F. C. Burtis, of the Kansas Station, has been appointed agriculturist and horticulturist of the station.

VIRGINIA COLLEGE AND STATION.—D. M. Cloyd has been appointed a member of the board of control in place of S. H. Graves. A. T. Eskridge, assistant chemist of the station, has been transferred to the college staff. A new barn, designed in part for station use, has been ordered by the college at a cost of $5,000. The college has completed a new cannery and cider and vinegar factory, which will also be used by the station for experimental purposes.

WASHINGTON COLLEGE AND STATION.—E. E. Elliott has been elected assistant in agriculture in the college and station and superintendent of the farm

EXPERIMENT STATION RECORD.

VOL. XI. No. 3.

The recent death of Henry Lêvêque de Vilmorin marks the passing of an eminent exponent of plant breeding, whose family for three generations has been prominently associated with the improvement of cultivated plants. Grandfather, father, and son were ardent students of plant breeding, and to their efforts are due many highly developed varieties of vegetables, grains, and ornamentals which to-day are regarded as standards. Their investigations taught us much regarding the possibilities of plant breeding and selection from a scientific as well as a practical point of view, and furnished important contributions on the methods of conducting such work. Acting upon the well-founded theory that plants, like animals, are "plastic," and can be profoundly influenced through systematic selection and breeding, they pursued their labors with a thorough, scientific spirit and an untiring energy that are worthy of emulation.

Prominent among their originations are varieties of sugar beets, carrots, wheats, and potatoes, as well as many ornamentals. The improvement of the sugar beet, which has made that crop one of such great commercial importance, is very largely due to the efforts begun by Louis de Vilmorin and continued by his son. The latter was also greatly interested in wheats, and two cross-bred varieties, Datel and Lamed, are rapidly gaining favor, not only in France but elsewhere.

In 1893 Henry de Vilmorin visited this country and presided over some of the deliberations of the Horticultural Congress held in connection with the World's Columbian Exposition. He took a prominent part in the Hybridization Conference held during the past summer in London, at which time he announced the successful hybridization of an annual and a perennial poppy, explaining the peculiarities of the plants and exhibiting water-color sketches of the parent plants and the results of the crossing.

Although not a prolific writer, he contributed the results of his investigations and observations to a number of journals, and prepared several more elaborate works. A recent article by him in this journal gives an excellent description of the methods of selection and its effects on cultivated plants. That he did not write more is possibly due to the fact that he was at the head of the seed firm of Vilmorin-Andrieux & Co., the largest establishment of its kind in France, and gave personal attention to much of their work in the improvement of varieties. He was a member of a large number of learned and scientific societies, and had been decorated a number of times by various European governments in honor of his services in the promotion of agricultural and horticultural science. In 1896 he was the recipient of the Veitch medal in recognition of his contributions to horticulture.

With the greater specialization in the field of agriculture there is evidence of a growing interest among the experiment stations of this country in the work of selection and plant breeding. It seems not unlikely that eventually this may in large measure replace the indiscriminate testing of varieties, for which there has been such a popular demand. It is perhaps a quite natural outgrowth of variety testing, for its aims are similar and in a measure it anticipates the work of seedsmen and nurserymen.

Scientific selection is the refining and systematizing of a process which in one form or another has been going on since the beginning of cultivation, and which is practiced by a few farmers in nearly every neighborhood. Combined with plant breeding, its possibilities are almost unlimited, and it affords opportunity for the exercise of the qualities which characterize the trained experimenter. It requires a thorough knowledge of the plant and the conditions of its growth, and the ability to discriminate between that which is inherently good in a plant and that which owes its excellence to superior environment.

The records of the experiment stations already furnish many striking examples of the benefits of selection and breeding in improved quality, yield, or hardiness of a number of agricultural plants. Probably the most extensive work of this kind at any American station is that conducted by Professor Hays in Minnesota. A recent bulletin of that station gives the results of ten years' experimentation in breeding wheats, and describes in an interesting manner the methods which are employed. In the course of this work many crosses were made, the object being to first induce as great variation as possible, after which desirable varieties were obtained by systematic selection. Increased production was the chief desideratum, and varieties were obtained that were from 10 to 25 per cent more prolific than the originals. Similar experiments are in progress with corn, barley, flax, beans, field peas, millets, and other forage crops. At the West Virginia Station the improvement of timothy by selection has been pursued for a number of years, and some very distinct and promising varieties have been obtained. A number of stations are investigating the possibility of increasing the protein content of maize by selection, and sugar-beet breeding has become a popular line of work. Sugar-cane selection has been carried on with very marked success by the Louisiana Stations for a number of years, and promising results in improving sorghum by selection have been secured by the Delaware Station. The breeding of upland cotton has been conducted at a number of stations in the South, and the very careful experiments with sea-island cotton are tolerably familiar.

One thing must always be kept in mind by the plant breeder, and that is the ideal plant for which he is striving. If hardiness is sought, everything must be subordinated to this idea. If greater productivity is desired, that, too, must always be preeminent in every selection. Sometimes selections may be made for more than one point of excellence, but certain antagonisms in plant breeding have been pointed out that at present seem unsurmountable. For example, extreme earliness and great productivity are not to be looked for in the same plant. Great size of fruit, flower, or other organ, and extreme fecundity are not usually attained in one selection.

The unit of every selection should be the individual plant. Whenever average individuals are selected average products may be expected. Selection based on the individual may be slower in bringing results, but in no other way can the ability of a plant to transmit its desirable qualities be so surely established.

That plants may, on the whole, degenerate under selection is not generally understood, but there is abundant evidence in proof of this. A careful study of all the characteristics of the selected plant is necessary to success. It not infrequently happens in improper selection that a new variety is produced which is desirable in many ways, but that in the process of its selection undesirable traits are developed that more than counterbalance all that has been gained. A cereal of increased productivity may be bred but so liable to fungus attacks as to be worthless when sown as a crop. Hardiness may be secured at the expense of quality. Flavor and color of fruit may be secured at the sacrifice of some equally desirable attribute. The intelligent plant breeder will consider all of these factors before announcing a new variety.

In every selection adaptation to environment must be considered. What may be valuable in one region may be worthless in another. In testing new varieties the conditions under which they were produced must be considered. This greatly restricts the range of operation, while multiplying the opportunities for such work. Greater success is likely to accrue from experiments in which an improved variety for a restricted range is sought rather than one of wider adaptation. It is quite possible that the variety best adapted for a given region may ultimately be found to be one bred in that region.

There is no more attractive field for work in horticulture than in plant breeding, and yet this is a subject which has attracted the attention of but few station horticulturists. The results secured by some of the leading originators show the wonderful possibilities in this line. There is a demand for work of this character, as evidenced, for instance, by discussion at the recent meeting of the American Pomological Society. It is believed that at least a portion of the present extensive testing of varieties might well be replaced by experiments directed toward the improvement of fruits and vegetables.

CONVENTION OF ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS, 1899.

E. W. ALLEN, Ph D.,
Office of Experiment Stations

The sixteenth annual convention of the Association of Official Agricultural Chemists was held at San Francisco, Cal., July 5–7, 1899. The convention was held in conjunction with the convention of the Association of American Agricultural Colleges and Experiment Stations, but its sessions were all separate except one. The sessions were held in the assembly hall of the Mills Building and in the Academy of Sciences. About 60 chemists and visitors were in attendance.

The president, Dr. R. C. Kedzie, of Michigan, presided over all of the sessions and delivered the presidential address at a joint session of the two associations the first evening of the convention. He considered the encouraging progress which the Association had made in testing and perfecting methods of agricultural analysis, and pointed out that the deliberations of the Association had become a subject of international interest. He called attention to some of the important advancements in methods and appliances for chemical analysis which have taken place in recent years, enabling far greater rapidity on the part of the official chemist without impairment of accuracy. He compared the problems for agricultural investigation in the East and in the West, and illustrated the difference in agricultural conditions and in the themes presented for study. In conclusion he urged continuing the study of methods of detecting food adulterations, and especially of identifying spurious dairy products and detecting adulterations of wheat flour with corn flour and other foreign substances.

Owing to the unusually short time which had elapsed since the last meeting of the Association, held the previous November, the reports of the referees on the different subjects included less analytical work than ordinarily. In some cases only two or three chemists were able to complete the examination of the samples sent them in time for reporting to the referee, and consequently very few recommendations were made for changes in the present methods.

The secretary of the Association, H. W. Wiley, read a paper entitled "Historical sketch of the Association of Official Agricultural Chemists." This was an interesting review of the origin and development of the Association, covering a period of nineteen years. It included an account of the meetings held previous to the organization of the present Association, and of the fifteen annual meetings of the latter. The reports of the earlier meetings were compiled from correspondence with persons who attended them. Following in this line, the referees on most of the subjects gave reviews of the progress of the Association in their respective subjects. As the reports of the earlier meetings are, some of them, very rare or entirely lacking, these summaries, giving a complete record of the progress of the Association, will prove of much interest and permanent value.

FERTILIZERS.

Potash.—The report on this subject, by B. B. Ross, gave a review of the work on methods of potash carried on by the Association since its organization, including the initial methods of the Association and the modifications and changes made from time to time. The report also gave the results obtained by 20 chemists on the samples distributed the past year, which were quite concordant. "The results bear strong testimony to the accuracy attained with the use of our present official method in the case of complex mixtures containing potash derived from a number of different sources."

The referee made no recommendations for changes, but suggested that the use of 1:1 sulphuric acid be allowed as an option for saturating mixed fertilizers preparatory to ignition.

The results obtained by the use of tared filters as compared with the Gooch crucible for collecting the platinum precipitate indicate that it is possible to secure quite satisfactory results with the former. The referee described a process which is being tested at the Alabama Station laboratory with a view to avoiding the second evaporation and ignition required by some fertilizers after treatment with sulphuric acid. "The residue in the dish is removed without addition of hydrochloric acid, rubbed with a pestle, and transferred to a beaker. It is next boiled with 300 cc. of water, as usual, and just before the conclusion of the boiling a small quantity of barium carbonate suspended in water is added and the boiling continued for a short time. The barium carbonate effects the precipitation of iron, alumina, some of the phosphates, and a part of the lime and magnesia. The solution, after cooling, is made up to 500 cc., an aliquot is filtered out, and a few drops of hydrochloric acid added and then an excess of platinum chlorid. The process is then continued as in the Lindo-Gladding method, using ammonium chlorid wash water." The results thus far obtained by this method are said to agree quite closely with those obtained by a solution in water by the regular Lindo-Gladding method.

It was voted to submit this method to further trial.

Phosphoric acid.—E. G. Runyan gave an interesting résumé of the work of the Association in testing methods for phosphoric acid, and traced especially the development of the volumetric method for more rapid work. Only a small number of results had been reported on the samples sent out, and these were not sufficiently complete to report upon.

B. W. Kilgore spoke of his investigations on precipitating phosphoric acid in the volumetric method by shaking, in continuation of his work the previous year. The precipitations were made at a laboratory temperature of about 20° C. or more, and no trials were made at a very low temperature. He reported the results as uniformly satisfactory, the precipitation being complete. A very large excess of molybdate solution could not be added without making the results too high.

M. A. Scovell gave the results of adding the phosphoric acid solution to the molybdate, instead of *vice versa*. This procedure was found satisfactory, the crystals not being so fine, the results concordant, and the molybdic acid not being precipitated. The solution filtered better and the precipitation was complete if sufficient molybdate of ammonia was added.

C. B. Williams presented some results obtained in making solutions for total phosphoric acid when aluminum phosphate was present, showing that the nitric and hydrochloric acids did not dissolve all of the phosphoric acid; and this was followed by a discussion of solvents to be used in case of different kinds of phosphates, the opinion being that individual judgment must be exercised largely.

Nitrogen.—The report on this subject, submitted by F. S. Shiver, in addition to the review of the progress in studies of methods for nitrogen determination, gave the results of a further study of the permanganate methods for determining the availability of organic nitrogen. With the alkaline-permanganate method (Jones) "it appears that many of the analysts experienced difficulty in securing concordant results." The referee considered the results very unsatisfactory in some cases, as, for instance, with cotton-seed meal and ground fish, the relative availability of the nitrogen as shown by this method being too low. With the neutral permanganate method (Street) the results were "quite satisfactory on the whole. . . . Practically everyone seemed to secure good duplicates." The method is considered very promising, " not only because of the uniformity of the results obtained by its use, but also because of the agreement of these results with those of vegetation tests." A finer grinding of the substance than that prescribed by the Association (to pass a sieve with holes 1 mm. in diameter) was found to slightly increase the amount of available nitrogen, and it was suggested that in future a sieve with 50 meshes to the inch be used.

The referee recommended that the neutral permanganate of potash method (Street) be subjected to trial another year.

SOILS AND ASH.

The referee on this subject, B. L. Hartwell, stated that so little work had been done during the past year it was determined to postpone reporting it until another year. He gave a review of the history of soil investigation, compiling the results obtained by the Association and reviewing its work in determining the more active constituents of plant food. It was shown that the analytical results obtained with the use of strong solvents were not in accord with what would be expected from the history of the fertilizing and cropping of the soil. This was thought to be due in part at least to faulty sampling of the soil, and extreme care was urged in this respect. Referrence was made to the occurrence in many soils of phosphoric acid largely associated with humus, in which form it is quite readily available to plants but not dissolved by weak hydrochloric acid. The belief was expressed that "success in drawing right conclusions in regard to the value of a solvent must depend in a very large degree upon our correct knowledge of the productiveness of the soil and to our carefulness in obtaining representative samples."

A. Goss suggested that the differences in results with the use of weak acids were frequently due to the neutralizing action of lime and magnesia in the soil. Other speakers emphasized the necessity of great care in sampling soils, i. e., taking samples at a sufficient number of places in the field and thoroughly mixing them.

The question of dividing the subject of soils and ash, which heretofore has been assigned to one referee, was discussed and it was voted to have a separate referee for each in the future.

FOODS AND FEEDING STUFFS.

The report of the referee, Thorn Smith, reviewed the work of the Association on this subject and especially on the determination of carbohydrates, and urged that more work on the latter subject be done. The results for the last year were not received in time for reporting.

The associate referee, C. A. Brown, jr., sent a paper on the determination of starch, which was principally a review of the work of the Association.

A. Goss read an interesting paper on "The protein factor of 6.25 as applied to beef," based upon analytical studies of a side of beef. He showed that the factors for different cuts varied from 5.95 in the case of the navel to 6.24 in the case of the sirloin. "In a general way it would seem that for such cuts as the sirloin, sirloin steak, and round steak, in which the greater part of the sample is pure muscular tissue, the 6.25 factor is more nearly correct than in the case of such cuts as the navel, lower thin flank, and leg, in which tendon and connective tissue is present in comparatively larger quantity." He suggested the factor 6.14 as the average for the whole side.

C. D. Woods called attention to the loss of nitrogen in drying meat, and believed that the protein factor must be obtained by separating the different kinds of tissue.

Food standards.—The report of the committee on food standards, presented by W. Frear, reviewed the work which has been done at the request of the committee by chemists throughout the country with a view to securing data to serve as a basis for standards. This work has been divided by topics among different chemists, and is progressing so well that it is the belief of the committee that it will soon be possible to formulate a system of standards such as the food bills now in Congress call upon the Association to provide. The committee asked authority to publish the system of standards as soon as it was possible to do so, and this was granted and the committee continued.

FUNGICIDES AND INSECTICIDES.

The report on fungicides and insecticides, sent by L. A. Voorhees, associate referee, was of special interest, as it was the first report on this subject which has been presented before the Association. It traced the growth of the study of fungus diseases and insect enemies of crops, and the increasing practice of spraying, which has resulted in a large demand for insecticide and fungicide materials. Certain of these, as copper carbonate, potassium cyanid, potash lye, formalin, tobacco preparations, Paris green, London purple, and other arsenicals, are either subject to adulteration or substitution, or vary widely in composition as the result of the method of preparation and the degree of purity. "It would seem that analytical work on insecticides and fungicides is much needed, and at present should include the following determinations: Copper, cyanogen, alkalis, formalin, nicotin, and arsenic." No analytical work was reported, but provisional methods were proposed which were adopted as such by the Association.

B. W. Kilgore suggested that "the best work which this Association could do would be to determine the definite form of the compounds in the arsenical insecticides," since the injuries from the use of such materials are frequently traceable to free arsenic, the effect of which may be neutralized by adding lime.

R. E. Blouin, of Louisiana, gave an account of the Paris green inspection in that State, which is provided for by law, and of the methods of analysis employed.

G. W. Shaw stated that he had found the potassium chlorate method most satisfactory for arsenic; and R. C. Kedzie spoke of the arsenid of lime which was coming into use and the practical method of its preparation.

DAIRY PRODUCTS.

The report of the referee, J. B. Weems, reviewed the work of the Association relating to this subject, and presented returns received from 7 chemists on the determination of the proteids of skim milk which had been preserved with formalin. No recommendations were made, but the suggestion was offered that the investigation of methods for this particular branch of the subject be continued another year.

No reports were presented by the referees on liquors and food adulteration, sugar, and tannin.

MISCELLANEOUS.

B. W. Kilgore presented a brief report for the committee on volumetric standards. This related principally to the question of temperature of laboratories and showed that 20 to 22° C. was more nearly the working temperature of southern laboratories than 15° C. H. W. Wiley referred to the discussion of this subject before the International Congress of Chemists at Vienna, at which the suggestion was made that different standard temperatures be adopted by different countries to suit their conditions. It was thought that 17.5° C. would be better adapted for Germany. The congress at Vienna voted unanimously to adopt the absolute standard of measure and to discontinue the use of the so-called Mohr liter as soon as possible.

The committee on rewriting the methods of the Association reported and presented a revised edition of Bulletin 46 of the Division of Chemistry of this Department as the result of its work.

The report of the committee on abstracting was presented by E. W. Allen. This report showed that the abstracting of literature relating to analytical methods had been continued by the members of the committee as in former years, the abstracts being published in current numbers of the Experiment Station Record.

The thanks of the Association were expressed to the various committees who were instrumental in entertaining the Association during its meeting, and especially to M. E. Jaffa, chairman of the local committee of arrangements, and to the retiring president, R. C. Kedzie.

OFFICERS OF THE ASSOCIATION.

The officers elected for the ensuing year are as follows: President' B. W. Kilgore; vice-president, L. L. Van Slyke; secretary, H. W. Wiley; additional members to the executive committee, M. E. Jaffa and A. Goss.

Following the suggestion offered in the Association, the incoming president continued the referees for another year as far as this could be done, in order that they might have further opportunity than had been afforded by the short period since the last meeting. The referees and committees as announced are as follows:

Phosphoric acid: Referee, E. G. Runyan, Washington, D. C.; associate referee, H. K. Miller, Lake City, Fla.

Nitrogen: Referee, F. S. Shiver, Clemson College, S. C.; associate referee, W. R. Perkins, Agricultural College, Miss.

Potash: Referee, B. B. Ross, Auburn, Ala.; associate referee, L. S. Munson, Washington, D. C.

Soils: Referee, B. L. Hartwell, Kingston, R. I.; associate referee, M. E. Jaffa, Berkeley, Cal.

Ash: Referee, A. E. Shuttleworth, Guelph, Canada; associate referee, G. S. Fraps, Raleigh, N. C.

Dairy products: Referee, J. B. Weems, Ames, Iowa; associate referee, F. W. Woll, Madison, Wis.

Foods and feeding stuffs: Referee, Thorn Smith, Moscow, Idaho; associate referee, C. A. Brown, jr., State College, Pa.

Liquors and food adulteration: Referee, H. A. Weber, Columbus, Ohio; associate referee, W. D. Bigelow, Washington, D. C.

Sugar: Referee, E. Fulmer, Pullman, Wash.; associate referee, G. L. Spencer, Washington, D. C.

Tannin: Referee, O. Carr, Corry, Pa.; associate referee, E. J. Haley, Ridgway, Pa.

Fungicides and insecticides: Referee, E. A. de Schweinitz, Washington, D. C.; associate referee, L. A. Voorhees, New Brunswick, N. J.

Abstract committee: E. W. Allen, Washington, D. C.; J. T. Anderson, Auburn, Ala.; W. H. Beal, Washington, D. C.; R. E. Blouin, New Orleans, La.; W. F. Hand, Agricultural College, Miss.; G. W. Shaw, Corvallis, Oreg.; J. P. Street, New Brunswick, N. J.; H. Snyder, St. Anthony Park, Minn.; C. B. Williams, Raleigh, N. C.

Committee on food standards: H. W. Wiley, Washington, D. C.; H. A. Weber, Columbus, Ohio; M. A. Scovell, Lexington, Ky.; E. H. Jenkins, New Haven, Conn.; W. Frear, State College, Pa.

Committee on fertilizer legislation: H. W. Wiley, Washington, D. C.; B. W. Kilgore, Raleigh, N. C.; H. B. McDonnell, College Park, Md.; H. A. Huston, Lafayette, Ind.; B. B. Ross, Auburn, Ala.

Committee on volumetric standards: B. W. Kilgore, Raleigh, N. C.; C. L. Penny, Newark, Del.; E. E. Ewell, Washington, D. C.; G. C. Caldwell, Ithaca, N. Y.; H. W. Wiley, Washington, D. C.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

An examination of commercial flour, H. KRAEMER (*Jour. Amer. Chem. Soc., 21 (1899), No. 8, pp. 650–663, figs. 2*).—Directions for the qualitative and quantitative examinations of flour with especial reference to adulteration with corn meal are given. The reagents for the qualitative examinations are enumerated, together with their effects upon the flour. The same reagents are used in the quantitative examination of the flour, the method proposed depending upon the inspection of a sample of known weight with the microscope. The author's principal deductions follow:

> "[Commercial flours may be divided into] (1) those that produce a stiff and cohesive dough in the proportion of 11 to 15 gm. of flour to 10 cc. of water; as, for example, a good spring wheat flour; (2) those that do not produce a stiff and cohesive dough in the proportion of 11 to 15 gm. of flour to 10 cc. of water.
>
> "These may be further divided into the following subclasses: (A) Those that form a smooth, jelly-like paste upon boiling 1 gm. of flour with 15 cc. of water for about 1 minute; as, good winter wheat and some of the blended flours. (B) Those in which a more or less granular or liquid paste results.
>
> "This subclass may be further subdivided into (a) those which give off an odor of roasting corn when heated in glycerin to boiling for a few minutes, as samples containing corn meal. (b) Those that do not give off an odor of roasted corn when heated to boiling with glycerin, as lower grades of flour.
>
> "The quality of these flours may be still further determined by a microscopic examination of either the flour or the gluten mass after removal of the starch, when the presence of fungi and other foreign substances are revealed.
>
> "It appears that in certain sections of the country the adulteration of flour, as of other powdered commercial products, is still practiced, yet it may be said that as a rule the article as found in the Eastern markets represents a higher grade of product than has formerly been reported."

Notes on milk analysis, L. DE KONINGH (*Analyst, 24 (1899), June, pp. 142–146*).—Sour milk is prepared for analysis by the addition of a definite volume of ammonia or caustic alkali, preferably sodium hydrate solution of 1.030 sp. gr., after which fairly accurate hydrometer readings (using given corrections) and centrifugal fat tests can be carried out.

The presence of cane sugar in milk is detected by a blue coloration upon heating 10 cc. of the sample with 2 cc. of saturated solution of ammonium molybdate and 8 cc. of hydrochloric acid (1 to 8) in a water bath for 5 minutes at 80° C.

In testing for boric acid 100 cc. of milk is heated to boiling in a covered beaker, 8 cc. of nitric acid (1 to 50) added and then cooled and filtered. The filtrate is evaporated to dryness with ½ gm. of sodium carbonate, and burned to a gray ash, the soluble portion of which should be examined as usual.—E. B. HOLLAND.

Note on boric acid in milk samples, E. G. CLAYTON (*Analyst, 24 (1899), June, pp. 141–143*).—A report on the examination of 403 samples for boric acid by testing the acidulated ash with tumeric paper, confirming the same with alkali. In the discussion following it was stated that the reaction is very readily obtained by heating ½ cc. of milk directly with a slightly acidulated tincture of tumeric.—E. B. HOLLAND.

Oxidation of the ammonia produced by the ferments of the soil, E. DEMOUSSY (*Ann. Agron., 25 (1899), No. 5, pp. 232–244*).—Culture solutions containing monomethylamin, trimethylamin, anilin, pyridin, and quinolin were inoculated with soil bacteria and the formation and oxidation of ammonia was observed. The amins underwent an apparently constant cycle of transformations when submitted to the action of the micro-organisms of the soil. Carbon was eliminated in the form of carbon dioxid, the excess of hydrogen as water, and the organic base was converted into ammonia, which was tranformed first into nitrous acid and finally into nitric acid. This held true even for the simplest amins closely analogous to ammonia. In no case was direct transformation of amins into nitrous acid observed. The more complex amins yielded ammonia and underwent nitrification very slowly.

A wash apparatus for the determination of nitric nitrogen according to G. Kühn, O. FOERSTER (*Chem. Ztg., 23 (1899), No. 19, pp. 196, 197, figs. 2*).—A rather complex tube attachment to the distillation flask, by means of which all gases and vapors must pass through water before reaching the condenser, thereby preventing the ammonia from carrying over with it into the condenser any alkali from the flask. At the same time, the wash liquid and accumulations from condensed steam are allowed to flow back into the flask, after they have reached a certain level.—J. T. ANDERSON.

A practical shelf for desiccators, H. BOMBERGER (*Chem. Ztg., 23 (1899), No. 23, p. 359, fig. 1*).—The shelf is made of porcelain, with circular, open-bottom, cup-like depressions of different sizes, to receive beakers, watch crystals, etc., as well as crucibles. A water bath also is described, on which this shelf takes the place of the usual copper rings. Substances to be dried, in suitable containing vessels, are placed on this shelf on the water bath, and when the drying is complete the shelf with its contents is transferred bodily to the desiccator for cooling.—J. T. ANDERSON.

Outline of industrial chemistry—a text-book for students, F. H. THORP (*New York: The Macmillan Co., 1898, pp. XX + 541*).

A text-book of physiological and pathological chemistry, G. VON BUNGE (*Lehrbuch der physiologischen und pathologischen Chemie. Leipsic: F. C. W. Vogel, 1899, 4. ed., pp. IV + 510*).

Report of the chemist, R. H. FORBES (*Arizona Sta. Rpt. 1898, pp. 170-181, fig. 1*).—In this report a brief account is given of the work of the chemical department of the station during the year ending June 30, 1898, in the following lines: Investigations of soils, especially of the Salt River Valley (see also Bulletin 28 of the station, E. S. R., 10, p. 420); experiments with cañaigre (see p. 240) and chemical studies of cañaigre extract; and analyses of sugar beets, sugar cane, water, milk, and fertilizers.

The use of compressed oxygen in elementary organic analysis and of soda-lime in the quantitative determination of carbon dioxid, F. G. BENEDICT and O. F. TOWER (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 389-398*).

The determination of oxygen in water, L. MUTSCHLER (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 6, pp. 481-484, fig. 1*).—A modification of Mohr's method is described, in which the reagents are introduced into the flask of water to be tested in sealed tubes which are broken, after the flask is closed, without access of air.

Determination of calcium and magnesium in ashes, J. K. HAYWOOD (*Jour. Amer. Chem. Soc., 21 (1899), No. 6, pp. 508-511*).—An abridgment of the method adopted by the Association of Official Agricultural Chemists in which washing of the iron and phosphoric acid precipitate is avoided.—L. H. MERRILL.

The determination of phosphorus in organic substances, E. LECOCQ (*L'Ing. Agr., 9 (1899), No. 10, pp. 611-617*).—A brief review of the various methods which have been proposed for this purpose.

The volumetric determination of iron in a hydrochloric acid solution, H. PELLET (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 10, pp. 980-982*).

A method for the exact determination of ash in the molasses of sugar factories and refineries, V. ZAMARON (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 10, pp. 967, 968*).

On the determination of invert sugar, G. BRUHNS (*Ztschr. Ver. Rübenz. Ind., 1899, No. 519, pp. 370-376*).

A new test for formaldehyde, N. LEONARD and H. M. SMITH (*Analyst, 24 (1899), April, p. 86*).—Milk "doctored" with formaldehyde when heated with an excess of hydrochloric acid containing a trace of some oxidizing agent, as ferric chlorid or bromin, takes on a violet color. The test is said to be sensitive to 1 part in 1,000,000.—E. B. HOLLAND.

Note on a possible source of error in modifications of the Leffmann-Beam method for estimation of fat in milk, H. D. RICHMOND and F. R. O'SHAUGHNESSY (*Analyst, 24 (1899), June, pp. 146-148*).—In the Gerber modifications of the Leffmann-Beam method, whereby the hydrochloric acid is eliminated, it was proved advisable to first add the sulphuric acid, then the milk, and finally the amyl alcohol, because if the sulphuric acid and amyl alcohol are left long in contact it has the tendency, especially in hot weather, to give high results.—E. B. HOLLAND.

The estimation of fat in milk, using petroleum ether as a solvent, H. D. RICHMOND and C. H. ROSIER (*Analyst, 24 (1899), July, pp. 172-175*).—The authors, working on a theoretical basis, evolved a process whereby the fat is separated as in the Gerber method, extracted from the acid liquid by petroleum ether, the ethereal solution washed several times with water and transferred to a tared flask. "This method compares well with others."—E. B. HOLLAND.

On the determination of added water in milk, A. G. WOODMAN (*Jour. Amer. Chem. Soc., 21 (1899), No. 6, pp. 503-508*).—The method rests upon the constant composition of milk serum. The milk is warmed with dilute acetic acid, cooled, filtered, and the specific gravity taken by means of a Westphal balance. Tables are given showing the specific gravity of the serum of pure milk and of milk of varying degrees of dilution.—L. H. MERRILL.

The estimation of pentosans and its application to the analysis of foods, O. HEHNER and W. P. SKERTCHLY (*Analyst, 24 (1899), July, pp. 178-183*).—The amount of pentosans, estimated by the phloro-glucin method, is used as an index of purity in certain foods.—E. B. HOLLAND.

Analysis of chicory, J. WOLFF (*Rev. Chim. Analyt. et Appl., 4 (1899), Nos. 5, pp. 157–162; 6, pp. 187–193*).—The methods followed by the author for the analysis of chicory are given and also the composition of typical samples.—H. SNYDER.

A glucosid of millet, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 323–325*).—This was abstracted from a more extended account (E. S. R., 10, p. 794).

On the pectins, E. BOURQUELOT (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 20, pp. 1241–1244*).

Solanin, P. CAZENEUVE and B. BRETEAU (*Bul. Soc. Chim. Paris, 21 (1899), No. 9, pp. 428–431; Jour. Pharm. et Chim., 6. ser., 9 (1899), No. 10, pp. 465–468*).

Analysis of wine ash, C. F. JURITZ (*Agr. Jour. Cape of Good Hope, 14 (1899), No. 7, pp. 461–463*).—Percentage of ash in 28 samples of wine and percentage of ash and of lime, potash, and phosphoric acid in ash of 11 samples.

A new indicator, E. RIEGLER (*Bul. Soc. Sci. Bucarest, 1898, No. 6; abs. in Bul. Soc. Chim. Paris, 21 (1899), No. 11, p. 559*).—The indicator is the nitrobenzene azoguiacol which alkalis color red and acids greenish yellow.

Upon the use of resorcin as an indicator, A. LEMOINE (*Bul. Assoc. Belge. Chim., 13 (1899), No. 4, pp. 177–189*).—The author states the various uses that may be made of resorcin as an indicator in volumetric work. The subject is discussed under the following heads: Analysis of water, analysis of commercial borax, determination of ammonia, of "fixed" fatty acids in butter, and acidimetry and alkalimetry.—H. SNYDER.

A new polarization apparatus with scale on the quartz wedge, G. BRUHNS (*Deut. Zuckerind., 24 (1899), No. 20, pp. 753–755, figs. 3*).

A new mercury pump, E. U. CHATELAIN (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 18, pp. 1131, 1132, fig. 1*).

Sediment trap, A. H. COOTE (*Chem. News, 79 (1899), No. 2061, p. 241, fig. 1*).

A serviceable generator for hydrogen sulphid, W. P. BRADLEY (*Amer. Chem. Jour., 21 (1899), No. 4, pp. 370–376, fig. 1*).

Ether extraction apparatus for liquids in quantitative determinations, F. BAUM (*Chem. Ztg., 23 (1899), No. 23, pp. 249, 250, fig. 1*).—The essential parts are an extraction flask on a water bath for the ether, and an extraction cylinder for the liquid under examination, the two being suitably connected with each other and with the condenser by means of glass tubes. A tube leaves the extraction cylinder horizontally near the bottom, bends upward at right angles, and at a suitable elevation connects with the condenser. The ether vapor from the flask reaches the condenser, condenses, accumulates in this tube, and when it reaches a sufficient height it is forced by its own pressure through the liquid to be treated, and collects above the latter in the extraction cylinder. Thence it passes through an overflow tube back into the flask, there to be again vaporized and sent out on its course.—J. T. ANDERSON.

BOTANY.

Experiments with native and foreign fodder plants, D. MCALPINE (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), p. 945*).—A brief abstract is given in which it is stated that 120 varieties of grasses and fodder plants received from this Department were given a trial in Victoria, the object being to test their growth under different conditions of soil, climate, heat, and moisture, but mainly to prove their drought resisting properties. Twenty-one species of grasses from America resisted drought, and of these 7 were very conspicuous for their fresh green growth. Among fodder plants other than grasses two were found to be suitable to Australian conditions and very resistant to drought. These were hairy vetch and *Polygonum* sp.

A study of the root systems of wheat, oats, flax, corn, potatoes, and sugar beets, A. M. TEN EYCK (*North Dakota Sta. Bul. 36, pp. 333–346, figs. 7*).—The author has made a study of the roots of these plants, following the method given in the annual reports of the Wisconsin Station for 1892 and 1893 (E. S. R., 5, p. 480; 7, p. 568).

The studies on the corn roots were made at different stages, the first being when the plants were 30 days from planting. At this time the main roots appeared to have developed laterally and but few were found to have penetrated to a depth of 12 in., the bulk of the roots lying within 8 in. of the surface of the soil. The second lot examined were 55 days from planting, when the plants were 54 in. in height. In this lot the primary roots had penetrated to a depth of 2½ ft., the horizontal roots had increased and the length was much greater than in the former case, many extending from hill to hill. The lateral roots frequently sent up feeders within 2 in. of the surface. In the third sample of corn examined the specimens were taken 10 days after the corn had been killed by frost. At this time, although the leaves were brown and dry, the roots seemed to be still alive and growing. These roots had penetrated the ground to a depth of 3½ ft., and the soil of the entire field was fully occupied by them.

Wheat roots were examined 110 days after sowing the seed. Most of the main roots were found to extend directly downward, sending out numerous small feeders which practically occupied the soil to a depth of about 4 ft. Oats were examined with nearly the same results as were found in the case of the wheat.

The sugar beet roots were examined at maturity, or 133 days after planting the seed. With this plant the tap root extends almost perpendicularly downward into the ground, the lower part being quite small and thread like and reaching to a depth of more than 3 ft. The lateral roots started 4 or 5 in. from the surface, and there was but little root development in the upper 6 in. of the soil.

The flax roots were studied about the time the crop was ready to cut for seed. The roots were very small and easily broken, and the sample was not considered sufficiently good for photographing. The root system of the flax is quite unlike that of any other plant studied. It consists of a single, small, thread like tap root running vertically downward and giving off small short side roots in the first 12 to 18 in. The tap root reaches a depth of about 3 ft.; and, unlike the roots of the other plants, the flax roots do not form a network near the surface of the soil, nor do they occupy it so completely.

The investigations of potato roots were nearly a failure on account of the plants having been frosted. The roots of this plant are said to be few in number and do not run deep.

In general, it is said that crops may be divided into 2 classes, those planted in rows and cultivated, and those sown broadcast or drilled a few inches apart and not cultivated. In the first class are placed corn, potatoes, beets, etc., while in the latter are wheat, oats, and flax. The roots of the latter penetrate deepest into the soil, but make only short rudimentary lateral growth, while the roots of the cultivated crops spread out horizontally in every direction and occupy more soil, but do not extend so deep into the ground as those of the sowed crops.

Selective absorption of mineral elements by plants, E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris. 127 (1898), No. 23, pp. 970–973*).—The author reports a number of experiments with colza, buckwheat, rye, and rye grass on their ability to absorb, through their roots the salts of potassium, sodium, calcium, magnesium, etc. Young buckwheat plants grown in cultures containing equal quantities of nitrate and chlorate of potash absorbed in 5 days 6.5 mg. nitrate and only 2.7 mg. chlorate. Colza in 8 days, from a similar solution, absorbed 10.9 mg. nitrate and 4.6 mg. chlorate. Similar results were obtained with rye.

Experiments with potassium and calcium on rye, colza, peas, and lentils showed a considerable preponderance of potash absorbed. Colza takes up a little less calcium than soda, maize a little more. The comparison between potassium and sodium showed a slight absorption of sodium compared with that of potassium.

In general, when mineral solutions not poisonous to plants are presented singly, they are absorbed in about the same proportion as they exist in the normal plant. Injurious minerals are absorbed through the roots in very small quantities only. When grown in complex solutions, the plants exercise a selective power between the different materials in the solutions.

The author calls attention to the fact that these experiments were all made on young plants, and the results are not necessarily the same on older ones.

Dextrin as a reserve material in plants, LECLERC DU SABLON (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 15, pp. 914, 915*).—The author states that most physiologists consider dextrin not as a reserve material but as a transitory product due to the action of diastase on starch. Investigations on a number of plants, however, seem to indicate that this view will have to be modified somewhat.

The author gives the starch and dextrin content in hyacinth bulbs for different periods of growth, from which it appears that the maximum dextrin content is found in the bulbs when in a resting stage. Other plants show similar characteristics. Tulip bulbs in a resting state contain 14 per cent of dextrin, and lily bulbs 18 per cent. In both these plants, as well as in hyacinths, the dextrin is always found in conjunction with starch. In the asphodel, where there is no starch, the dextrin amounts to 15 or 20 per cent, and sometimes even more. In this case there is no digestion of starch to form dextrin, and this latter substance must be considered as a reserve carbohydrate.

In conclusion, the author says that dextrin should be considered as playing 3 different rôles: (1) as a reserve in the organs during their formation, when it is used to form starch; (2) as a decomposition product of starch, and (3) as a reserve material independent of the starch during the resting period.

Formation and transformation of lecithin, J. STOKLASA (*Ztschr. Physiol. Chem., 1898, p. 398; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 2, p. 181*).—The author states that in lupines kept in the dark the decomposition of albumin, formation of asparagin and glutamin, and the decomposition of lecithin take place not only in the leaves but also in the root tubercles. Lecithin is said always to be an accompaniment of the albuminoids, and is decomposed as a consequence of the darkening of the green leaves. The formation of lecithin and of the albuminoids depends on photosynthetic assimilation.

Inulin, H. FISCHER (*Beitr. Biol. Pflanz.* [*Cohn*], *8* (*1898*), *pp. 53–106; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 3, pp. 291, 292*).—The author gives a detailed account of his investigation of the occurrence of inulin in plants, its properties, micro-chemical reactions, etc. This substance is said to be especially characteristic of the Compositæ, occurring in most of the tribes and in a large number of the genera of that order. It is also found in the allied orders Campanulaceæ, Lobeliaceæ, Goodeniaceæ, and occasionally elsewhere. It is said to occur very rarely in monocotyledons, and but one instance is reported of its occurrence in an annual plant. Its presence has been recorded in algæ, but has not been definitely determined in Gymnosperms, Pteridophyta, Bryophyta, or fungi. Its main function is undoubtedly that of a reserve food material in the dormant period of the plants, occurring especially in underground organs.

The author criticises the views of Nägeli, Meyer, and Bütschli respecting the nature of the swelling of this substance, and he claims that the mode of swelling by absorption of water is quite different from that of starch or gelatin. The sphæro crystals increase in volume, but do not pass gradually into a soluble condition, forming paste. On the contrary, they are said to dissolve completely like crystals or break up into numerous granules.

The making and improvement of wheats for Australian conditions, W. FARRER (*Rpt. Australasian Assoc. Adv. Sci., 7* (*1898*), *pp. 908, 909*).—A brief abstract is given of a paper read by the author before this association, giving an account of the origin of the work and principles on which it had been conducted. The qualities desired for improvement were increased rust resistance and increased gluten content. The methods adopted for improving the wheat plant were by selection and cross breeding combined with selection, the latter being considered the more advantageous. For Australian conditions the author states that the qualities of wheat especially demanded are ability to thrive in dry soils, stool sparingly, and ripen early. For rust resistance the author expresses the opinion that the solution of the problem has probably already been accomplished so far as the interior of Australia is concerned.

The bacteria of leguminous root tubercles, MAZÉ (*Ann. Inst. Pasteur, 13 (1899), No. 2, pp. 145–155*).—In previous papers (E. S. R., 9, p. 118; 10, p. 318) the author discussed the physiology and morphology of the bacteria which assist in the assimilation of free atmospheric nitrogen. In the present article the practical utilization of these organisms is discussed and the theories reviewed. The soil inoculation of Salfeld and the pure cultures of Nobbe are described, and the advantages of each pointed out. The author does not agree with Nobbe in that there is a separate race of bacteria for each species or group of nearly allied species of plants. He claims that such conclusions are not warranted either by field trials or a study of the physiology of the organisms themselves. He believes there are certain physiological forms of bacteria which are determined by the nature of the media in which they are developed. These are able to inoculate the roots of plants growing in soils offering the proper condition for their development. The same principle will probably apply to Alinit.

The author believes that the use of pure cultures of these organisms is not destined to play a very important part in agricultural practice.

On the distribution of bacteria through the soil, P. P. DEHÉRAIN (*Ann. Agron., 25 (1899), No. 6, pp. 289–293*).—Studies are reported in which the presence and activity of nitrogen-assimilating bacteria in soil which had been devoted exclusively to vine growing for 25 years were investigated. Pots were filled with soil from the vineyard, fertilized with superphosphate and stable manure, and from a plat where vetches had been grown the previous year. Comparisons were made between the crop of vetches grown in the different pots, from which it appears that the pots receiving manure gave the greatest yield, and those without fertilizer, but supposedly well inoculated with organisms for nitrogen assimilation, the least. Examinations of the roots showed an abundance of tubercles in every pot, although no leguminous crop had been grown on the vineyard soil for at least 25 years. .

The author believes there is an abundance of bacteria carried by the winds, etc., to all soils, and the addition of cultures such as Alinit and Nitragir are unnecessary. In order to obtain the best results, he says, it is better to provide the proper conditions for both the bacteria and the plants themselves.

His observations are said to substantiate those of Mazé in that there are apparently distinct classes of bacteria for calcareous soils and for sandy ones.

Nitragin experiments, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 327–329*).—The author conducted a series of experiments to ascertain whether any advantage would be derived from inoculating North Dakota soils with germs obtained from cultures from the roots of peas. The material used was that known commercially as Nitragin. A series of pot experiments was conducted in sand and garden soils, and the results obtained indicate a marked advantage resulting from the inoculation of the soil in the case of the sand cultures, but with the garden soil already rich in organic matter the advantage was very slight.

In order to test the experiment more fully the same experiment was conducted in plats, with similar results.

The general conclusion reached from the experiment is that where the soil is well stocked with organic matter the gain obtained is not sufficient to warrant recommending the use of Nitragin. In the case of light sandy soils and for truck gardening it is possible that it might prove valuable.

Chemical analyses were made of the plants grown in the various experiments with the following results:

Chemical composition of peas grown with and without Nitragin.

	Moisture.	Protein.	Fat.	Crude fiber.	Nitrogen-free extract.	Ash.
PLAT EXPERIMENTS.						
Grown in sand:	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
With Nitragin	4.10	14.18	6.57	20.05	47.80	7.30
Without Nitragin	5.25	11.06	5.14	21.15	48.80	8.60
Grown in garden soil						
With Nitragin	6.60	20.12	6.87	20.20	36.31	6.60
Without Nitragin	4.15	20.56	6.75	21.60	37.64	4.15
FIELD EXPERIMENTS.						
With Nitragin	4.92	22.50	5.50	16.30	42.40	4.92
Without Nitragin	3.49	22.50	5.68	20.83	38.15	3.49

Elementary science bulletins, W. J. BEAL (*Proc. Mich. Hort. Soc., 1897, pp. 343-363, figs. 43*).—Notes are given on a number of seeds before and after sprouting and observations recorded on the behavior of leaves of clovers, etc., at different times of day.

Cereals and their relations to the life zones in North America, C. S. PLUMB (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 137-140*).—Notes are given on investigations on the distribution of corn, wheat, and oats as influenced by the different life zones. The details of these have been published as Bulletin 11 of the Division of Biological Survey of this Department (E. S. R., 10, p. 723).

American grasses—II, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Agrostology Bul. 17, pp. 349, figs. 325*).—This bulletin is in continuation of Bulletin 7 of the Division (E. S. R., 10, p. 327). Illustrated notes are given on 325 species of grasses, many of which are illustrated for the first time. The prominent characteristics, habitat, distribution, and time of flowering of each species are given.

The flat pea, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Division of Agrostology Circ. 11, pp. 6, figs. 3*).—Descriptive notes are given of the flat pea, which is a variety of *Lathyrus sylrestris*. The history of its introduction is stated, and the various uses to which these plants have been put are described. The methods of cultivation are given and chemical analyses are quoted from various station publications. The value of the flat pea as determined at a number of the stations is outlined, and in conclusion the author states that in the sandy arid regions of the West, especially in the limestone and chalky regions of the Southwest, the flat pea may be considered as having some value, but where other forage crops can be grown, such as corn, sorghums, rye, barley, clovers, or the ordinary tame grasses, it will not pay to cultivate this plant for fodder.

Grazing problems in the Southwest and how to meet them, J. G. SMITH (*U. S. Dept. Agr., Division of Agrostology Bul. 16, pp. 47, figs. 9*).—Notes are given on the free ranges and effects of overstocking. The investigations of the author of various problems of grazing are given at some length. Destruction of grasses by animal pests and the deterioration through the increase of weeds, the principal of which are prickly pear and mesquite, are discussed.

Various methods of renewing cattle ranges are briefly mentioned, and as additional aids to range improvements the author mentions stack silage, hay, and attention to the water for stock. The grazing regions of Texas and New Mexico are divided into a number of regions, each of which is bounded and its characteristics described.

Notes on Panicum colonum (*Queensland Agr. Jour., 4 (1899), No. 5, p. 364, pl. 1*).—This grass, which is highly esteemed, is figured and described. It is claimed to be valuable for pasturage and hay.

Notes on one of the so-called native millet grasses, J. H. MAIDEN (*Agr. Gaz. New South Wales, 10 (1899), No. 6, pp. 494, 495, pl. 1*).—Notes are given on a variety of *Panicum decompositum*. This grass is said to grow well and provide abundant fodder. Horses do not seem to like it, although sheep thrive on the grass and hay. This plant differs from the highly esteemed *P. decompositum* in having narrower leaves and permanently erect branches and panicles.

Some notes on the progress of variety study in timothy, A. D. HOPKINS (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 120–122*).—Notes are given in which the author briefly describes 8 varieties of timothy which have resulted from selection. The important characters which are exhibited by the different varieties are readily retained, and the author thinks that larger yields and superior qualities of hay and seed may be obtained in this manner.

Ramie, or China grass (Bœhmeria nivea), W. SOUTTER (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 380–382, pls. 2*).—Illustrated notes are given of this fiber plant, together with directions for its cultivation and utilization.

Plants of the rabbit-infested country of South Queensland, J. F. BAILEY (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 448–451, pls. 6*).—A list is given of a number of plants which are able to withstand the severity of the climate of the rabbit-infested regions along Bulloo River and which thrive when all other plants seem to be destroyed by drought.

Plants reputed poisonous to stock, F. M. BAILEY (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 465–468, pls. 2*).—Notes are given on *Hibbertia bennetti* and *Nicotiana suaveolens*, *Acacia cunninghami*, *A. delibrata*, and *A. penninervis*. The acacias, or some of them, are regarded as valuable forage plants at certain stages of growth, and their poisonous qualities are said to be due to the presence of saponin in the unripe pods. *Trema aspera*, which has been considered poisonous, probably owes its injurious quality to its forming bezoars in the stomachs of cows and horses.

The supposed poisonous plants of western Australia, F. TURNER (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 910–919*).—The author popularly describes 13 species of indigenous and introduced plants which are suspected of poisoning or causing injury to cattle, horses, and sheep.

Notes on Yuccas (*Prometheus, 9 (1898), No. 165, pp. 775–778, figs. 3*).—Illustrated descriptive notes are given of *Yucca filamentosa*, *Y. aloifolia*, *Y. gloriosa*, *Y. filifera*, and *Y. brevifolia*, together with an account of the method of their fertilization, etc.

Distinctive characteristics of the sexes of Ginkgo biloba, L. HENRY (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), Feb.; Bul. Assoc. Anciens Élèves École Hort. Versailles, 1898, p. 592; cited in Gard. Chron., 3. ser., 25 (1899), No. 640, p. 201*).—It is claimed that female trees retain their leaves longer than male trees, at Paris a difference of 3 or 4 weeks being noticed. Early frosts may accelerate the fall, but appreciable differences can be noted in the two sexes.

Concerning the pollination of Cucurbita, A. BRIZI (*Bul. Soc. Bot. Ital., 1898, pp. 217–222; abs. in Bot. Centbl., Beihefte, 8 (1899), No. 6, pp. 435, 436*).

Investigations on the development of the seed coat and pericarp of the Gramineæ, P. GUÉRIN (*Ann. Sci. Nat. Bot., 8. ser., 9 (1899), No. 1, pp. 1–59, figs. 70; Bul. Soc. Bot. France, 45 (1898), No. 6–8, pp. 405–411*).

Investigations on the growth of plants, L. MONTEMARTINI (*Atti Inst. Bot. Univ. Pavia, 2. ser., 5 (1899), pp. 75–143*).—Investigations on the growth of a number of plants are reported, from which the author concludes that growth is not due to turgescence, but is a vital function of protoplasm. An extensive list of works consulted in the preparation of this paper is given.

Winter growth of buds, E. KÜSTER (*Beitr. Wiss. Bot., 2 (1898), p. 401; abs. in Bot. Centbl., Beihefte, 8 (1899), No. 6, p. 420*).—The buds of maple and pine are said to show a small amount of growth between November and February during an ordinary winter.

The leafing of trees, A. C. FORBES (*Gard. Chron., 3. ser., 25 (1899), Nos. 649, p. 353; 652, p. 406*).—Notes are given on the order of leafing of a number of forest trees and some of the phenomena by which they may be influenced.

Physiological investigations on the utilization of the reserve material in seeds during germination, C. POURIEWITSCH (*Mem. Soc. Nat. Kiew, 15 (1896–98), pp. 519–621*).

Notes on transpiration, H. H. DIXON (*Proc. Roy. Irish Acad., 3 (1898), pp. 618–635, figs. 2; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, pp. 300, 301*).—The author regards transpiration as a vital rather than a physical phenomenon. The elevation of the water of the transpiration current when the leaves are surrounded by a saturated atmosphere is said to be effected by a pumping action proceeding in the living cells of the leaves. This pumping action is said to be capable of raising water against all external hydrostatic pressure. In common with other vital actions, this is accelerated by a moderately high temperature and is dependent on the supply of oxygen. This activity is possessed by the cells adjoining the terminal portion of the water conduits and in plants provided with water glands the pumping action is not limited to the secreting tissues of these glands.

Assimilation of nitrates by plants, T. WÖLFER (*Rostock, 1898, pp. 61, pls. 7; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, p. 300*).—From a series of experiments on the absorption, distribution, and assimilation of nitrates by cultivated plants, the author concludes that plants grown in the dark store up nitrates very rapidly and more abundantly than those grown in the light. Plants grown either in the dark or light in an atmosphere containing a larger amount of carbon dioxid than normal contain no starch and only traces of glucose. Nitrates could be detected only in small quantities in the vascular bundles A larger quantity is found in the bundle sheaths, and the largest amounts occur in the cells of the cortex and parenchyma.

METEOROLOGY.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 27 (1899), Nos. 1, pp. 1–40, figs. 4, charts 9; 2, pp. 41–87, pls. 6, charts 13; 3, pp. 89–138, charts 13*).—In addition to the usual reports on forecasts and warnings and on weather and crop conditions, and meteorological tables and charts, No. 1 contains special contributions on Recent titles of papers bearing on meteorology, by W. F. R. Phillips; Hints to observers of shooting stars, by W. Harkness; The northwest gales of the southern Blue Ridge and Piedmont region, by B. C. Hawkins; and Hydrology of the Lake Minnetonka watershed, by G. W. Cooley (see p. 223); and notes by the editor on meteorological records in Iowa, history of weather telegraphy, the Tugrin fog dis peller, the international date, sensible temperatures, origin of the word "blizzard," forests and snowfall, and recent earthquakes.

No. 2 contains special contributions on Snow temperatures, by E. B. Calvert and W. F. R. Phillips; Recent papers bearing on meteorology, by W. F. R. Phillips; and Wave of billow clouds, by A. J. Henry; and notes by the editor on the weight or mass of the atmosphere, the Weather Bureau in Alaska, solar halo, frequency of injurious phenomena, barographs on ships, why do birds migrate? ice jam in the Niagara River, international cloud names, forecasts on letter boxes, the depth of atmospheric cold waves, the benefits of severe winters, weather versus climate, experiments in protection from frost, the dust in the atmosphere, the blessing of cold weather, recent earthquakes, the Weather Bureau and the ice business, and history of weather predictions.

No. 3 contains special contributions on Experiments in weather prediction, by W. A. Eddy; Selenium and its use for the measurement of sunshine, by N. E. Dorsey; Snow rollers, by A. H. Thiessen; Recent papers bearing on meteorology, by W. F. R. Phillips; and Utilization of fog, by A. McL. Hawks; and notes by the editor on the Pacific Coast division of the Canadian meteorological service, mirobia and seiches, meteorological reports by cable from Iceland, the International Meteorological Committee, meteorology in Russia, the daily weather map for Mexico, the utility of the weather map, obscure points in meteorology, meteorology in Great Britain, breaking up of the ice at Pierre, South Dakota, liquid air as a source of power, dust whirls and fairy dances, monthly charts for the West Indies, vertical temperature gradients, utilization of fog, the blue color of the sky, abstracts of university theses, and storm centers in the Pacific.

The importance of meteorology for the farmer (*Fühling's Landw. Ztg., 18 (1899), No. 10, pp. 361-366*).

Meteorological observations, J. E. Ostrander and A. C. Monahan (*Massachusetts Hatch. Sta. Met. Buls. 124, 125, 126, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during April, May, and June. The data are briefly discussed in general notes on the weather of each month.

Meteorological observations (*Compt. Rend. Ann. Sta. Agron. Ploty, 1896, pp. 99-124, figs. 2, charts 3*).—These include observations on rainfall, evaporation, soil moisture and temperature, pressure, temperature and humidity of the air, sunshine, cloudiness and solar radiation, wind, and miscellaneous phenomena. The observations are recorded in tables and charts.

The meteorology of 1898 (*Trans Highland and Agr. Soc. Scotland. 5. ser., 11 (1899), pp. 317-324*).—A table "gives a comparison of the winds, mean pressure, temperature, rainfall, cloud, and sunshine of 1898 as compared with the previous 42 years' averages" for all Scotland. The general features of the weather of each month of 1898 and the effect of the season on the growth of crops, especially wheat, barley, oats, potatoes, and turnips, are briefly discussed.

Cloud observations in Victoria, P. Baracchi (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 259-265, pls. 4*).—A report of progress in observations made in pursuance of the plan adopted by the International Meteorological Committee in 1894 on form, position, and direction of movement of clouds, with special notes on cirrus clouds and on direction and force of the surface wind, temperature of the air, weather characteristics, etc.

Weather predictions and weather reports of the fifteenth and sixteenth centuries, G. HELLMANN (*Wetterprognosen und Wetterberichte des XV und XVI Jahrhunderts, No 12, Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus. Berlin: A. Asher & Co., 1899*).

Weather forecasting, W. L. MOORE (*U. S. Dept. Agr., Weather Bureau Bul. 25, pp. 16*).—"The article is written in popular style, and contains information as to the movements and progression of storms, the different kinds of storms, how forecasts are made, etc., and, in addition, a brief history of the early researches in meteorology and of the organization of the Weather Bureau." It is a reprint of an article which was published in *The Forum, May, 1898.*

Phenological observations in Klagenfurt, 1895–1898, H. SABIDUSSI (*Jahrb. Naturhist. Landes Mus., Kärnten, 25 (1899), pp. 49–60*).

The causes of the earlier or later appearance of the vegetation period in different years in the Scandinavian countries, O. PETTERSON (*K. Landt. Akad. Handl., 38 (1899), No. 1, pp. 3–13*). —The vegetation period is shown to stand in close relation to the surface temperature of the Atlantic Ocean during the winter months.

Hydrology of the Lake Minnetonka watershed, G. W. COOLEY (*U. S. Dept. Agr., Weather Bureau Doc. 194, pp. 10, figs. 4*).—A discussion of data (in tables and charts) on rainfall (1881–1889), evaporation, and run off, reprinted from *Monthly Weather Review, 27 (1899), No. 1.*

Monthly bulletin of the River and Flood Service, H. C. FRANKENFIELD (*U. S. Dept. Agr., Weather Bureau Doc. 182, pp. 16, chart 1*).—A summary of observations on river stages and the condition of navigation during October, 1898.

Measurement of precipitation, W. L. MOORE and C. F. MARVIN (*U. S. Dept. Agr., Weather Bureau Doc. 193, pp. 28, figs. 10*).—This is a pamphlet of instructions for the measurement and registration of precipitation by means of the standard instruments of the U. S. Weather Bureau.

Water in the Sahara, LAHACHE (*Rev. Sci. [Paris], 4. ser., 11 (1899), No. 21, pp. 651–654*).

WATER—SOILS.

Analyses of water for irrigation, G. L. HOLTER and J. FIELDS (*Oklahoma Sta. Bul. 38, pp. 3–7*).—Analyses of the solids of 44 samples of stream, well, and spring water are reported, including a number already published (E. S. R., 9, p. 696). A summary of the conclusions reached is as follows:

"(1) The water of the Salt Fork of the Arkansas and of the Cimarron River is unfit to be used for irrigation, except in very limited amounts.

"(2) The water of the North Canadian and of the South Canadian may be safely used for irrigation.

"(3) None of the smaller streams that have been examined, except the Black Bear, are unfit to be used for irrigation.

"(4) Well waters vary greatly in the amount and character of the dissolved mineral matter which they contain, and should be analyzed before being arranged to be used for irrigation.

"(5) A partial survey of the conditions which must be met in the construction of reservoirs for the retention of storm river waters has been made, and it is not clear that this method is entirely feasible in all cases."

The alkali soils of Montana, F. W. TRAPHAGEN (*Montana Sta. Bul. 18, pp. 21–50*).—The formation of soil; the origin, source, and rise of alkali; the treatment of alkali lands; the effects of alkali upon plants and soils, and the vegetation of alkali flats are discussed, and determinations of sulphuric acid, calculated as sodium sulphate, and of alkalinity in terms of sodium carbonate of 325 samples of alkali soils taken at different depths at about 50 localities in the State are reported. "Almost without exception where alkali exists in Montana, it is of the 'white' kind and not the 'black.' It owes its origin to the rock from which the soil was formed and is present because the annual precipitation is not sufficient to carry it away in solution."

Underdraining, where it will pay, judicious surface flooding, growing of alfalfa, and cautious irrigation are suggested as a means of amelioration. The use of gypsum on black alkali is recommended.

Soil studies, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 310-322*).—These include chemical analyses of 9 samples of soil (2 from Mayville, 1 from Edgeley, and 6 from the station rotation plats), the grading of 6 samples with reference to gumbo properties, and studies of the humus and humates of 26 samples.

The water-soluble matter of the gumbo soils was determined, but the results apparently threw no light on the peculiar properties of these soils. The soil on which there had been the greatest crop rotation contained the largest amount of nitrogen and organic and volatile matter and the smallest amount of sand and silica. Almost the reverse was true of the soils showing the most marked gumbo properties.

Ordinary chemical analyses of the soil of adjacent fields, one of which had been cropped, mainly in wheat, for 17 years, and was beginning to show a decline in productiveness, and the other had remained in native sod, gave little "to indicate why there should be any marked difference in the productivity of the two soils." A study of the humus and humates gave the following results:

Humus and humates in old and new soils.

	Old soil.	New soil.
	Per cent.	*cent.*
Humates	3.04	4.27
Humus	1.56	2.53
In the humates:		
Phosphoric acid	.179	.192
Calcium oxid	.892	1.030
Potassium oxid	.075	.089
Nitrogen.	.041	.094

"Humus is that portion of the organic or vegetable matter in the soil that has reached a certain stage of decay, while humates refer to all the matter that is extracted with the humus[1] and is the mineral portion of the soil together with the humus. It will be seen that by processes of cropping the humus in the old soil has been reduced 39 per cent as compared with the adjoining new soil, and it is not probable that this represents the full extent of loss. Of nitrogen in the humus there has been a loss from the old field of 56 per cent. It has been assumed[2] that a soil for wheat growing should contain not less than 5 per cent of organic matter, and in this case we have only 1.56 per cent of humus and 5.26 per cent of volatile matter, not all of which was organic matter, and the amount of humus nitrogen is very low, 0.041 per cent, which is less than one fourth of the average humus nitrogen as determined for other soils. Is it not possible that we have here an answer to the question, What is the probable reason for loss of productive power in this soil? The remedy would seem to be to increase the humus matter in the soil by such a system of crop rotation as would best insure this end.

---

[1] By means of 4 per cent ammonia solution.

[2] North Dakota Sta. Bul. 32 (E. S. R., 10, p. 129).

"In the soil we have just been examining we find that along with the humus there is extracted considerable mineral matter. In case of the above soil 48 per cent of the total phosphoric acid in the soil was extracted with the humus, 42 per cent of the lime, and 31 per cent of the potash."

As the humus decreased the percentage of phosphoric acid, potash, nitrogen, and lime extracted with the humus decreased. Analyses of other soils show that an increase of humus in the soil is accompanied by an increase of mineral constituents associated with the humus, although the increase is not always uniform.

The 4 per cent ammonia extract of a soil was subjected to fractional precipitation by hydrochloric acid with the following results:

Composition of fractional precipitate of soil humus extract.

	One third	Two thirds.	Complete.
	Per cent	*Per cent.*	*Per cent.*
Humus	54.38	49.19	29.35
Ash	45.62	50.81	70.65
Nitrogen in precipitate.	6.67	3.67	1.33

"In washing the precipitate it was found quite soluble in water, and it can not be said that all of the ammonium chlorid formed was washed out, and there was also dissolved a small amount of the humates.

"The humates while still moist on the filter paper will be largely dissolved by continued washing with water, leaving not to exceed 20 per cent of residue on the paper. On ignition this residue is found to contain 68 per cent mineral matter and 32 per cent of humus. The residue is a black, shiny product resembling the broken surface of lignite coal. On boiling with water a portion of these humates are found to be soluble.

"On the other hand these humates, in the fresh condition, soluble in water, on drying and igniting, leave a mineral residue of 61 per cent, of which 86 per cent is not soluble in hydrochloric or nitric acid."

The humus, humates, and mineral matter contained in the humates were determined in 24 samples of soil. The following is a summary of the results:

Humus, humates, and mineral in humates of 24 samples of soil.

	Humates.	Humus.	Nitrogen.		Phosphoric acid.		Calcium oxid.		Potassium oxid.	
			Total.	In humus.	Total.	In humus.	Total.	In humus.	Total.	In humus
	Per ct.	*Per ct.*	*Per ct.*	*Per ct*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Minimum	3.84	1.56	0.180	0.041	Trace	Trace.	Trace.	0	0.18	0.075
Maximum	15.26	7.90	.456	.362	0.40	0.199	2.70	1.03	.73	.233
Average	9.15	4.77	.292	.163	.269	.138	.944	.436	.409	.153

On the average the humates contained 56 per cent of the nitrogen of the soil, 51 per cent of the phosphoric acid, 37 per cent of the potash, and 46 per cent of the lime, while the humus constituted 52 per cent of the total humates extracted.

The soil of the Red River Valley wheat lands, A. M. TEN EYCK (*North Dakota Sta. Bul. 36, pp. 346-358, figs. 2*).—The soil of the station farm is fairly typical of these lands. It is described as "a very fertile, deep, black loam, underlaid by a subsoil slightly finer in texture and lighter in color, often called a clay, but which is more properly a compact, heavy loam."

Samples of the soil, taken at depths of 1 to 6, 6 to 12, 12 to 24, 24 to 36, and 36 to 48 in., were subjected to mechanical analysis. The method of analysis recommended by the Division of Soils of this Department (E. S. R., 8, p. 481) was followed with this exception: "Previous to the separation, instead of rubbing up the moistened sample in a mortar, or revolving it in a shaker for several hours, each 30 gm. was treated with 100 cc. of distilled water, stirred occasionally, and allowed to stand for 36 hours." The water capacity, weight per cubic foot, and water-soluble salts were also determined. "The water-soluble salts were determined from the filtrate obtained by placing 10 gm. of soil in 100 cc. of distilled water for 24 hours and then boiling the whole briskly for 10 minutes."

"The soil of the station farm is sticky and heavy to handle when at all wet, and below the depths to which it is annually loosened by the plow it is generally compact and often gummy. Spots of real gumbo are frequently met with." Analysis showed, however, that the soil contains a large percentage of pure sand (about 61 per cent) and that the second 6 in., the gummy portion, is the coarsest in structure of any of the samples analyzed. The weight per cubic foot varied from 56.12 lbs. in the surface foot to 99.44 lbs. in the fourth foot.

Reclamation of bog land in Ayrshire, J. CLARK (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 150-161*).—An account is given of the methods pursued and the results obtained on two bogs, reclaimed with a view to their use in the growth of timothy hay. "The land [in the first case] was of a benty nature, mixed with heather and draw moss growing on black peat moss, varying in depth from 18 in. to 5 ft., with a cold, blue clay subsoil." Reclamation of this bog was commenced in 1893. The first important operation was the draining which the author describes as follows:

> "I first laid off the main drain, which I almost invariably made in the natural water course. The ordinary field drains were laid off 18 ft. apart at right angles to the main wherever this was practical. The main drain was made 3 in. deeper than the ordinary drains, to give a fall to the water from the latter.
>
> "As moss drains are distinctly different from clay ones I cut the main to the very far side of the field from its outlet and allowed it to remain open. I next cut the farthest away ordinary drain—that is, the one at the top of the main—and always tiled the drains from the top downward. This prevented any sludge from getting into the tile and obviated any fear of choking. The depth of the drains was regulated according to the depth of the moss. In this instance they vary from 2 ft. 3 in.

to 3 ft. 6 in. I do not like them far into the clay—not more than 6 in.—as the greatest volume of water is usually found between the moss and clay. But where the moss was found to be over 3 ft. 6 in. in depth—which was the rule in this instance—I placed a beech wood sole under the tile to prevent it from sinking."

The soil was given a heavy dressing (60 cartloads per acre) of ashes and roadside parings and 5 tons of gas lime per acre. It was plowed in 1894 and seeded to oats, with a top-dressing of 4 cwt. of dissolved bone per acre. The crop was light, but the succeeding crop of turnips, fertilized with 20 cartloads of barnyard manure, 3 cwt. of superphosphate, and ¾ cwt. of ammonium sulphate per acre, was good. Following the turnips, oats were again grown, with 5 cwt. of dissolved bone, with good results. The land was then seeded to grain and top-dressed in the fall with 10 tons of barnyard manure per acre. In the spring 1 cwt. of nitrate of soda was applied as a top-dressing. A fair crop of hay was obtained. With the above rotation the first cost of reclamation was repaid.

The second bog was deeper than the first but similar in other respects. The method pursued was much the same as in the first experiment. The tiles were laid 3½ ft. deep, but "it is now becoming very evident that this depth is not sufficient for land so soft and spongy as this was. The land has since become a great deal more consolidated, resulting in some places in a general subsidence of about 18 in., and even more in some of the softest parts. This is gradually bringing the pipes very near to the surface and at some time in the near future they will require to be deepened if the land is to be kept under cultivation."

The rotation has been oats, potatoes, and mixed grasses containing timothy with which manures and fertilizers were freely used, since, in the author's opinion, the liberal use of manures and fertilizers is essential to success in reclaiming such soil. The results while not so good as in the first experiment are considered very satisfactory.

On the dissemination of ferments in the soil, P. P. DEHÉRAIN (*Ann. Agron., 25 (1899), No. 6, pp. 289–293*).—Vetch was grown in pots of 50 kg. capacity on vineyard soil which had borne no leguminous plants for 24 years and on soil which had been cultivated in vetch the previous year. In each case one pot received no fertilizer and one 3 gm. of superphosphate. In addition one pot containing soil on which vetch had not previously been grown received 400 gm. of manure.

The results show that the soil which had not previously borne vetch gave the larger yield. Superphosphate did not increase the yield to any very great extent, but the beneficial effect of the manure was very marked.

Mazé has suggested that the tubercle bacteria of leguminous plants are of two classes, those which act in calcareous soils and those which act in siliceous soils. The soils at Grignon are calcareous, and the results reported above indicate that the organisms active in such soils are very generally disseminated there. This indicates the futility of applying Nitragin and Alinit. Instead of adding more organisms it would be better to make the conditions more favorable to those already present. One of the means of accomplishing this, suggested by the above experiments, is to increase the humus content of the soil by the addition of manure.

On the utilization by plants of the fertilizing constituents of soils containing different amounts of sand, E. Grosz (*Fühling's Landw. Ztg., 18 (1899), No. 8, pp. 291–297*).—Pot experiments were made with barley grown in (1) soil containing 0.155 per cent of nitrogen, 0.14 per cent of potash, 0.07 per cent of phosphoric acid, and 0.43 per cent of lime, and (2) the same soil mixed with ¼, ½, and ¾ its weight of sand. Data for yields and composition (fertilizing constituents) of the crop from the different pots are reported. These show that the fertilizing constituents were more completely utilized in the soils containing the larger proportion of sand than in those containing less sand but a larger amount of plant food.

The use of coloring matters in tracing the movement of waters in the soil, A. Trillat (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 10, pp. 956–968*).

The phosphoric acid content of arable soil, Maizières (*L'Engrais, 14 (1899), No. 27, pp. 636, 637*).—A discussion of the work of Pagnoul, Dehérain, and others bearing on the limits of the profitable use of phosphates.

Examination of soils (*Compt. Rend. Ann. Sta. Agron. Ploty, 1896, pp. 89–96*).—Mechanical and chemical analyses of the soil at different depths of the experimental fields of the station are reported.

Note on the correspondence between the results of the chemical analysis of a soil and its productiveness, A. N. Pearson (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 947–952, fig. 1*).—This correspondence is worked out for four unmanured plats on which sugar beets were grown. Making certain arbitrary allowances for (1) a deficiency of phosphoric acid, (2) nitrogen, (3) the favorable mechanical effect of lime in the soil, and (4) the injurious effect of an excess of soluble salts, a curve "representing the total effect of the constituents disclosed by the analysis" is obtained which agrees closely with the curve representing the actual productiveness.

Humates and soil fertility, E. F. Ladd (*Jour. Amer. Chem. Soc., 20 (1898), No. 11, pp. 861–867*).—A more complete account of this work is noted above under the title of soil studies (see p. 224).

Soil moisture and temperature (*Compt. Rend. Ann. Sta. Agron. Ploty, 1896, pp. 102–110*).—Observations at different depths are recorded.

Soil temperatures at Riga, G. Schweder (*Die Bodentemperatur bei Riga. Riga, 1899, pp. 24*).

FERTILIZERS.

The home mixing of fertilizers, C. E. Thorne (*Ohio Sta. Bul. 100, pp. 123–160, figs. 2*).—This is a republication in large part of an earlier bulletin on the same subject (E. S. R., 10, p. 532) to which is added the results of a continuation on corn and wheat of the comparative tests of home-mixed and factory-mixed fertilizers, partially reported in the earlier bulletin, and the conclusions of other experiment stations and investigators who have studied the subject of home mixing.

In experiments in 1898 "the various factory brands of fertilizers produced practically the same increase of corn as their duplicate home mixtures . . . but the wheat gave, not simply an equal, but a better return for the home mixture than for the factory brand."

The fertilizer control for 1898, A. W. BLAIR (*North Carolina Sta. Bul. 158, pp. 79–92*).—The bulletin gives a list of the publications of the North Carolina department of agriculture containing fertilizer analyses for 1898; notes on valuation; explanation of terms; and tabulated matter, including a list of firms registering brands for sale in the State during 1898, the number of brands licensed in the State each year during the last 14 years, the brands credited to the several States, comparisons of the fertilizer trade in 9 States, average composition of three classes of fertilizers, and number of brands of each below guarantee during 1897 and 1898.

"The number of brands registered for sale in North Carolina during 1898 exceeded by 150 the registration for 1897, which was the highest up to that time, and also shows a greater increase than in any previous year. This rapid increase has been noticeable since 1890, when there was a change from the brand tax to the tonnage tax.

"The consumption of commercial fertilizers has increased very rapidly each year, amounting to about 246,000 tons in 1898, valued at nearly $6,000,000, as against 208,000 tons during 1897, valued at about $5,000,000.

"The larger part of the fertilizers now used in the State are manufactured in North Carolina and Virginia.

"The average percentage composition of commercial fertilizers for 1898 is slightly above that for 1897, with the exception of available phosphoric acid in complete fertilizers, and this falling off is probably due to an interpretation of the law which allows a fertilizer high in ammonia and potash to fall below 8 per cent in available phosphoric acid.

"One out of every four and one-fifth of the whole number of fertilizers analyzed fell below its guarantee in some ingredient, and one out of eighteen and one-half in valuation."

Value of sheep manure, W. A. HENRY (*Breeders' Gaz., 35 (1899), No. 8, pp. 210, 211*).

Modern views concerning the changes in and treatment of barnyard manure, J. SEBELIEN (*Norsk Landmandsblad, 18 (1899), Nos. 10, pp. 116–119; 11, pp. 129–133*).

Methods of applying manure, C. F. CURTISS (*Breeders' Gaz., 35 (1899), No. 2, p. 36*).

Investigations on the use of 1 per cent sulphuric acid to check the fermentation of urine, A. M. LEONI (*Staz. Sper. Agr. Ital., 31 (1898), No. 3, pp. 209–221*).

Analysis of seaweed, F. B. GUTHRIE (*Agr. Gaz. New South Wales, 10 (1899), No. 6, p. 528*).—The fertilizing constituents in a sample of *Phyllospora comosa* are reported.

On the fertilizing constituents of apples and pears, E. HOTTER (*Jahrb. Pom. Landes Vers. u. Samen Control Sta., Graz, 5 (1897), pp. 22–24*).—The average percentages of various ash constituents are reported.

Analyses of commercial fertilizers, H. B. MCDONNELL ET AL. (*Maryland Agr. Col. Quart., 1899, No. 3, pp. 51*).—Tabulated analyses and valuations of 388 samples of fertilizers examined during the period from August, 1898, to January, 1899, inclusive, and a list of fertilizers licensed for sale up to February 1, 1899, accompanied by explanatory notes on valuation, etc.

Analyses of commercial fertilizers, B. W. KILGORE (*Mississippi Sta. Bul. 57, pp. 7*).—Analyses and valuations of 37 fertilizers are reported.

Analyses of commercial fertilizers, B. W. KILGORE (*Mississippi Sta. Bul. 55, pp. 22*).—This bulletin reports analyses and valuations (with guaranties) of 96 samples of fertilizers and gives a list of brands of fertilizers registered for sale, accompanied by explanations of terms and notes on valuation.

Phosphatic fertilizers, MAIZIÈRES (*L'Engrais, 14 (1899), No. 24, pp. 564, 565*).—A general discussion of this subject.

Notes and analyses of some New South Wales phosphatic minerals and phosphatic deposits, J. C. H. MINGAYE (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 332, 333*).—Analyses of pyromorphite, apatite, marsupial excrement, phosphatic deposits from caves, and coarse and fine gem sand from gold fields (largely small zircons).

On the occurrence of phosphatic deposits in the Jenolan caves, New South Wales, J. C. H. MINGAYE (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 327–331*).—In the samples analyzed the phosphoric acid varied from about 10 to 40 per cent. The deposits are probably limited.

Artificial slag, MAIZIÈRES (*L'Engrais, 14 (1899), No. 12, pp. 276–278*).—Discusses the Wiborgh phosphate (E. S. R., 10, p. 32).

The future of the potash industry, MAIZIÈRES (*L'Engrais, 14 (1899), No. 9, pp. 204, 205*).

The use of fertilizers in the spring, MAIZIÈRES (*L'Engrais, 14 (1899), No. 13, pp. 299–301*).

Lime and its uses in agriculture, A. P. AITKEN (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 220–245*).—This treats in a popular way of the sources, properties, and agricultural uses of lime and of its chemical, physical, and biological effects in the soil.

A summary of fertilizer experiments (*L'Engrais, 14 (1899), Nos. 21, pp. 495–498; 23, pp. 512–540; 25, pp. 591–594, figs. 3*).

A test of plaster on ordinary clover, A. DAMSEAUX (*L'Engrais, 14 (1899), No. 13, p. 302*).

FIELD CROPS.

Records of certain experiments conducted by collegiate centers aided by the Board of Agriculture (*Bd. Agr. [London], Rpt. Agr. Ed. Great Britain, 1897–98, pp. 37–127*).—The work here reported comprises fertilizer and rotation experiments carried on for different lengths of time at various agricultural institutions in Great Britain. Fertilizer tests were made with cereal, root, and hay crops and with grasses in permanent meadows and pastures. The results are given in tables and discussed.

Culture and fertilizer experiments with hops in 1897 showed that an application of 10 cwt. of mixed superphosphate and ground Carolina phosphate gave the best results. The amount of soft resins in the hops increased with each increase in the application of phosphates. Potash as a fertilizer decreased the crop and reduced its quality. Applications of lime gave an increase in yield of 14 per cent. The East Kent system of training the hop vines gave the best crop as compared with 5 other systems. Different methods of cultivation had practically no effect on the yield, but deep cultivation at the end of the season gave a low percentage of soft resins. Temperatures of hop drying are shown in diagrams. It is concluded that in general the results indicate that the percentage of soft resins is increased by applications of phosphatic fertilizers and diminished by applications of potash and late nitrogenous dressings.

Alfalfa, Spanish peanuts, unknown cowpea, and velvet beans, W. C. STUBBS (*Louisiana Stas. Bul. 55, 2. ser., pp. 107–123*).—This bulletin reports the results of field and laboratory investigations on the legumes enumerated in the title, and gives a brief description including cultural notes of each crop. The report of the experiments is prefaced with a discussion of the use and value of leguminous crops in connection with farming in the South. The following table gives the composition of alfalfa grown at Calhoun, Louisiana:

Composition of different cuttings of alfalfa based on the air-dried substance

	Moisture.	Protein.	Ether extract.	Nitrogen-free extract.	Crude fiber.	Ash.	Fertilizing constituents.		
							Nitrogen.	Phosphoric acid.	Potash.

The comparative merits of Spanish peanuts, unknown cowpea, and velvet beans for fertilizer or forage purposes were studied. When the analyses were made the peanuts were matured, while the cowpeas and velvet beans contained but a few rudimentary pods. The yields and fertilizing ingredients are given in the following tables:

Comparative yield per acre of Spanish peanuts, unknown cowpea, and velvet beans.

Parts of plant.	Green.			Air dry.			Dry matter.		
	Spanish peanut.	Unknown cowpea.	Velvet bean.	Spanish peanut	Unknown cowpea.	Velvet bean.	Spanish peanut.	Unknown cowpea.	Velvet bean.

Velvet beans, J. F. DUGGAR (*Alabama College Sta. Bul. 104, pp. 109-125*).—This bulletin reports the results of experiments with velvet beans for soil improvement. An introductory statement regarding the plant in general is made, and the uses of the beans as human food and food for live stock are noted. A comparison of the yield of hay from velvet beans and cowpeas is also shown.

Sorghum was grown on 3 plats, on 2 of which cowpeas and velvet beans had been plowed under. The plats were fertilized with acid phosphate and muriate of potash, and the crops of cowpeas and velvet beans were intended to supply the nitrogen. The increase of sorghum on the cowpea plat over the plat on which no leguminous crop had been plowed under was at the rate of 3,216 lbs. per acre, and the increase on the velvet-bean plat at the rate of 3,272 lbs. per acre.

Velvet beans grown on poor soil fertilized at the rate of 240 lbs. of acid phosphate and 48 lbs. of muriate of potash per acre yielded 19,040 lbs. of green material per acre. The weight of the hay after 5 days' curing was 8,240 lbs. The weight of the roots and stubble, excluding fallen leaves, was 1,258 lbs. The beans were planted April 20 in rows 3½ ft. apart at the rate of 110 lbs. per acre, and harvested October 12, when they were too mature to make good hay. Determinations based on analyses show that the hay per acre contained 188.7 lbs. of nitrogen and the roots and stubble 12.5 lbs. The author states that this amount of nitrogen is equal to the amount contained in about 2,800 lbs. of cotton seed meal. The cured vines contained 2.29 per cent of nitrogen and the air-dried roots 1 per cent.

The average yield of hay per acre from velvet beans and Wonderful cowpeas sown broadcast and in drills and grown on different kinds of soil was 5,183 and 5,477 lbs., respectively. It is thought best to plant velvet beans in drills at the rate of about 1 bu. of seed per acre.

Soil improvement by velvet beans and cowpeas as measured by increased yield of oats is reported from a previous bulletin (E. S. R., 10, p. 739).

Cultural experiments with beets in the years 1896 and 1897, SCHINDLER (*Separate from Oesterr. Ungar. Ztschr. für Zucker Ind. u. Landw., 1898, No. 5, pp. 36, pls. 5; abs. in Bot. Centbl., 78 (1899), No. 8, pp. 218-251*).—From experiments with *Beta maritima* and *B. vulgaris*, the investigator, E. von Proskowez, concluded that all the different forms tested belong to one species, the variations having their origin in the conditions of environment, and that the cultivated varieties are derived from this species. The transition from native to cultivated forms was observed to be rapid and every generation showed improvement. Progress in culture and breeding experiments with 3 varieties or forms of beets from India is reported.

Experiments on premature seed production of beets, A. CSERCHÁTI (*Bl. Zuckerrubenbau, 6 (1899), No. 4, pp. 49-57*).—These experiments were made to determine the influence of the time and depth of planting, the size of the seed, and the variety of the beet on premature seed production. It was found that planting prematurely-produced seed resulted in more plants producing seed the first year than when seed from normal beets was used, and that the tendency was not the same for all varieties. The longer the weather conditions interfered with the growth of the plant the greater was the percentage of beets producing seed the first year, and the variety, early planting, and the use of prematurely-produced seed were factors which seemed to give impetus to this tendency.

Best varieties of corn, J. H. CONNELL and B. C. PITTUCK (*Texas Sta. Bul. 49, pp. 1188-1201, fig. 1*).—The subject of varieties of corn best suited to different sections of Texas is discussed in a popular manner. Late and medium early varieties are briefly described and the number of days required to mature them when tested is given. The conditions of soil and climate in relation to corn culture in different parts of the State are considered, and the rainfall and daily mean temperature for the year are recorded.

For milling and feeding purposes the author recommends Welborn Conscience, Mosby Prolific, White Southern Bread, and Mexican June corn.

Field tests with corn at College Station and Beeville Substation, B. C. PITTUCK (*Texas Sta. Bul. 49, pp. 1177-1187, pl. 1*).—Results of variety tests and of experiments in planting corn at different distances in 1898 are given in tables, and the yields for 1895, 1896, and 1898 are compared. The methods of cultivation are described.

At the station 42 varieties were grown. Blount Prolific, St. Charles White, and Southern White Gourd Seed were the most productive varieties, yielding 40.7, 39.5, and 37.2 bu. per acre, respectively. The seed of Blount Prolific had been grown in Virginia, the seed of St. Charles White in Illinois, and that of Southern White Gourd Seed in Delaware. A comparison of the yields of varieties grown for 3 or 4 years showed that Blount Prolific gave the largest average yield. "This indicates the pressing need of more distinctly southern-grown seed corn."

Among 25 varieties tested at the Beeville Substation under different soil and weather conditions, these same varieties produced the largest yields. This season corn planted 4½ by 2½ ft. gave the best results. The same results were obtained in previous investigations on the distance of planting.

Farm manures for cotton, C. M. CONNER (*South Carolina Sta. Bul. 40, pp. 8*).—This bulletin reports fertilizer experiments with farm manures and commercial fertilizers during one season on sixteenth-acre plats. Barnyard manure was compared with cotton-seed products and with a compost. The compost was mixed in the proportion of 600 lbs. each of barnyard manure, cotton-seed meal, and acid phosphate, and 200 lbs. of kainit. In computing the results the lint was valued at 5 cts. per pound and the seed at $9 per ton. The money value of the increase per acre of lint and seed with the application of the different manures was as follows:

2,714 lbs. per acre of manure from cows fed on cotton-seed meal and hulls	$10.88
145 lbs. of cotton-seed meal and 580 lbs. of cotton-seed hulls per acre	2.73
2,960 lbs. per acre of manure from mule stables	5.93
5,428 lbs. per acre of manure from cow barns	6.23
1,320 lbs. compost per acre	14.81
2,640 lbs. compost per acre	22.74

When acid phosphate was used at the rate of 192 lbs. per acre in addition to the manure from mule stables and at the rate of 292 lbs. per acre with the other applications, the value of the increase over no fertilizer was as follows:

Manure from cows eating meal and hulls	$12.36
Cotton-seed meal and hulls	10.91
Manure from mule stables	10.12
Manure from cow barn	13.65

Leguminous plants and the fertilizers which they require (*L'Engrais, 14 (1899), Nos. 6, pp. 134–136, figs. 3; 8, pp. 182–185, figs. 4; 10, pp. 232–234*).—A brief history of the experiments with leguminous plants is given, and the results of various investigations on this subject are summarized. It is concluded that leguminous plants remove from the soil of meadows large quantities of nitrogen, phosphoric acid, potash, and lime, but that it is unnecessary to apply nitrogenous fertilizers. In the experiments referred to barnyard manure applied directly did not produce as good results as commercial fertilizers, and hence it is recommended that barnyard manure be applied to other crops in the rotation. For soils of medium fertility an application of 300 to 400 kg. of superphosphate or Thomas slag and 150 to 200 kg. of muriate of potash per hectare is recommended.

On soils rich in potash it is recommended to replace a portion of the potash fertilizer by gypsum or carbonate of lime.

Experiments with oats, J. F. HICKMAN (*Ohio Sta. Bul. 101, pp. 161–179, 181–183*).—These experiments comprise variety, seed, and culture tests. During the seasons of 1896, 1897, and 1898, 66 varieties of oats were tested. These varieties are classified into 4 groups: Welcome, Seizure, Wideawake, and a division known as the Mixed group. The Welcome group includes varieties having an open panicle, coarse but usually weak straw, and short, plump grain; the Seizure group comprises those varieties in which the head is more or less one-sided and which are usually known as side oats; and the Wideawake group, those varieties which have a general resemblance to the Welcome class but have a longer, more pointed, and usually lighter berry and a stronger straw. Under the remaining group the author classifies a number of black and mixed groups similar to the Welcome group but usually lighter.

The average yield per acre for 3 years of the Welcome, Seizure, and Wideawake groups, including duplicate plats, was 54.33, 52.33, and 50.99 bu., respectively. The highest average yields for 6 years were produced by the following varieties in the 3 named groups: In the Welcome group, Lincoln, Improved American, Clydesdale, White Belgian, and Kernel; in the Seizure group, Early Swedish, White Swiss, Wilson Prolific, Egyptian, and Japan; and in the Wideawake group, Banner, White California, Alabama, and Kansas Hybrid.

Early Archangel and Hargett White have given the highest average weight per bushel. Early varieties are regarded as usually having weaker straw and being less productive than late maturing sorts. The latest varieties, however, were found not to yield quite as well as those ripening at the intermediate period.

Rolling the ground before seeding gave results apparently better than rolling after seeding. Covering the seed about 1 in. deep was found preferable to deeper covering. Preparing the seed bed by plowing gave better results than simply stirring the surface; while cultivating the seed in, without any preparation of the soil, gave poorer results than either of the other methods.

Mixing several varieties of oats for seed was not found profitable. The selection of heavy seed did not increase the yield of grain but gave better yields of grain and straw than light seed under the same conditions. The results of 2 years' experiments indicate that new seed gives better yields of grain and straw than seed one year old.

Third potato report, F. W. RANE (*New Hampshire Sta. Bul. 63, pp. 39-73, figs. 8, map 1*).—This bulletin is a report of variety tests of potatoes carried on at the station and on different farms throughout the State. Individual reports are given for the cooperative tests. Previous reports in this series have been noted (E. S. R., 9, p. 45; 10, p. 432). This season 104 varieties were tested, 80 of these having been described in former reports. In this bulletin descriptions are given of varieties not previously described. The following varieties, mentioned in the order of their productiveness, have given the largest average yield for the years 1896-1898: Reeve Rose, White Beauty, Vaughan, Red American Wonder, Late Puritan, Sir William, Seneca Beauty, Harvest Queen, Sir Walter Raleigh, Fillbasket, Woodhull Seedling, Dewdrop Rose, Breck Chance, Prolific Rose, Orphan, White Rose, and Wilson First Choice. Of these varieties White Beauty, Red American Wonder, Breck Chance, and Prolific Rose have been grown for one season only.

Commercial fertilizers for potatoes, II, W. H. JORDAN (*New York State Sta. Bul. 154, pp. 335-345*).—The work here reported is in continuation of previous experiments (E. S. R., 10, p. 431), and on a similar plan. In 1898 the application of 1,500 lbs. of fertilizer per acre gave the best financial results. The Long Island formula increased the yield 6.3 bu. per acre over the formula based on the composition of the potato.

The new tests were made on 64 eighth-acre plats on 4 different farms. The object of this work was to ascertain the effect of the amount of potash furnished in either the "potato" or the Long Island formula as compared with ⅔ as much, ⅓ as much, or no potash at all. Variations of the amount of potash showed no influence.

Sugar-beet experiments during 1898, A. J. McCLATCHIE and R. H. FORBES (*Arizona Sta. Bul. 30, pp. 190–225*).—During this season the work was conducted as previously outlined (E. S. R., 9, p. 833). The results are reported from summer-sown and winter-sown plats. The temperature record for 1898 is given in a table, and the field work of the season is discussed. The soil of each plat and the methods of cultivation are described. Analyses of the water and limestone supplies of Arizona are reported in connection with a consideration of factory requirements. The average results of 10 plats varying from ⅛ to ¾ acre in size, and located on 10 different farms near Phenix, showed a yield of 12.85 tons of beets per acre, a sugar content of 13.8 per cent, a purity coefficient of 78.53, and a yield of 2,438 lbs. of sugar per acre. It is concluded that early planting is essential and that the best time for planting is from January 1 to February 15.

The sugar beet in Indiana in 1898, H. A. HUSTON and A. H. BRYAN (*Indiana Sta. Bul. 75, pp. 20, fig. 1*).—Previous work in this line has been reported in a former bulletin (E. S. R., 10, p. 143). The present bulletin gives a statement of the results obtained in 1898 and a discussion of the climatic conditions for the season. An unfavorable combination of weather conditions interfered with the experiments, and the results are considered unsatisfactory to some extent. The general conditions of the season favored a high yield with a low sugar content. Beets of good quality, however, were produced in many parts of the State. The results varied considerably and no averages are given.

Sugar beets, J. T. WILLARD and R. W. CLOTHIER (*Kansas Sta. Bul. 83, pp. 16*).—This bulletin is a report on the cooperative culture experiments with sugar beets in 1898. Similar work has been previously reported (E. S. R., 10, p. 346). Directions are given for the culture of sugar beets, and the results of analyses are tabulated. Experiments for the coming season are outlined. The results for the season show an average sugar content in the juice of 11.56 per cent and a coefficient of purity of [illegible]7.8 per cent. The average weight of the beets in the samples was 1.45 lbs. The average yield was estimated at about 16 tons per acre. Considering only those plats which were ¼ or ½ acre in size, the sugar content was 12.7 per cent and the purity 83. The author concludes from his observations that the seed should be planted before May 1, in rows 16 to 21 in. apart and in soil such that the roots can be kept from growing above the ground to any extent.

The sugar beet, H. W. WATERS (*Missouri Sta. Bul. 45, pp. 20–32*).—Cooperative tests in the culture of sugar beets were carried on in 1898 as in previous years (E. S. R., 9, p. 944). This bulletin reports the results obtained in 1898, reviews previous experiments in this line, and describes the weather conditions for the season. From 69 out of 114 counties in the State 150 samples of beets were obtained for analysis. The average weight of the beets in the samples was 24 oz.; the average per cent of sugar in the juice, 8.73; and the average coefficient of purity, 72.52. Only 5 samples contained 12 per cent of sugar in the beet. The percentage of sugar in the juice ranged from 3.72 in a sample from Montgomery County to 14.58 in a sample from Atchison County.

Sugar-beet investigations for 1898, J. L. STONE ET AL. (*New York Cornell Sta. Bul. 166, pp. 417-467, pls. 3, figs. 2*).—This bulletin reports observations and conclusions based upon a study of field conditions in growing sugar beets, results obtained in sugar-beet culture at the station, and results of analyses of beets grown in various parts of the State. A comparison of the weather conditions of 1897 and 1898 shows that the season of 1898 was not favorable to the best results in sugar-beet culture. Previous experiments along this line have been reported in a former bulletin (E. S. R., 10, p. 143).

The observations made in the cooperative tests with sugar beets during this season show that the heavier soils were more favorable than the lighter soils, and that the more fertility and tillage a crop requires the better it is suited to prepare the land for a crop of beets. The reported yields average 12.98 tons per acre. An average of 14 tons of trimmed beets per acre was obtained by 152 farmers who had grown 252 acres of beets for sugar manufacture. The average cost of growing an acre of beets as estimated by 45 farmers is $38.15, and the average cost per ton, based on 43 estimates, is $3.25. The results of a number of cooperative fertilizer experiments show that, while in some instances the fertilizers applied were very effective, the average increase in yield was not so marked. The quality of the beets was not perceptibly affected by the application of fertilizers.

The work at the station comprised distance, tillage, thinning, subsoiling, and fertilizer experiments, and variety tests. Beets planted in rows 20 in. apart yielded 2 tons per acre more than beets grown in rows 24 in. apart. In the tillage tests cultivating 5 times gave a better yield than cultivating either 4 or 6 times. Beets planted May 11 were thinned June 3, 10, and 17, and yielded 22.3, 23, and 28 tons per acre, respectively, for the different dates of thinning. It is concluded that when conditions are favorable considerable range may be taken as to time of thinning. Subsoiling immediately before planting increased the yield at the rate of 2.9 tons per acre. The authors recommend that when subsoiling is done during the season of planting it be done early enough to give ample time for the restoration of capillarity before the dry weather of summer.

Among 9 varieties Kleinwanzlebener gave the largest yield per acre and Pitzschke Elite the highest percentage of sugar in the juice. The results of fertilizer experiments indicate that nitrate of soda applied alone is conducive to the growth of large beets of poor quality.

The average results of the analyses of 496 samples of sugar beets grown in 1898 show the following percentages: Solids in the juice, 18.30; sugar in the juice, 15.29; sugar in the beet, 14.53; and purity, 83.60.

Sugar-beet investigations in 1898, L. L. VAN SLYKE (*New York State Sta. Bul. 155, pp. 347–373*).—This bulletin reports the results of experiments with sugar beets undertaken by the station in cooperation with 17 farmers in 10 different counties. Previous work in this line has been reported in a former bulletin (E. S. R., 10, p. 145). The results of the cooperative culture experiments for the season are given in the following table:

Results of culture experiments with sugar beets.

	Yield per acre.	Sugar in the beet.	Purity.	Weight of beets	Cost of growing beets		Value of crop per acre.
					Per acre	Per ton.	
	Pounds	*Per cent*	*Per cent.*	*Ounces.*			
Minimum	8,670	10.1	72.5	5.0	$33.34	$2.60	$18.42
Maximum	58,990	18.5	87.3	27.0	108.86	10.00	95.86
Average	26,720	15.5	82.3	15.7	59.87	4.50	63.46

In connection with these cooperative tests, fertilizer experiments were carried on to test the effect of fertilizers on the yield, quality, and cost of sugar beets. The fertilizer consisted of 1,000 lbs. acid rock, 350 lbs. sulphate of potash, 450 lbs. dried blood, and 200 lbs. nitrate of soda, and was applied at the rates of 500 and 750 lbs. per acre. The smaller application gave an average increase in yield of 3,874 lbs. per acre and the larger application an increase of 5,264 lbs. The use of 500 lbs. did not affect the sugar content and proved most economical. The heavier application caused an average decrease of 0.5 per cent in sugar content. The use of fertilizers had little effect upon the purity.

The 343 samples obtained from 33 counties and analyzed at the station gave an average percentage of 14.2 of sugar in the beet with a purity of 85.

Some special investigations were made at the station and also at a farm near Fayetteville to study the effect of different amounts of commercial fertilizers and the use of 20 tons of stable manure per acre. The influence of growing beets at different distances in the row was also investigated. The fertilizer mixture employed consisted of 200 lbs. nitrate of soda, 200 lbs. dried blood, 150 lbs. acid rock, and 150 lbs. sulphate of potash. The use of 500, 1,000, and 1,500 lbs. of this mixture per acre increased the yield, while 2,000 lbs. gave a smaller yield than applying 1,000 lbs. The sugar content was reduced 1 per cent by the use of each of the 3 smaller applications as compared with beets grown without fertilizers. The smallest application gave the largest profit, and when 1,500 lbs. or more were used there was a loss. The results further show that the size of the beets was increased and the purity slightly decreased.

The use of stable manure gave an average increase in yield of 8,720 lbs. per acre and of 1.5 and 1.6 per cent in sugar content and purity, respectively. The beets were decreased an average of 2.75 oz. in weight.

The results of growing beets at different distances in the row show that there was an increase in yield, purity, and size of beets as the distance increased from 6 to 10 in. The variation in the percentage of sugar was very small.

Among a number of varieties of sugar beets investigated Pitzschke Elite gave the best returns, yielding at the rate of 43,736 lbs. per acre, with a sugar content of 14.2 per cent in the beet and a purity of 84.1. Vilmorin French Very Rich produced the richest beets, the percentage of sugar in the beet being 14.7 and the purity 84.6. Kleinwanzlebener beets from seed grown in New York contained 12.7 per cent of sugar, with a purity coefficient of 81.9.

Sugar-beet investigations in 1898, J. H. STEWART and B. H. HITE (*West Virginia Sta. Bul. 55, pp. 79–93*).—This bulletin reports the results of cooperative culture experiments with sugar beets in different sections of the State. The results of analyses of 125 samples are tabulated and popular directions for the culture of the crop are given. The average sugar content of the juice in the samples from different counties varied from 7.39 to 17.35 per cent and the purity from 57.4 to 82.2 per cent.

Experiments with commercial fertilizers were made at the station on a series of 9 plats. The results showed considerable variations. Nitrate of soda decreased the sugar content and lime decreased both the sugar content and the purity. The average analyses of 238 samples grown within the State show a sugar content of 13.4 per cent and a purity coefficient of 76.7 per cent.

Report of the agriculturist and horticulturist, A. J. McCLATCHIE (*Arizona Sta. Rpt. 1898, pp. 182–189, pl. 1*).—This is a report on the work of the agricultural and horticultural department of the station. The cooperative work with sugar beets and the experiments with date palms, wheat, cowpeas, and melons at the Phenix Substation are briefly discussed.

Field experiments at Ghent, Belgium, P. DE CALUWE (*Exposé Cult. Exper. Jard. Gand, 1896–97, pp. 75, plan 1*).—This publication is the annual report on experiments in progress at the experiment garden of the Province of East Flanders. Fertilizer, culture, and variety tests with rye, wheat, barley, oats, maize, peas, flax, sugar beets, turnips, potatoes, and grasses are reported. Comfrey and sachaline were grown experimentally and fertilizer tests were made upon natural meadows. Daily meteorological observations for the year beginning October 1, 1897, are tabulated. Similar work has been previously reported (E. S. R., 9, p. 349).

It was found that injuries to rye due to fertilizing with nitrate of soda were overcome as the crop reached maturity, provided the injury was not too marked. The injury was noticed to affect the yield of straw more than the yield of grain.

Fifth annual report on field experiments, 1898, D. A. GILCHRIST (*Jour. Reading Col., England, Sup. 6, pp. 80*).—This is a report on the work for the season of 1898 in

Berkshire, Dorset, Hampshire, and Oxfordshire, England. The field experiments consisted mainly of fertilizer tests on most of the principal farm crops, including grasses in meadows and pastures, wheat, root crops, potatoes, sainfoin, and lucern. The effects of manures throughout entire rotations were studied. Suggestions for the manuring of various crops and notes on different fertilizing substances are given. The results obtained by each experimenter are reported separately but no general conclusions are drawn.

Alfalfa by irrigation, J. SHOMAKER (*Amer. Farmer Mag., 6 (1899), No. 1, pp. 38–40, figs. 2*).—A popular article on the subject.

Arrowroot, A. J. BOYD (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 335–339, pl. 1*).—An article on the culture of arrowroot and the process of obtaining its starch.

The importance of the selection of varieties and of the condition of the crop at harvesting time in the production of barley for brewing purposes, H. FALKENBERG (*Centbl. Agr. Chem., 28 (1899), No. 4, pp. 264–267*).—An abstract of a lecture on this subject by T. Remy.

Report on tests of smooth brome grass (Bromus inermis), T L. LYON (*Nebraska Sta. Bul. 57, pp. 37–45*).—Cooperative experiments with smooth brome grass were made by 33 parties in different parts of the State. Brief reports of 29 trials are given. Of these, 13 were favorable, 10 unfavorable, and 6 doubtful. No conclusions are drawn.

The cultivation of broom corn, D. JONES (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 424–426*).—Popular suggestions on the culture of broom corn in Queensland. A number of varieties are described.

Buckwheat, H. A. TARDENT (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 327–331, fig. 1*).—A popular article on the culture and uses of buckwheat and its distribution.

Cañaigre, R. H. FORBES (*Arizona Sta. Rpt. 1898, pp. 174–178, fig. 1*).—Culture experiments with cañaigre to test the effect of different sorts of seed roots, depths of planting, soils, fertilizers, and dates of harvesting on yield were made during the season. The results, taken as a whole, were contradictory; but data taken from what are considered the more reliable portions of the field show that old roots gave better yield than new roots, that small new roots were more productive than large new roots, that the yield from the second year harvest was nearly double that from the first year harvest, and that the best yield in the field was produced on the plat receiving the nitrate of soda

Manual of coffee culture, M. S. BERTONI (*Rev. Agr. Cien. Apl., Paraguay, 1 (1897), Nos. 1, pp. 1–27; 2, pp. 49–71; 4, pp. 145–159; 6, pp. 241–255*).—This article treats in a popular way of coffee culture in Paraguay.

Hybrid coffee (*Planting Opinion, 4 (1899), No. 23, p. 139*).—A note on the advantage of hybridizing coffee and the difficulties in the way of such work.

Experiments with corn and cotton, H. BENTON (*Alabama Canebrake Sta. Rpt. 1898, pp. 12–15*).—Among 4 varieties of corn Welborn Conscience was the most prolific. Tests of deep and shallow cultivation for corn and cotton did not give conclusive results in 1897 and 1898. Among 6 varieties of cotton Truitt gave the best returns. Cultivating cotton weekly gave better results than cultivating once every 2 weeks. A partial report on an experiment with leguminous crops is given, but no conclusions are drawn.

Report of the retting of flax by the Doumer-De Swarte process, E. DIXON (*Bul. [Min. Agr. France] 18 (1899), No. 3, pp. 293–296*).—This report gives a description of the method and the necessary apparatus for this system of retting and points out its advantages. A comparison was made of flax retted by this process and flax retted in the Lys. The Lys retted flax was inferior in fineness, strength, and color of fiber.

On the growth and future of flax culture and the flax industry in Sweden, G. A. SELLERGREN (*K. Landt. Akad. Handl., 38 (1899), No. 1, pp. 23–36*).

Ginseng (*Bul. Bot. Dept. Jamaica, 6 (1899), No. 6, pp. 87–89*).—Popular notes on the culture, distribution, and market value of ginseng.

Experiments with grasses for lawn, pasture, or hay, H. M. SESSIONS (*Proc. Columbus Hort. Soc., 13 (1898), pp. 24–27*).—Notes are given of two series of experiments with about a dozen species of grasses and clovers, testing their relative value for the above purposes. The first series was conducted at Atlanta, Georgia, and the second at Tougaloo, Mississippi. The different grasses are grouped, showing their value for lawns, hay, etc.

On the practical valuation of oats, N. H. NILSSON (*Tidskr. Landtmän, 20 (1899), No. 9, pp. 145–152*).

Experiments in acclimatizing winter oats, SCHACHT (*Deut. Landw. Presse, 26 (1899), No. 45, pp. 515, 516*).—An article containing suggestions on the methods of conducting experiments in acclimatizing winter oats.

Irish potato culture, A. B. MCKAY (*Mississippi Sta. Bul. 54, pp. 8*).—Popular directions are given for the culture of spring and fall crops of potatoes. The topics discussed are soil, drainage, plowing, subsoiling, fertilizers and their application, time and method of planting, cultivation, harvesting, and storing during summer. Early Rose, Peerless, Red Triumph, and Beauty of Hebron are considered desirable varieties for Mississippi.

The potato, W. SOUTTER (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 332, 333*).—A brief article on potato culture, with several references to its history.

Profitable potato fertilizing, II, F. H. HALL and W. H JORDAN (*New York State Sta. Bul. 154, popular ed., pp. 4*).—A brief popular review of Bulletin 154 of the station (see p 235) on commercial fertilizers for potatoes.

Fertilizer experiments with cereals and potatoes at Luleå chemical plant-physiological station, 1897 (*Meddel. K. Landtbr. Styr., 1898, No. 6, pp. 330–348*).

Root crops (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 417, 418*).—Popular notes on the culture of carrots, parsnips, turnips, and beets.

Sugar-beet experiments, H. BENTON (*Alabama Canebrake Sta. Rpt. 1898, p. 9*).—"The analysis of the large beets showed only 3.7 per cent of cane sugar, while the smaller beets contained 5.1 per cent sugar."

Sugar-beet success for the season, F. H. HALL and L. L. VAN SLYKE (*New York State Sta. Bul. 155, popular ed., pp. 8*).—This is a brief popular review of Bulletin 155 of the station (see p. 238).

Sugar-beet experiments, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 325–327*).—A brief account is given of the sugar-beet work carried on by the station during different seasons. In 1898 the analysis of 15 samples grown in the State showed an average of 14.38 per cent of sugar in the juice and a purity of 79.4.

Experiments in the growth of sugar-beet root in Great Britain (*Jour. Bd. Agr. [London], 6, No. 1, pp. 45–55*).—This article discusses sugar-beet culture in Great Britain in 1898 and gives tabulated statements of cooperative experiments carried on during the season. The average results of samples analyzed show a sugar content of 15.65 per cent in the juice, with a purity of 85.19.

The present status of the knowledge of fertilizing for sugar cane in Java, J. D. KOBUS (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 11 (1899), No. 132, pp. 111–115*).—A paper on the subject reviewing the experimental work in this line.

The Florida velvet bean, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 329, 330*).—A culture test with the Florida velvet bean and an analysis of the plant are reported. The plants grew about 18 in. high and were in bloom at the time of the first frost in early autumn Peas grown under like conditions with the velvet beans contained 3.6 per cent of nitrogen in the air-dry substance, while the beans contained 2.57. The author does not consider velvet beans valuable for North Dakota.

Wheat culture, M. S. BERTONI (*Rev. Agr. Cien. Apl., Paraguay, 1 (1899), No. 4–5, pp. 229–233*).—A report on variety tests with wheat at Assuncion, Paraguay.

On the origin and descent of the different kinds of wheat, N. WILLE (*Tidsskr. Norske Landbr., 6 (1899), No. 3, pp. 130–137*).

Notes on the milling qualities of the varieties of wheat most commonly grown in New South Wales, F. B. GUTHRIE (*Agr. Gaz. New South Wales, 10 (1899), No. 6, pp. 518–525*).

Catch cropping in Scotland, R. P. WRIGHT (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 1–39*).—This article describes the methods and practical advantages of growing catch crops. Directions are given for growing the following crops as catch crops: Italian rye grass, rye, barley, vetches, clovers, rape, mustard, kale, cabbage, and white turnips.

Experiments in acclimatizing foreign plants in Paraguay and Argentina, M. S. BERTONI (*Rev. Agr. Cien. Apl., Paraguay, 1 (1899), No. 4–5, pp. 224–229*).—The experiments are described and the results thus far obtained are noted.

New plants for Paraguay, J. KRIESE (*Rev. Agr. Cien. Apl., Paraguay, 1 (1899), No. 9–10, pp. 414–422*).—The article considers species of Sesamum, Ricinus, Rhus, Cæsalpinia, Manihot, Aleurites, Stillingia, and Bassia.

Plants from dry regions and their culture in Paraguay, J. KRIESE (*Rev. Agr. Cien. Apl., Paraguay, 1 (1899), No. 8, pp. 364–370*).—A popular article on the adaptation of certain plants growing in dry regions to the conditions existing in Paraguay.

Haymaking, P. WAGNER (*Braunschw. Landw. Ztg., 67 (1899), No. 25, pp. 116–119; Ztschr. Landw. Ver. Hessen, 1899, No. 25, pp. 318–320*).—A popular article calling attention to the results that should be obtained in making hay. Methods of haymaking are discussed.

HORTICULTURE.

Plants starved by excessive feeding, E. COURTOIS (*Bul. Chambre Syndicale Hort. Maraîchers Amiens, 1898, Dec.; Rev. Hort., 77 (1899), No. 8, pp. 182, 183; Garden, 55 (1899), No. 1432, p. 281*).—A statement of the principles of osmosis as exhibited in the living plant cell, and an exposition of their economic application in fertilizing plants with liquid manures. In order that the endosmotic current may be the stronger and more rapid the liquid absorbed by the roots must be less dense than the cell sap. Since cell sap contains about 4 gm. of soluble matter to the liter, a liquid fertilizer must contain less than that proportion. In practice this amount should not be over 2 to 3 gm. to the liter. In respect to the amount of water or liquid manure that should be applied to plants, especially in pots, it is stated on the basis of investigations that this amount should be one and two-thirds of what the plant is able to absorb.

Tomatoes, cabbage, and onions, C. L. NEWMAN (*Arkansas Sta. Bul. 56, pp. 21*).—Experiments in transplanting tomatoes are reported. Seeds of 10 varieties were sown January 1 ½ in. deep in rows 3 in. wide. Ten plants of each variety were subjected to different treatments after the first rough leaf appeared up to the time they were transferred to their permanent place in the field. The treatment of the different lots was as follows:

"*Plat 1.*—When the third or first rough leaf appeared the plants were shifted to other flats and set 1 by 1 in. Before they became crowded they were again shifted to flats and set 3 by 3 in. Each plant was taken up with its allotted portion of soil. . . . When the 3 by 3 in. plants began crowding they were again cut out and shifted to quart strawberry boxes, where they remained until transplanted in the field on March 30. . . . In transplanting to the field the plants were not taken from the berry boxes, but set box and all so that the top of the box was 4 in. beneath the surface of the ground. . . .

"*Plat 2.*—The treatment of this lot of plants was identical with those of plat 1 up to the time they were transferred to the strawberry boxes. Instead of the berry boxes flats 3½ in. deep were used, the plants being set 4 by 4 in., where they remained until the final transplanting on March 30, when a block of soil 4 by 4 by 3½ in. was removed with the plants. The plants were set as were those in the berry boxes, 4 in. deeper than they had grown in the flats. . . .

"*Plat 3.*—This lot of plants was treated as lots 1 and 2 up to the shift to 3 by 3 in. into flats, where they remained until the final transplanting on March 30, when, with a 3-in. square of earth, they were set 4 in. deeper than they stood in the flats. . . .

"*Plat 4.*—These plants were shifted to 2-in. pots when the first rough leaf appeared, and later to 3-in pots, from which they were transferred to the field on March 30 and set so that the top of the ball of earth was 4 in. below the surface of the ground. . . .

"*Plat 5.*—These plants were not disturbed until the final transplanting of March 30. They . . . were set 4 in. deeper than they stood in the flats. . . .

"*Plat 6.*—These plants were treated the same as plat 5, except that they were set only as deep as they grew in the trays."

The results are summarized in the following table:

Average results of experiments with tomatoes.

	Average number of fruits per plant that ripened before July 1.	Average weight per plant.	Average weight of tomatoes.	Average weight of largest tomatoes.	Yield per acre in bushels—50 lbs. to bushel.
	Pounds.	*Pounds.*	*Ounces.*	*Ounces.*	*Bushels.*
Plat 1	18.81	6.90	5.85	10.5	500.94
Plat 2	17.61	6.12	5.45	10.3	444.31
Plat 3	18.48	5.82	4.95	7.5	422.53
Plat 4	12.30	3.65	4.61	6.8	264.99
Plat 5	17.39	3.40	3.34	5.3	246.84
Plat 6	13.02	2.26	2.80	3.9	164.07
Average	16.26	4.69	4.50	7.38	340.49

Plat 1 ripened first and plats 5 and 6 last. The difference in yield between plats 1 and 6 is 336.87 bu. per acre, yet the total difference in cost of growing the fruit was less than $20 per acre. These results indicate that "the productiveness, size, and earliness of the fruit are proportionate with the vigor of the young plants and that the vigor of the plants is controlled by their early treatment."

Experiments were made in thinning tomatoes to increase the size of the fruit. The test was conducted with 2 lots of 25 plants each. In lot 1, not more than 3 fruits were allowed to remain on 1 cluster, and generally only 2. The thinning was done when the young tomatoes were ½ or ¾ in. in diameter. The other lot was not thinned. The total weight of fruit per vine was a little less when the fruit was thinned than when it was not thinned, but the average weight of a single fruit in the former case was 15.82 oz., as against 6.86 oz. in the latter case. In the lot that was thinned the weight of the largest single fruit was 18.9 oz.; in the lot not thinned, the weight of the largest fruit was 15.56 oz.

Experiments were made on the effects of removing tomato fruit clusters upon the weight and quality of the fruit. Forty plants of Mikado were divided into 8 lots of 5 plants each.

> "Plat 1 was restricted to 1 fruit cluster, plat 2 to 2 fruit clusters, and so on through plat 8, which bore 8 clusters. The leaves of the plants of plat 1 became very large, fleshy, and were in the majority of cases covered with adventitious buds, which developed into branches, some of which bore fruit of inferior quality. These adventitious buds did not develop until the fruit of the one-cluster plat was well advanced toward ripeness. The fruit of plat 1 was practically worthless, but few specimens either ripening or coloring uniformly. Several cracked open, and all had an acrid or bitter taste and were hard and knotty in places. The fruit of plat 2 was considerably superior to that of plat 1 but partook to a more or less extent of its abnormal characteristics. An occasional adventitious branch appeared upon the leaves, and but few of the tomatoes were of good quality. The remainder of the plants bore excellent fruit with the exception of plats 7 and 8. These were smaller and more irregular in shape than plats 3 to 6, inclusive."

Vines bearing 4 and 6 clusters gave the largest yield; those bearing 3 or 4 clusters gave the largest average weight of individual fruits.

Tests have been made for 5 years to compare the yields of onions grown directly from seed with transplanted onions.

"The transplanted onions ripened from 2 to 19 days earlier than the others and averaged 9¼ days earlier. The average of culls was 5½ and 14 per cent in favor of transplanting. The keeping qualities of the two lots in the years 1895 and 1896 were slightly in favor of the transplanted onions."

They also yielded on an average throughout the test 18.4 per cent more than those not transplanted.

Tests of subsoiling light sandy soil are reported. Land that was subsoiled to the depth of 18 or 20 in. gave considerably larger yields of cabbage, cauliflower, tomatoes, Irish potatoes, eggplant, and corn than land not subsoiled. The difference in yields was probably exaggerated by the facts that the season was very dry and that the area upon which experiments were conducted had probably never before been plowed 4 in. deep. It is believed, nevertheless, "that larger areas of the lighter soils of the State would be greatly benefited by subsoiling once in 4 or 5 years, if the subsoil were left in its original position and not brought to the surface."

A test of level and ridge culture with cabbage gave results much in favor of the former. Tests were made of deep and shallow setting of cabbage. The plants were 4 in. high when transplanted. One lot was set with the bud just level with the surface of the soil, another no deeper than the plants grew in the flats, and a third halfway between. The plants that were set with the bud level with the surface of the soil produced the largest number and average weight of heads. A test of 30 varieties of cabbage is reported.

The root killing of nursery stock, E. S. Goff (*Florists' Exchange, 11 (1899), No. 26, p. 672*).—It is the author's opinion that in the severe freeze of last winter soil exposure or other unknown conditions were generally more potent in determining the amount of damage to fruit trees than hardiness of varieties. Trees on sod or poorly cultivated ground generally escaped injury more often than those on well-cultivated lands, though this was not always the case. The effects of the freeze give force to the fact "that in the breeding of hardy fruit trees we have 2 distinct problems in hand, i. e., to produce a hardy top and a hardy root to support it." It is suggested that seedlings grown from various kinds of crabs, like the Virginia, would be preferable for root or crown grafting to those of the common apple; and that the Virginia crab might be bred in the course of a few generations to come true enough from seed for all purposes of grafting. In like manner the sand cherry and the wild red cherry should be experimented with as stocks for the cherry, and the plum should be confined to American stocks. Among the Rubus fruits the Loudon raspberry among the reds and the Older among the blacks are mentioned as having established claims to remarkable hardiness.

Referring to the planting of nursery stock injured by freezing, it is said that "if only the fibrous roots are killed, the trees may be transplanted with as much safety as if no injury had occurred, for the fibrous roots are mostly sacrificed in transplanting by our present systems."

Notes on plum culture, C. S. CRANDALL (*Colorado Sta. Bul. 50, pp. 48, pls. 9*).—This bulletin is a general treatise on plum culture. Specifically the topics treated are as follows: Derivation and distribution of our plums, propagation of the plum, pruning, soils, irrigation, distance of planting, arrangement of varieties for cross pollination, and self-fertility of plums.

Contrary to the common practice of setting trees 15 by 15 ft., a distance of 15 by 20 ft., or even 20 by 20 ft. is recommended. The best-formed trees in the station orchard are those headed 30 to 36 in. from the ground. As a preventive against frost cracks the station has found wrapping with burlap effective and inexpensive.

Observations were made on the blossoming season of plums in Colorado, and a chart was constructed for the station orchard of 56 varieties. A comparative study was made of the blossoming seasons, as shown by this chart and the chart constructed for the latitude of Denton, Maryland, by the Vermont Station (E. S. R., 9, p. 839). The latitude of Denton is nearly the same as that of Colorado Springs, but differences in altitude and climate make a considerable difference in the season of growth.

"The two striking differences between the Maryland and Colorado tables are in the commencement of blooming, and in the length of the periods. Variations in climate would lead us to expect differences in the commencement of blooming. This difference here appears as 17 days, and it is probable that variations in seasons might either increase or diminish this. The variation in length of period is extreme. The shortest period recorded in the Maryland table is 2 days. Our shortest is 12 days.

The longest periods are 7 days in Maryland and 31 days in Colorado. The great length of the periods observed here may in part be accounted for by the weather conditions prevailing at the time. It will be observed that 11 varieties began blooming on April 30, and that 9 varieties began on May 7, none opening in the interval. This is directly attributable to a storm which prevailed between these dates."

In the study of the self-fertility of plums, 629 flower buds, representing 40 varieties, were covered with paper sacks. When the flowers had opened and the stigmas were viscid each stigma was copiously covered with pollen, either from the same flower or another flower of the same cluster. The pollen was in good condition. An examination June 6 showed 113 apparently well-formed fruits, or 17.94 per cent, and 105 imperfect fruits, or 16.69 per cent. June 23 there remained but 6 fruits, or less than 1 per cent.

Again, 699 flower buds, representing 41 varieties, were covered but not hand pollinated. June 6 there were 123 well-formed fruits or 14.73 per cent and 129 imperfect fruits, or 15.59 per cent. June 23 the number of fruits remaining was 7, or about 1 per cent. "In final results, then, there is a remarkably close agreement between the 2 sets. The natural conclusion is that the infertility did not lie in the failure of the stigmas to receive the pollen, but must be looked for either in an inherent antipathy which the plant has for its own pollen or in some outside influences." Definite conclusions can not be satisfactorily drawn because the "June drop" was very heavy from all the trees.

Popular notes are given on the powdery mildew of the plum and cherry (*Podosphæra oxyacanthæ*), black knot (*Plowrightia morbosa*), plum pockets (*Exoascus pruni*), and a blight disease, the nature of which was not well understood. Descriptive notes are given on a number of varieties.

Strawberries, S. M. EMERY (*Montana Sta. Bul. 16, pp 69–82*).—A test was made to determine the practicability of maintaining the productiveness of berry plants at a profitable point after the second year. Fifty-eight varieties were set in the spring of 1895. After fruiting in 1896 the beds were thoroughly cultivated, irrigated, and mulched in the winter. The yields of each variety for 1896 and 1897 are tabulated. With all but 5 varieties the second crop was heavier than the first, the average gain, excluding the varieties that showed a decrease, being 10⅝ lbs. to 25 plants. The very free irrigation employed did not, however, appear to have a favorable effect on the flavor of the fruit.

Ten days after the occurrence of a white frost observations were made on the extent of the damage. Varieties differed much in hardiness, the number of injured plants varying from zero in the case of Bisel, Crescent, Gen. Putnam, Princeton Chief, Parker Earle, Robinson, Stevens, Shuster Gem, and Warfield, to 12 per cent of Columbian, with an average of 4 per cent for all varieties that had suffered injury. The extent of damage did not appear to be correlated with the blossoming period.

In this connection a microscopic study was made by the station biologist, E. V. Wilcox, to determine whether there is any recognizable variation in the anatomical characters of strawberries to account for the physiological differences. Some anatomical differences were discovered, but not enough on which to base a safe conclusion. "There is not a question of doubt but that there is a vast difference in the makeup of the different varieties of strawberry blooms and fruits in respect to frost resistance."

On the influence of the removal of the runners of strawberry plants upon their fertility, U. DAMMER (*Gard. Chron., 3. ser., 25 (1899), No. 641, pp. 217, 218*).—A report on an experiment made by Mr. Duerkoptf to decide whether it is better to remove runners as often as possible or not until after fruiting. Fifty Sharpless strawberries were planted in each of 6 rows. "At the beginning of September, when the plants began to grow, the runners of all the plants were cut off. From this date, September 5, the plants of row 1 were deprived of their runners weekly, . . . those of row 2 fortnightly, . . . those of row 3 every third week, . . . and so forth, each following row being treated a week later. . . . On October 17, 1897, the experiment was interrupted, as no more new stolons or runners were formed. At the beginning of June, 1898, the first new runners appeared. On June 5, 1898, the stolons of all plants were removed. Then the plants in the single rows were cultivated in the same manner as during the previous year until June 19. During the week, from June 19 till 25, the number of leaves, fruiting stalks, and fruits of each of the 300 plants were counted." The result was as follows:

Effect of removing runners of strawberry plants.

Row	Runners removed	Number of following parts in each row June 19–25			Average number of following parts produced by each plant.			Number and per cent of ripe fruits June 21		
		Leaves	Fruiting stalks	Fruits	Leaves	Fruiting stalks	Fruits	Whole number fruits	No ripe fruits	Per cent ripe fruits.
1	Weekly	1,175	177	916	23.50	3.54	18.32	916	53	5.78
2	Fortnightly	1,137	159	841	22.74	3.18	16.82	841	59	7.01
3	Every 3 weeks	1,139	167	860	22.78	3.34	17.20	860	36	4.18
4	Every 4 weeks	1,009	127	628	20.18	2.54	12.56	628	55	8.75
5	Every 5 weeks	970	105	618	19.40	2.10	12.36	618	78	12.62
6	Every 6 weeks	928	73	482	18.56	1.46	9.64	482	54	11.20

Except as to row 3, the results show that the number of fruits is increased by removing the stolons as often as possible. The time of ripening, however, is delayed by the operation. As to row 3 the experimenter thinks that some peculiarities in the soil may have influenced the result.

The grape, R. H. PRICE and H. NESS (*Texas Sta. Bul. 48, pp. 1145–1176, figs. 8 pls. 11*).—The first part of this bulletin treats of experimental work, and comprises classification, descriptive notes on 205 varieties, and recommendations. The varietal descriptions include date of bloom in the station vineyard, condition of stamens, whether erect or re-curved, date of ripening, and average yield per vine. Considerable care is taken to give the specific race of each variety to aid in the scientific selection of sorts. "Certain racial types and certain species are being found to be best adapted to certain isothermal lines. . . . No variety with any great amount of Labrusca blood has stood our climate successfully. On the other hand, those varieties possessing Lincecumii and Bourquiniana blood have stood the climate remarkably well. Nearly all varieties with much Vinifera blood are about dead."

The classification presented is that of Munson as modified by Bailey, with a few alterations by the present authors. The following varieties have done well at the station: "As table grapes, Brilliant, Bailey, Delaware, Dracut, Duchess, Golden Gem, Gold Coin, Green Mountain, and Herbert. The following are wine grapes of much promise: America, Catawba, Herbemont, Hermann, Le Noir, and Mrs. Munson."

The second part of the bulletin treats of propagation and cultivation. Notes are given on the following diseases and insect enemies of the grape, with preventive or remedial measures: Black rot, brown rot, anthracnose, root rot, grape-leaf blight, grape-leaf folder, grape-leaf hopper, and grape berry moth.

Self-fertility of the grape, S. A. BEACH (*New York State Sta. Bul. 157, pp. 395-141, figs. 3, pls. 5*).—This bulletin is a full report to date on work already noted (E. S. R., 6, p. 46; 8. p. 601). Tests of self-fertility have now been made with 169 varieties.

A feature of the work not heretofore reported is an attempt to determine whether environment may modify self-fertility. Several varieties which had been previously tested at the station were tested again in two other localities. Some showed a little difference in the degree of self-fertility, while others gave practically identical results. Tests made in different localities showed somewhat greater differences. Varieties of similar sorts tested different seasons showed a like degree of fertility in the majority of cases. Rarely was the degree of variation marked. It is inferred from these results that variable sorts would differ in self-fertility in different parts of the same vineyard.

In regard to the author's previously published lists of self-fertile, imperfectly self-fertile, and self-sterile grapes, the question has arisen whether the variation in the degree of self-fertility in some varieties is sufficiently great to make such a classification unreliable. A comparison of the present classification and previous ones shows that while some varieties have been transferred from one list to another, in the majority of cases the results have been practically similar with the same variety in different seasons and different localities. Variations in self-fertility were in no case sufficient to be of cultural importance. "Changes from one class to a widely different one are not to be expected."

To assist in the selection of varieties for cross pollination, observations were made on the blossoming seasons of the varieties in the station vineyard. The data are tabulated for the years 1892 to 1898, inclusive. Vulpina (Riparia) is the first species to come into bloom, followed by Aestivalis and Labrusca successively, with Lincecumii and other southwestern species last.

An attempt was made to determine the causes of self-sterility in the grape. In nearly all the varieties under experiment the discharge of pollen from the anthers was observed; hence in these cases self-sterility could not be due to an insufficient supply of pollen. Self-pollination takes place in varieties having long stamens, since most of such, though not all, are self-fertile. But, as has been previously reported, all varieties having short stamens are self-sterile or nearly so. Since in this case also fruits are sometimes formed, it is concluded that self-pollination of short-stamened varieties also takes place; hence self-sterility is not due to lack of self-pollination but to self-fertilization. Three explanations are suggested for the fact of nonfertilization:

> "First, the stigma may not be receptive when the pollen is discharged and the pollen may perish before the tubes enter the stigma; or second, either the pollen or the pistils may be imperfectly developed; or third, the pollen may be incapable of fertilizing a pistil of its own variety because of a lack of affinity between the two. . . .
>
> "The evidence that self-sterility in general is due neither to defective pollen nor to defective pistils may be summarized as follows: Pollen is formed abundantly. Pollen retains its vitality till long after the pistil should become receptive. Pollen of self-sterile grapes may successfully fertilize other grapes. Pistils of self-sterile grapes are usually well developed. They develop no fruit when cross pollinated.
>
> "In view of the following considerations, the most satisfactory explanation of self-sterility which can be presented appears to be that with self-sterile grapes there is a lack of affinity between the pollen and the pistils of the same variety. Nearly all of the self-sterile list and of the list of varieties which give very imperfect self-fertilized clusters are known to be hybrids. Possibly all are hybrids. Self-sterility is often found among plant hybrids."

Referring to the reliability of the method of testing self-fertility by covering the clusters, the author states that "out of 169 cultivated varieties of the grape which have been tested here by this method, 103 produce on the average marketable clusters when the blossoms are covered." Further discussion of the pollination of the grape is reserved for a future report.

Plant individualism, L. F. KINNEY (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 144-149*).—Attention is called to the importance of considering the individualism of the plant and its peculiarities as factors in gardening experiments and in teaching horticulture.

Miscellaneous analyses, G. S. JENMAN and J. B. HARRISON (*Rpt. Agl. Work Bot. Gard. [British Guiana], 1893-1895, pp. 121-127*).—Analyses are reported of fresh kola nuts, local-grown Irish potatoes, *Calathea allouya*, slippery callalu, caterpillar and Indian callalus, pumpkins, unripe ochroes, white and red Mandura beans, purple-flowered and podded Bonavis beans, *Sesbania ægyptiaca*, and the fruit of the calabash tree.

Spontaneous hybrids of hardy plants, C. W. DOD (*Gard. Chron., 3. ser., 25 (1899), Nos. 636, p. 132; 637, p. 148; 638, pp. 164, 165; 641, p. 210; 644, pp. 259, 260; 645, pp. 276, 277*).—Notes on a number of hybrids.

Reciprocal influence of stock and scion, T. J. BURRILL (*Trans. Illinois Hort. Soc. 1898, pp. 62–72*).—A review of the present conflicting opinions as to the reciprocal action of stock and scion. The article includes translations of parts of articles by L. Daniel on the creation of new varieties by graftage[1] and on the amelioration of the wild carrot by grafting it on the cultivated carrot.[2]

The flavor in fruit (*Garden, 56 (1899), No. 1444, p. 65*).—A gardener's notes on variations of flavor in a number of sorts of fruit under different conditions of culture.

Peat as a fruit preservative (*Jour. Agr. and Ind. South Australia, 2 (1899), No. 11, pp. 887, 925*).—The antiseptic properties of peat have recently been utilized by European fruit growers for the preservation of fruit. The fruit is merely buried in the peat without wrapping in paper. Apples and pears acquire no taste from it and keep for many months. One hundred pounds of fruit require about 10 lbs. of dried peat. Grapes and lemons were preserved in the same way with excellent results.

The use of chemical fertilizers in horticulture, OMNIS (*Monit. Hort., 1899, May 10, p. 108; abs. in Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), pp. 454, 455*).—It is stated that while barnyard manure must remain the fundamental fertilizer for the garden, its use is advantageously supplemented with a quick-acting and very assimilable fertilizer, according to the peculiar requirements of the particular kind of plant.

Vegetables cultivated for their leaves, as salad plants and cabbage, require especially nitrogen and phosphoric acid. In addition to the usual fertilizers, salad plants may advantageously receive 1.5 kg. of nitrate of soda and 2 kg. of superphosphate per are. For cabbage these amounts should be doubled. Vegetables cultivated for their roots do well on the same fertilizers as cabbages, to which should be added, however, 1 or 2 kg. of muriate or sulphate of potash, according to the nature of the soil. Leguminous vegetables should not receive any barnyard manure. In a well-arranged system of culture they come at the end of a rotation. They do well on mineral fertilizers, and may receive per are from 3 to 5 kg. of Thomas slag or superphosphate of lime and 2 kg. of muriate or sulphate of potash. Bulbous and tuberous vegetables may receive a supplementary dressing of 2 kg. of nitrate of soda, 3 kg. of superphosphate, and 1 kg. sulphate of potash per are.

The vegetable garden, C. H. GREATHOUSE (*U. S. Dept. Agr., Farmers' Bul. 94, pp. 24, figs. 8*).—The bulletin contains suggestions for the cultivation of the kitchen garden, and specific cultural directions for the most common vegetables.

Vegetable tests for 1898, L. R. TAFT ET AL. (*Michigan Sta. Bul. 170, pp. 251–283*).—Tests of and descriptive notes on numerous varieties of bush beans, pole beans, cabbage, cauliflower, kale, kohl-rabi, cucumbers, lettuce, onions, peas, potatoes, radishes, sweet corn, and tomatoes. Tests have been made of various materials as preventives of the scab upon potatoes. The materials used were chlorid of lime, formaldehyde gas, formalin solution, lysol solution, carbolic-acid solution, chlorin gas, and corrosive sublimate. Potatoes soaked 2 hours in ½ per cent formalin solution or ½ hour in $\frac{1}{2000}$ corrosive sublimate gave best results.

Culture of string beans, H. THEULIER fils (*Rev. Hort., 71 (1899), No. 10, pp. 240, 241; Garden, 55 (1899), No. 1438, p. 401*).—Detailed cultural directions in which the reason is given for each operation.

Culture of the ginger plant, G. LANDES (*Rev. Cult. Coloniales, 4 (1899), No. 31, pp. 357–366*).—An article treating the subject from the cultural and commercial points of view.

Etymology of the word haricot (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), p. 420*).—A French scholar believes that he has proven that the words haricot, tomato, cacao, and avocado, the derivation of which have been hitherto unknown, are only transliterations of the words which were used in an ancient American dialect to designate these vegetables. It is believed that this etymology furnishes a new proof of the American origin of *Phaseolus vulgaris*.

[2] Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 2, pp. 133–135.

Autumn vs. spring-sown onions, G. MacKinlay (*Gard. Chron., 3. ser., 25 (1899), No. 633, pp. 92, 93, fig. 1*).—In the summer and early fall of the very dry season of 1898, spring-sown onions were more or less attacked by maggots and mildew, against which remedies were of little avail. The attack was worse on spring-sown onions than on those that were sown in autumn and transplanted. This is attributed to the fact that the transplanted onions had become better established.

Winter turnips, J. Rudolph (*Rev. Hort., 71 (1899), No. 14, pp. 339–341, figs. 4*).—Notes on culture and classification and descriptions of varieties.

Licorice (*Pacific Rural Press, 57 (1899), No. 24, p. 371*).—Historical and cultural notes.

Cultivation of the vanilla bean in Mexico, A. B. Jones (*U. S. Consular Rpts., 1899, No. 224, pp. 151–155*).—Cultural and commercial notes.

Vanllia (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 477–483, figs. 4*).—Notes on the culture of the plant and the preparation of the pod for market. The subject of pollination is treated at some length.

Variety tests of fruits and vegetables, H. Benton (*Alabama Canebrake Sta. Rpt. 1898, pp. 4–8, 10–12*).—Reports tests of 52 varieties of watermelons and 56 varieties of cantaloupes grown from seed imported from Russia by this Department. Most of the watermelons are classed as poor and the larger part of the cantaloupes died. Of those that lived only 3 are classed as good. Notes are also given on Russian varieties of maize, pumpkins, smooth brome grass, turnip, sunflower, and cabbage. Notes are given on 25 varieties of strawberries. Lady Thompson, Hoffman, Mary, and Darling are classed as very prolific. Variety tests of tomatoes are also reported.

Nursery hints, L. C. Corbett (*West Virginia Sta. Bul. 54, pp. 143–175, figs. 33*).—Popular notes on the propagation of plants by natural processes, by cuttings, layers, grafts, and buds, together with hints on pruning.

Guide to fruit culture, A. Breden (*Leitfaden für den Obstbau. Vienna: W. Frick, 1898, pp. 78, figs. 43*).—A practical work on fruit culture based on the underlying principles.

Fruits of Ontario, L. Woolverton (*Toronto: Ontario Dept. Agr., 1898, pp. 95, figs. 160*).—Carefully prepared original descriptions and illustrations of a considerable number of varieties of apples, cherries, currants, gooseberries, grapes, pears, peaches, strawberries, and quinces cultivated in Ontario.

The experiment orchard, S. M. Emery (*Montana Sta. Bul. 16, pp. 82–89*).—Notes are given on fruit stocks for Montana. Transcendent and Virginia crabs are recommended. Trees are protected in winter by wrapping the stems from the ground to the crotches with newspapers. A list of varieties of apples, pears, crabs, cherries, apricots, plums, and prunes set in the station orchard is given showing the number set and the number still living. Currants did well at the station but gooseberries, dewberries, and blackberries were a failure.

Dwarf fruit trees, F. Boulon (*Florists' Exchange, 11 (1899), No. 25, p. 655, figs. 3*).—Dwarf fruit trees are stated to have certain advantages over high trees: "(1) A large number can be grown in very limited space; (2) the cultivation of vegetables and flowers near them can be accomplished without fear of shade; (3) they produce beautiful and excellent fruits; (4) they are an ornament to the vegetable garden; (5) they have the advantage of resisting the winds of autumn which cause the fruit of high trees to fall before maturity.

Manuring fruit trees in Holstein (*Gard. Chron., 3. ser., 25 (1899), No. 650, p. 381*).—Every other winter a few holes are dug in the ground about 4 or 5 ft. from the trunk of the tree and about 1 ft. deep, or closer and shallower in the case of small trees, and filled with liquid manure about four times during the winter months. The trees are said to produce excellent fruit in abundance without any cultivation.

Hardiness of peaches, L. C. Corbett (*Amer. Gard., 20 (1899), No. 239, p. 512*) —The author's observations have led him to the conclusion that age, exposure, and soil conditions are greater factors in determining what is called hardiness in the peach tree than varietal difference, provided they belong to the same races. It is believed that young trees and old trees are less able to stand cold than those in their prime.

Frozen trees and their treatment, L. R. TAFT (*Michigan Sta. Spec. Bul. 11, pp. 4*).—Notes on the injuries to fruit trees and grapes in Michigan during the extreme cold of last winter and suggestions for their treatment. Notes are given on spraying for leaf curl. An experiment was made to determine the best time for making the application. Trees sprayed in March showed little or no signs of the disease, while those not sprayed until the latter part of April were seriously injured.

Some effects of last winter on nurseries and orchards in Iowa, J. CRAIG (*Gardening, 7 (1899), No. 163, pp. 294, 295*).—Notes on the hardiness of the various common orchard fruits and fruit stocks in Iowa. Much of the injury is believed to be due to root killing. The conditions which cause root killing are stated to be severe freezing on bare ground unprotected by vegetation or snow. The branches may throw out leaves and bear blossoms, but after exhausting the stored food in the buds and twigs wither and die with the entire tree.

Resistance of blossoms of different varieties of peaches to frost, J. T. BOGUE (*Pacific Rural Press, 57 (1899), No. 24, p. 370*).—It is believed that varieties with small, partly closed flowers escape frosts which make the large wide-open blooms infertile. Observations are not yet conclusive.

Stone splitting in peaches (*Garden, 56 (1899), No. 1443, p. 35*).—This undesirable trait is said to be more frequently observed in some varieties than others, and is due generally to faulty cultivation. Too rapid growth of trees at the ripening period is one of the principal causes. Root pruning and applications of lime to the soil will correct the trouble to some extent.

Judging or scoring fruits, W. R. LAZENBY (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 156-161*).—A discussion of the ideal qualities of the apple for commercial purposes and scale of points for judging the fruit of the apple, grape, strawberry, and tomato.

The cultivation of the olive, A. K. ROLLOV (*Tiflis, 1899, pp. 111 + 64; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Mar., pp. 702, 703*).

Kakis, A. DE BOSREDON (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 18, pp. 546-550, figs. 2; 19, pp. 579-584, figs. 3; 20, pp. 610-613, figs. 2*).—A full discussion of the subject, comprising botanical and pomological descriptions, use as a decorative plant, descriptions of 22 varieties, and detailed cultural directions.

Loquats in California (*Pacific Rural Press, 57 (1899), No 24, p. 369, fig. 1*).—Notes on the work of a specialist in the improvement of this fruit. Advance is considered the best variety and notes are given on it.

Notes from the South Haven Substation, L. R. TAFT and T. T. LYON (*Michigan Sta. Bul. 169, pp. 141-250*).—Variety tests with varietal notes are reported of a large number of strawberries, red raspberries, blackberries, currants, gooseberries, grapes, apples, cherries, peaches, pears, and plums. The wineberry, Japanese mayberry, Loganberry, and strawberry-raspberry are reported on unfavorably. The last named "bids fair to become a troublesome weed and, as it has no value, its introduction should be discouraged."

Among the more productive varieties of strawberries were Acme, Arkansas Traveler, Aroma, Arrow, Auburn, Avery, Beauty, Bickle, Bouncer, Bubach No. 5, Crescent, Daisy, Fountain, Giant, Greenville, Haverland, Irene, Isabel, Knight, Lehigh, Leroy, Lincoln, Little No. 42, Longfield, Orange Co., Princeton, Shawnee, Sherman, Shyster, Smith, Stahelin, Star, Tennessee, Wood, and Woolverton.

Among the more productive of the red raspberries were Brandywine, Church, Cuthbert, Early King, Golden Queen, Hansell, Kenyon, London, Marlboro, Miller, Reeder, Thwack, and Turner.

Bush fruits for 1898, L. R. TAFT ET AL. (*Michigan Sta. Bul. 171, pp. 285-290*).—Tests and descriptive notes on a number of varieties of blackberries, raspberries, and grapes.

Strawberries for market, J. DWYER (*Amer. Gard., 20 (1899), No. 235, pp. 449, 450*).—Notes on the varieties that a commercial gardener has found most profitable for market purposes. The varieties are: Michel Early, Lovett Early, Marshall, Wm. Belt, Brandywine, Parker Earle, and Gandy. Any of these sorts can be shipped a distance of 150 miles and arrive at their destination in good condition.

Grapes, J. S. MOORE (*Mississippi Sta. Bul. 56, pp. 22*).—A popular bulletin on grape culture. A large number of varieties are described. The following varieties, given in the order of maturity, are recommended: *Shipping list.*—Champion, Ives, Perkins, Niagara, Delaware, Lindley, Concord, Hilgard, Moench. *Table or local market.*—Perkins, Niagara, Delaware, Agawam, Brighton, Lindley, Concord, Hilgard, and Moench. Sacking did well with most varieties at the station and is recommended.

The preparatory work in grapevine culture, DAL PAIZ (*Sci. Amer. Sup., 48 (1899), No. 1228, pp. 19690, 19691, figs. 10*).—An article treating of the operations preceding planting, as drainage, terracing, trenching, and methods of plowing.

Why some grapes fail to fruit, F. H. HALL and S. A. BEACH (*New York State Sta. Bul. 157, popular ed., pp. 8, figs. 2, pl. 1*).—A popular edition of Bulletin 157 (see p. 248). In this edition a large number of varieties are grouped according to their blossoming period to aid in the selection of varieties for cross pollination.

DISEASES OF PLANTS.

Report of the botanist, J. W. TOUMEY (*Arizona Sta. Rpt. 1898, pp. 160–169, figs. 2*).—Considerable attention has been paid to the date palm in southern Arizona (E. S. R., 10, p. 851). The author's conclusion is that in certain portions of southern Arizona the cultivation of the date fruit can be profitably carried on.

Some 3 years ago the author's attention was directed to an alfalfa field where the plants were dying in spots in various parts of the field. The following year the disease became so bad that the field was plowed and part of it set with nursery stock, while another portion of the field was planted in tobacco. About 7 months after the nursery stock was planted a large portion of it, without reference to variety, began to die, and the disease made such progress that it became necessary to destroy all the plants. The tobacco was uninjured. Many other fields have been similarly affected throughout southern Arizona, and, in addition to alfalfa, in some localities apples, peaches, apricots, almonds, many small fruits, and a great variety of ornamental trees and shrubs are attacked.

The cause of the disease is attributed to a common root-rot fungus (*Ozonium auricomum*). An examination of affected alfalfa fields in Salt River Valley showed that the fungus was most abundant on the lower portion of the roots and extended to within 2 or 3 in. of the surface. As the disease spreads by contact, it is recommended that a trench be dug around all regions of contagion. The recent serious injury from this disease has called for more extended investigation, which is now in progress.

Several times during the past 2 years the author's attention has been drawn to a number of fruit trees dying from no apparent cause, death occurring soon after the trees come into full foliage. The injury is indicated by the leaves turning brown and curling up, and as it progresses the leaves become dry and finally fall away. The peculiar curling tendency is quite characteristic of sunburn and is in itself sufficient to enable anyone to recognize it. The cause of the sunburn is said to be the inability of the leaves to secure sufficient water to meet the demands of rapid transpiration. All plants that have been weakened from any cause whatever are most subject to sunburn, while trees with a good root system, well fed, and having a good water supply in well-aerated soils are able to stand extremes which would kill other trees not growing under these favorable conditions. Crown knot and a lack of nitrogen, which is so apparent in many of the soils of Arizona, would also weaken trees and make them liable to sunburn.

Notes are given on the care of fruit trees, with instructions for supplying the deficiency in nitrogen, cultivation, etc.

Sour clover, crimson clover, alsike clover, burr clover, Bokharà clover, sainfoin, Japanese clover, and cowpeas were tested for green manuring, being grown under as similar conditions of soil and moisture as could be obtained. The ones coming nearest to the requirements were sour clover, crimson clover, Bokhara clover, and cowpeas. The latter, however, are not suited for winter growing. To this list should be added alfalfa, which is a most valuable forage plant and under most circumstances the best suited for green manuring purposes.

Anthracnose of beans, E. GAIN (*Extrait Compt. Rend. Assoc. Franc. Avanc. Sci. 1898, pp. 389–391*).—This disease, which is due to *Colletotrichum lindemuthianum*, is said to be quite common in the United States, England, and Germany, and to have been lately observed in France. The author reports having recognized it in at least 20 varieties of cultivated beans. In some cases he found from 5 to 18 per cent of the beans diseased. In some experiments conducted in 1897 the anthracnose reduced the yield of beans in 2 cases to only 8 and 9½ times the amount of the seed, while sound seed produced from 100 to 120 fold.

A number of investigations of the author are briefly reported upon, from which he concludes that the value of seed is greatly depreciated by the presence of the fungus. The specific weight is reduced from 3 to 5 per cent and a great many of the seeds lose the power to germinate.

Some pot experiments are briefly reviewed, in which the effect of infested soil and of diseased seed in propagating the disease are shown. Plat experiments conducted in the same line gave similar results. The author recommends that seed be carefully selected before planting, as a means of greatly reducing the disease. By following out this suggestion and spraying with Bordeaux mixture the bean anthracnose could probably be held in subjection.

Experiments on finger-and-toe (club root) of swedes (*Bd. Agr.* [*London*] *Rpt. Agr. Ed. Great Britain, 1897–98, pp. 89–93*).—A report is given of a number of experiments on the effect of soil treatment with caustic lime, copper sulphate, gas lime, bleaching powder, chalk, and basic slag for the prevention of the club root, due to *Plasmodiophora brassicæ.* The results show that the sulphate of copper and bleaching powder were of little value, while the caustic lime, chalk, and gas lime, when thoroughly mixed with the surface soil, tend to greatly prevent the disease. It also appears that the lime should be applied to the soil a considerable time before swedes or turnips are grown. Basic slag had but a slight effect in checking the disease. Where this disease is prevalent all manure produced from affected roots should be applied to parts of the farm where turnips and allied crops are not grown; and in severe cases the growing of such crops should be entirely discontinued for a number of years, gradually restoring the soil by careful dressing with some form of lime.

Phytophthora infestans as a cause of potato rot, L. HECKE (*Jour. Landw., 46 (1898), Nos. 1, pp. 71–74; 2, pp. 97–142, pls. 2*).—The author states that *Phytophthora infestans* is an indirect cause of potato rot, and while a rot of the tubers always follows an attack of this fungus, yet it can not be considered as the immediate cause. *Clostridium butyricum* is reported as parasitic on the potato.

The life history of *P. infestans* is reviewed at considerable length and the effect of dry weather on the development of the conidia is shown. The different methods of dissemination are discussed, the principal ones being insects and winds.

Experiments were conducted for the prevention of the disease, and it was found that fertilizers which increased the nitrogen content of the tubers rendered them more resistant to the rot. Fungicides were also successfully employed.

The relation between starch content of potatoes and their diseases, ECKENBRECHER (*Berlin: P. Parey, 1898, pp. 34; abs. in Ztschr. Pflanzenkrank, 9 (1899), No. 3, pp. 187, 188*).—Investigations are reported on the resistance of 11 varieties of potatoes to potato rot. It is claimed the liability to disease decreases with the increase in starch content. The greatest amount of disease, 7.7 per cent, was found in 1897 in a variety containing 17.7 per cent of starch, and the least, 0.05 per cent, in one which had a starch content of 20.6 per cent. The intervening varieties were diseased in about the proportion of the amount of starch found. The average percentage of disease observed on 2 varieties for 10 years as shown, varied from 0.03 to 8.3 per cent of the crop. No relation was found to exist between starch content and potato-scab infection.

Notes on apple and potato diseases, H. H. LAMSON (*New Hampshire Sta. Bul. 65, pp. 101–108, figs. 5*).—Brief notes are given on the blights and scab of potatoes and the brown spot and apple scab of apples and pears. The results of experiments for the prevention of these different diseases are given. Formalin proved as efficient as corrosive sublimate for the prevention of potato scab.

A number of experiments are reported in which the effects of different fertilizers on the development of the scab were tested. Phosphate, stable manure, plaster, air-slaked lime, and wood ashes seemed to favor the development of the scab to a greater or less degree, air-slaked lime, plaster, and ashes being especially liable to increase the amount of scab. For the other diseases described, spraying with Bordeaux mixture is recommended, formulas for the preparation of which are given.

Experiments in combating downy mildew of the grape with copper acetate, G. Briosi (*Atti Inst. Bot. Univ. Pavia, 2. ser., 5 (1899), pp. 145–157*).—A condensed report is given of extensive experiments conducted, at a number of places in northern Italy, in which the efficiency of copper acetate as a fungicide was tested upon several thousand vines. Five different mixtures containing copper acetate were tested, comparisons being made in many cases with a solution of sodium carbonate, borol or sodium borosulphate, and Bordeaux mixture. It is claimed that the different forms of copper acetate proved quite efficient in controlling the Peronospora and were without injurious effect to the vines. The different mixtures should be carefully employed, and the strength of solutions of none should exceed 1 per cent. Copper acetate solutions are said to be easier prepared and applied, adhere nearly as well as Bordeaux mixture, and are more efficient in preventing this disease. The borol and the sodium carbonate solutions were of little value, as shown by these experiments.

A pineapple disease, H. Tryon (*Queensland Agr. Jour., 3 (1898), No. 6, pp. 458–467, pls. 4*).—Under the name "a fruitlet-core rot of pineapple" the author describes a disease in which the individual components of the multiple fruit of the pineapple are attacked. In Queensland the variety known as Prickly Queen seems especially subject to the disease. Externally the fruit appears to ripen unevenly, and although the symmetry is preserved individual segments or groups of segments here and there remain pale green. Internally the fruit will be observed to contain well-defined dark-brown elongated markings or areas of diseased tissue. They differ greatly in shape, but owing to color and dimensions are always very conspicuous. These discolored areas are found to occur immediately opposite the pale-green surface markings already alluded to. The central axis of the fruit does not show any abnormal change. Upon separating the compound fruit it was found, at least in the earlier stages, that each of these discolored areas is confined to a single segment.

Various causes have been attributed to this disease and the author in his investigation has found the brown tissue to invariably contain the mycelium of a species of Monilia closely related to *M. candida*. The fungus, which seems to be new, is described without specific name. While this fungus may cause the rotting of the fruit, the immediate cause of the disease, the author states, is a species of mite, the fungus gaining access through the injury caused by the insect. This mite, which appears to be new, is figured and described under the name

Tarsonemus ananas. In addition to this mite other means of possible infection are mentioned, among them a fungus-eating acarid (*Tyroglyphus ananas*, n. sp.).

In the discussion of remedies the author states that the Tarsonemus mites occur throughout the entire pineapple plant, and when once infested the plant should be rooted out and burned, thus preventing the further spread from that source. In replacing these plants, or in starting a new plat, suckers should be derived exclusively from plants in which the disease has not previously been observed. As an additional precaution they should be soaked in a lime-and-sulphur wash or treated with a carbolic-acid wash for some time prior to planting.

A new disease of the pansy, R. E. SMITH (*Bot. Gaz., 27 (1899), No. 3, pp. 203, 204, fig. 1*).—This disease is said to be characterized by the appearance of dead spots on the affected leaves. At first these are small with a distinct black margin, but soon becoming larger give to the leaf an appearance very similar to that produced by the well-known violet-leaf spot (*Cercospora violæ*). The petals also become affected, dying in spots and along the edges. Many of the petals do not develop fully and the flower thus appears malformed and unsightly. Such flowers produce no seed, and in a large field where pansies were raised for seed considerable loss was experienced. The fungus, which appears to be new, is characterized as follows:

"*Colletotrichum violæ-tricoloris*, n. sp.—Parasitic on leaves and petals of cultivated pansy (*Viola tricolor*), causing pale yellowish spots upon the leaves and dead areas on the petals, together with more or less deformation of the blossoms. Spots at first orbicular and definite in outline, but later becoming confluent and irregular. Acervuli numerous, 50 to 150 μ in diameter, often confluent; stroma usually only slightly developed, but sometimes abundant and forming a sort of pycnidium closely approaching Vermicularia. Setæ mostly single or in pairs, 20 to 70 μ long, deep brown, once or twice septate, tapering gradually to a point. Basidia short, hyaline. Conidia oblong or slightly curved with blunt ends; hyaline, continuous, granular with vacuoles, averaging 20 by 5 μ."

Seeding on different soils to exterminate smut, J. F. HICKMAN (*Ohio Sta. Bul. 101, pp. 179–181*).—A cooperative experiment between the Kansas and Ohio stations is described in which the effect of soil on the propagation of smut was investigated. Smutted seed oats were exchanged between the two stations and grown on different soils. The results indicate that the common belief that changing oats to different soil will eliminate smut is not founded on fact.

Spraying cucumbers in the season of 1898, F. A. SIRRINE and F. C. STEWART (*New York State Sta. Bul. 156, pp. 376–396, pls. 5*).—In continuation of experiments previously reported (E. S. R., 9, p. 248, and 10, p. 454), the authors give an account of cooperative spraying experiments with late cucumbers which were conducted in 4 different localities on Long Island during the season of 1898. In each case an entire field was sprayed, 2 fields receiving 7 applications of Bordeaux mixture, one 8, and one 5. Owing to late planting and a general lack of fertility, the crop in one case was a failure.

The cost of spraying for each application was: At Greenlawn $3.39, Deer Park $2.76, Mattituck $3.20, and at Smithton Branch $2.43. The value of the increased yield above the cost of spraying was: At Greenlawn $73.74, Deer Park $22.51, and at Smithton Branch $37. At the market rate of $1.25 per thousand, it is shown that pickles can be profitably grown on Long Island, if spraying is practiced and the crop given the proper care. The cost of spraying as given represents the maximum cost, and in practice the authors believe this could be reduced one-half or in large fields even more. They recommend on Long Island spraying cucumbers commencing between July 15 and August 1, after which the vines should be sprayed every 8 or 10 days until frost.

Spraying apple trees, with special reference to apple-scab fungus, J. C. BLAIR (*Illinois Sta. Bul. 54, pp. 181–201, figs. 27*).—The two most important enemies of apple growing in the State are the apple-scab fungus and the codling moth. According to the statistics offered, they very greatly injure the crop, causing a depreciation of about 60 per cent in the apple crop of the State. Experiments have been conducted by the station since 1888 for controlling fruit enemies, and in 1898 experiments were inaugurated for the purpose of accurately determining what could be accomplished by thorough and systematic spraying. The trees were first sprayed with solutions of copper sulphate in varying strengths, using 1 lb. of the sulphate to from 5 to 15 gal. of water. Later applications of Bordeaux mixture were given the trees and Paris green was added to the Bordeaux mixture, three applications being given. The results of the treatment showed that it is very efficient in producing larger and better crops of apples. Comparisons were made in which lime wash was applied to the trees with little effect. The bulletin concludes with descriptions of various forms of spraying apparatus and a number of formulas for the preparation and directions for the application of fungicides and insecticides.

Spraying experiments, H. M. DUNLAP (*Trans. Illinois Hort. Soc., 1898, pp. 336–355, pls. 6*).—A report is given upon a series of experiments in which apple and pear trees were sprayed at different times. The first lot was sprayed once with copper sulphate before the buds started in the spring; the second was sprayed once with Bordeaux mixture after the blossoms had fallen; the third was sprayed twice with Bordeaux mixture, the first time just after the falling of the blossoms, the second, 10 days later; the fourth was sprayed once with copper sulphate before the swelling of the buds and once after; the fifth was sprayed once with copper sulphate before the buds started and twice with Bordeaux mixture after the blossoms fell. The effect of the different sprayings on foliage and fruit is stated. Among the deductions drawn from the experiments, the author states that it is necessary to spray whether a crop of fruit is expected or not, on account of the effect which the spraying exerts on the next year's crop; that Bordeaux mixture is effective on fruit and foliage; and that 2 applications after the blossoms fall are necessary to secure the best result. The application of copper sulphate before the buds started in the spring did not show any superior advantage in this series of experiments. The formula for the Bordeaux mixture used was 20 lbs. copper sulphate, 15 lbs. lime, and 300 gal. of water..

Notes on nematodes occurring on cultivated plants, E. HENNING (*Landtbr. Akad. Handel. Och. Tidskr., 1898, pp. 217–265*).—The author gives a general characterization of nematodes and describes in particular *Tylenchus hordei*, *T. scandens*, *T. devastatrix*, *Heterodera schachtii*, *H. radicicola*, and *Dorylaimus condamni*. For each of these species the more important host plants are given, together with notes on their geographic distribution, means of distribution, the symptoms of disease produced on different host plants, the development and life history of the nematodes, and means for their suppression. Of the nematodes occurring in the northern part of Europe he mentions *T. hordei* as having been found on barley in Sweden, Norway, and Northern Finland; on Elymus in Norway, Denmark, and Scotland; upon *Poa pratensis* and possibly also upon oats in Sweden; *T. scandens* is reported occurring in Sweden, where it is very common on wheat but is unknown in Denmark or Norway. *T. devastatrix* is known to occur in Denmark on clover, potatoes, and English rye grass; in Norway upon clover; but is not known to occur with certainty in Sweden. *H. schachtii* occurs in Denmark on beets and is especially injurious to oats. In Sweden it occurs on the same plants, but is as yet unknown in Norway, So far as the Scandinavian peninsula is concerned, *H. radicicola* is unknown and has only been reported in Denmark on species of Balsamina. The distribution of *D. condamni* is said to be unknown.

New spraying devices, B. T. GALLOWAY (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Circ. 17, pp. 4, figs. 3*).—A description is given of a new spraying apparatus devised by the author, for use in place of the more expensive forms of apparatus where a limited amount of spraying is to be done. This consists of an ordinary hand syringe fitted with a Vermorel nozzle provided with a separate intake. A second form of apparatus described is a greenhouse nozzle for the application of water. It consists of a flattened casting which contains a narrow slit through which the water issues, and with a pressure of 30 to 40 lbs. the leaves of plants can be thoroughly washed without soaking their roots.

A review of the fungus diseases observed during 1897, G. BRIOSI (*Atti Inst. Bot. Univ. Pavia, 2. ser., 5 (1899), pp. 327–352*).—Notes are given of the occurrence of diseases of grapes, cereals, orchard fruits, garden products, forage plants, ornamentals, forest trees, etc. Among the notes on the garden products, experiments are reported with copper acetate for the prevention of downy mildew (*Phytophthora infestans*) on tomatoes. The different solutions used are said to be somewhat more efficient than copper sulphate solutions.

Bacterial rots of plants, L. BUSSARD (*Rev. Vit., 1899, No. 282, pp. 525–527*).

Yellow rust (Puccinia glumarum) on barley in Denmark, L. P. LAUVITSEN (*Landmandsblade, 31 (1898), No. 52, pp. 747–750*).

Potato diseases and their treatment, B. T. GALLOWAY (*U. S. Dept. Agr., Farmers' Bul. 91, pp. 12, figs. 4*).—Popular notes are given describing the early leaf blight, late blight or rot, brown rot, potato scab, and scald of potatoes, with suggestions for prevention. With suitable apparatus and labor at $1.50 per day, the author states that potatoes may be sprayed 6 times at $6 per acre, and considering the increased yield which follows the application of the fungicides, whether diseases are present or not, the writer feels warranted in recommending the application of the treatment.

Potato-scab experiments made in 1898, H. GARMAN (*Kentucky Sta. Bul. 81, pp. 5-11, fig. 1*).—A report is given of experiments made to test the efficiency of different strengths of solutions and time of soaking seed potatoes in corrosive sublimate and formalin for the prevention of potato scab. The results obtained show the superiority of corrosive sublimate treatment over that of formalin. The most effective treatment was that in which 4 oz. of corrosive sublimate was dissolved in 30 gal. of water and the seed tubers soaked for one hour in this solution.

All methods of treatment reduced the production somewhat, the untreated rows yielding a few more pounds of potatoes than the treated ones, but when the worthless scabby potatoes were thrown out, the advantage was decidedly in favor of the treated lots.

Bacterial diseases of potatoes, C. WEHMER (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 9, pp. 308, 309*).—A reply is made to the criticism of Frank of a previous paper by the author on the bacterial diseases of potatoes.

Some diseases of the sweet potato and how to treat them, C. O. TOWNSEND (*Maryland Sta. Bul. 60, pp. 147-168, figs. 17*).—This bulletin is apparently a compilation of New Jersey Stations Bulletin 76 (E. S. R., 2, p. 416).

Fungus diseases of the apple and pear, M. B. WAITE (*Proc. Michigan Hort. Soc., 1897, pp. 184-191*).—Popular lecture on pear and apple scab, pear-leaf blight, and the bacterial blight of pear and apple, with suggestions for their prevention.

Diseases of the apple, W. J. BEAL (*Proc. Michigan Hort. Soc., 1897, pp. 174-183, figs. 4*).—A semipopular address describing apple scab, soft rot or blue mold, black rot, bitter rot or anthracnose, spot of Baldwin apples, leaf rust, powdery mildew, fly speck (*Leptothyrium pomi*), and twig blight.

A little-known mildew of the apple, A. J. GROUT (*Bul. Torrey Bot. Club, 26 (1899), No. 7, pp. 373-375, pl. 1*).—Notes are given on *Sphærotheca mali*. This mildew is thought to occur abundantly, but as the perithecia are borne upon the young shoots and do not mature until late in the autumn it is usually overlooked.

Canker on apple trees (*Jour. Bd. Agr. [London], 6 (1899), No. 1, pp. 66-69*).—Popularly describes diseases due to *Nectria ditissima* and *Bacillus amylovorus*, both of which are said to be commonly confused in England under the name of canker.

Can leaf curl of the peach be controlled? A. D. SELBY (*Proc. Columbus Hort. Soc., 13 (1898), pp. 84-88, pls. 2*).—Notes are given of experiments on the control of leaf curl (*Exoascus deformans*) of the peach. The author states that it can be controlled and a fair crop of peaches saved by the proper use of Bordeaux mixture.

Report on black rot in 1898, A. PRUNET (*Prog. Agr. et Vit. (Éd. L'Est), 30 (1899), Nos. 28, pp. 45-50; 29, pp. 75-80*).—This is essentially the same article as that given in *Bul. [Min. Agr. France] 18 (1899), No. 2, pp. 265-286*.

Parasites of the grape, F. NOACK (*Bol. Inst. Agr. São Paulo, 10 (1899), No. 2, pp. 91-114, pls. 2*).—Notes are given descriptive of mildew, anthracnose, powdery mildew, bitter rot due to *Melanconium fulgineum*, a root rot, and sooty mold or "fumagine" due to *Apiosporium brasiliense*, n. sp. The drying of the foliage by the wind is also mentioned.

Cryptogamic parasites of the grape, J. DE CAMPOS NOVAES (*Bol. Inst. Agr. São Paulo, 10 (1899), No. 2, pp. 51-90*).—Notes are given on the attacks of *Plasmopara vitis*, *Cercospora vitis*, *Oidium tuckeri*, *Glæosporium ampelophagum*, black rot, Botrytis, bitter rot, and *Saccharomyces ellipsoideus* on ripe grapes.

Some enemies of the vine (*Rev. Agr. Cien. Apl., Paraguay, 1 (1898), No. 6-7, pp. 289-299*).—Notes are given on *Margarodes vitium* and grape anthracnose, together with directions for their prevention.

A new micromycete of the grape, L. MONTEMARTINI (*Atti Inst. Bot. Univ. Pavia, 2. ser., 5 (1899), pp. 69-73, pl. 1*).—The author describes, under the name *Aureobasidium vitis album*, a new variety of micromycete which attacks the petioles and leaf blades of the grape, causing the latter to dry up and roll in. The fungus is characterized as follows: Pustules at length confluent, white; basidia hyaline, 6 to 7 μ broad and 13 to 22 μ long; spores cylindrical, 6 to 8 μ long and 1.5 to 2 μ broad.

A new disease of coffee, M. S. BERTONI (*Rev. Agr. Cien. Apl., Paraguay, 1 (1898), No. 1-5, pp. 211-223, figs. 5*).—A review is given of a number of the fungus and other diseases of the coffee plant and a new one described. This disease, which attacks the roots of the plant, is said to be quite destructive. It is due to *Rhizoctonia subepigea*, n. sp., and the parasite is described at length. Humidity of soil favors the disease. When severely attacked the author advises rooting out and destroying the diseased plants as the only preventive.

The strawberry-leaf blight, P. PASSY (*Rev. Hort., 71 (1899), No. 12, pp. 282-284, figs. 6*).—Notes are given on *Sphærella fragariæ*, with suggestions for prevention.

A method of avoiding lettuce rot, H. GARMAN (*Kentucky Sta. Bul. 81, pp. 1-4, pls. 2*).—The disease of lettuce known as rot, which is particularly severe on this crop when grown under glass, may be checked or entirely avoided, according to the author, by preventing the portions of plants above ground from becoming wet. This may be done by subirrigation or any other way so that the moisture be kept off the leaves. In order to keep the tips of the leaves from coming in contact with the wet soil, the author has found that a mulch of excelsior is very beneficial.

The aster disease, A. F. WOODS (*Gardening, 7 (1899), No. 162, p. 277*).—Notes are given of a disease of Chinese asters which is thought to be undoubtedly due to a species of Fusarium. Diseased plants should be destroyed whenever found and the soil surrounding the roots be thrown out. Asters should not be planted in soil where the disease is known to have previously existed.

A new disease of Azalea indica, P. VOGLINO (*Malpighia, 13 (1899), pp. 73-86, pls. 2*).

Diseased Hemerocallis leaves, W. G. SMITH (*Gard. Chron., 3. ser., 25 (1899), No. 652, p. 415*).—Notes the occurrence of a species of Asteroma on leaves of Hemerocallis.

A new violet disease, A. N. BERLESE (*Riv. Patol. Veg., 7 (1898), No. 5-8, pp. 167-172, pl. 1*).—Under the name *Cladochytrium violæ* the author describes a new species of fungus which is said to attack the roots of *Viola tricolor*, destroying the plant. As each dead plant is a center of infection, all such should be dug out and destroyed. If the attack becomes especially severe, violet growing may have to be abandoned for a time. Further investigations on this disease are in progress.

A violet disease (*Jour. Soc. Nat. Hort. France, 3. ser., 31 (1899), pp. 422, 423*).—The ocurrence of a severe outbreak of a disease of violets, due to *Phyllosticta violæ*, is mentioned. So severe was the attack that all leaves were destroyed in 15 days. Experiments were made which seemed to indicate that the disease could be controlled by copper fungicides.

Bacteriosis of the walnut (*Pacific Rural Press, 57 (1899), No. 25, p. 387*).—A note is given of the very destructive effect of this disease on the walnut crop. The disease may be recognized by black sunken areas in the outer hull of the fruit. All diseased material should be destroyed, the trees carefully pruned, and sprayed with Bordeaux mixture. Winter applications to young trees are thought advisable. By this method N. B. Pierce, a special agent of the U. S. Department of Agriculture, has demonstrated that more than half the loss may be saved.

A new mildew on Caragana arborescens, P. MAGNUS (*Ber. Deut. Bot. Gesell., 17 (1899), No. 4, pp. 145-151, pl. 1*).—*Microsphæra caraganæ* is figured and described.

Notes on Peridermium plowrighti, C. B. PLOWRIGHT (*Gard. Chron., 3. ser., 25 (1899), No. 652, p. 415*).—Attention is called to specimens of *Peridermium plowrighti* produced by artificial inoculations. In one case teleutospores of *Coleosporium tussilaginis* were placed upon *Pinus sylvestris* in October, and in April the Peridermium was abundant. In another series of experiments young plants of *Tussilago farfara* infected with Peridermium æcidiospores in April produced uredospores in May.

A fungus disease of Douglas fir, G. LEVEN (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, pp. 319, 320*).—Notes the occurrence of *Phoma pithya* on the Douglas fir in Scotland, where this tree was thought to be free from disease. Fully 10 per cent of the plantings for 3 years are reported as having been destroyed by the disease.

Pathological conditions of plants due to animals, DE STEFANI (*Agr. Calabro Siculo, 23 (1898), Nos. 15, 19, 21-23; abs. in Bot. Centbl., 79 (1899), No. 2, pp. 68, 69*).—Describes a number of galls, swellings, etc., due to various insects.

Nematodes of coffee roots, A. ZIMMERMANN (*Meded. S'Lands Plantentuin, 1898, No. 27, pp. 64, figs. 17; abs. in Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 11, pp. 415-419*).

A study of the alterations in the roots of the grape due to phylloxera, A. MILLARDET (*Extr. Actes Soc. Linn. Bordeaux, 53 (1898), pp. 29, pls. 5*).—The author recognizes two forms of injury to all grape roots except those of *Vitis rotundifolia*, viz, nodosities and tubercles. The former are produced at the extremities of very young roots and root hairs, while the tubercles may be formed on any portion of the root where longitudinal growth has ceased. The effect of each on the structure of the root is shown and the ultimate injury discussed.

Investigations on the cause of "beet sickness" with special reference to the carbon bisulphid treatment, A. KOCH (*Untersuchungen über die Ursachen der Rebenmudigkeit mit besonderer Berücksichtigung der Schwefelkohlenstoffbehandlung. Arb. Deut. Landw. Gesell., 1899, No. 40, pp. 44, pls. 5*).

Spraying will save the pickle crop, F. H. HALL (*New York State Sta. Bul. 156, popular ed., pp. 8, pls. 2*).—This is a popular edition of Bulletin 156 of the station (see p. 257).

Suggestions as to spraying, J. A. TILLINGHAST and G. E. ADAMS (*Rhode Island Sta. Bul. 52, pp. 48*).—The authors have brought together in convenient form the information necessary for the practical use of fungicides and insecticides for preventing attacks of the more common insects and plant diseases infesting orchard, garden, and other crops. Formulas for the preparation of the fungicides and insecticides recommended for use are given, and descriptions of the different forms of apparatus complete the bulletin.

The spraying of plants, W. M. MUNSON (*Maine Sta. Bul. 52, pp. 8*).—Gives a brief account of the reasons for spraying, together with directions for preparing Bordeaux mixture, potassium sulphid, Paris green, kerosene, and tobacco, and advice concerning the choice of pump, hose, and nozzle.

Spraying of fruit trees (*Jour. Bd. Agr. [London], 6 (1899), No. 1, pp. 1-5*).—Popular notes are given showing the advantages of spraying for the prevention of fungi and insects, and formulas for a number of fungicides and insecticides.

A copper fungicide designed especially to combat black rot, J. PERRAUD (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 23, pp. 978-980*).—A fungicide composed of copper sulphate, sodium carbonate, and resin is described. The formula for preparation is given and its efficiency and adhesiveness compared with alkaline Bordeaux mixture, and a mixture of copper sulphate and soap. It is claimed that the resin mixture as recommended is much more adhesive and that it carries a larger proportion of soluble copper than either of the other fungicides. The total copper content is also larger.

Influence of Bordeaux mixture on fruit development, E. PYNAERT (*Bul. Arbor. et Flor., 1899, pp. 81-83*).

The addition of common salt to Bordeaux mixture, L. DEGRULLY (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 24, pp. 710-712*).—In a previous number of this journal the author recommended the addition of a small quantity of common salt to Bordeaux mixture when employed for the prevention of black rot of grapes. This recommendation was based upon a series of observations in which the saline solutions seemed to have given the best results. In the present note the experience of a correspondent is given from which it is advised to add not more than 250 gm. per hectoliter of solution, dependent upon the amount of copper and lime used.

Apparatus for the application of powders to plants, P. FERROUILLAT (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 29, pp. 69-75, figs. 5*).—Describes a number of kinds of improved apparatus for applying powdered fungicides to plants and compares their efficiency.

ENTOMOLOGY.

Insect pests of domesticated animals, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 162-204, figs. 21*).—The author gives a general classification of the insects which are injurious to domestic animals, including the common Mallophaga, Pediculidæ, Diptera, and Pulicidæ. Of the Mallophaga, the writer gives descriptions and economic notes on the following genera: Trichodectes, Ornithobius, Lipeurus, Goniodes, Goniocotes, Docophorus, and *Menopon pallidum.* Of the Pediculidæ, notes and descriptions are given of Phthirius, Pediculus, and Hæmatopinus.

As remedies for both these orders, the author suggests the use of an ointment to be rubbed into the hair for the purpose of suffocating the pests, which is to be made of 1 part of sulphur to 4 parts of lard. Several washes are also suggested: (1) A decoction of 1 oz. of stavesacre seed to a quart of liquid, half water, half vinegar. (2) Benzin 1 part, soap 6 parts, water 15 to 20 parts. Kerosene emulsion and tobacco decoction are also recommended as washes.

Descriptions and economic notes are given of the human flea, dog flea, and bird flea. The more common methods of controlling these pests are described and recommended, and it is stated that a Southern Mexican plant, *Asclepias curassivica,* which the Indians make into brooms, is effective as a repellent for fleas.

Among the Diptera, the author chooses for consideration the ox gadfly, gnats, botflies, ox warble fly, horse botfly, sheep botfly, house fly, bluebottles, flesh flies, and *Melophagus ovinus.* Notes by way of description and on the life history and economic importance of these insects are of considerable length in each case, and the most approved remedies are recommended.

Injurious insects and fungi (*Jour. Bd. Agr.* [*London*], *6 (1899), No. 1, pp. 56-69, figs. 5*).—The larvæ of crane flies (Tipulidæ) are reported as having caused considerable injury to wheat, winter oats, winter barley, and strawberry plants. Notes are given on the habits and life history of these insects.

The Scotch fir trees (*Pinus silvestris*) were attacked by *Oscinis maura.* The insect is described in its various stages, and among other remedies it is suggested that infested shoots be cut off, especially on the young trees where it is more convenient, and that larger trees be sprayed with solutions of soft soap and quassia chips.

The raspberry moth (*Lampronia rubiella*) is said to have been exceedingly injurious to raspberries, the young larvæ living in the buds and preventing their development. The insect is described and figured in its various stages. The caterpillars pass the winter in the earth and rubbish near the raspberry cane. The author, therefore, recommends that the ground be thoroughly stirred up about the canes so as to destroy the pupæ in the spring, or that soot and lime or kainit be dug into the ground so as to destroy the insects. Tomtits are reported as feeding upon the insects to a considerable extent.

The raspberry weevil (*Otiorhynchus picipes*) in its larval condition causes much injury to hop stocks and the roots of various plants, such as strawberries, gooseberries, and vines. The beetles are also injurious to wall-fruit trees, the injury being done by gnawing the bark off the shoots. The author recommends as a preventive remedy frequent hoeing of the ground about the raspberry plants.

The fruit-tree beetle (*Scolytus rugulosus*) is reported as increasing in numbers. The author mentions the symptoms by which it may be recognized that a tree is infested with these insects. It is recommended that badly infested trees be cut down and burned during the winter.

Destructive insects of North Dakota, C. B. WALDRON (*North Dakota Sta. Bul. 31, pp. 293–301*).—The author gives brief popular notes on the grain aphis, the wheat-stem maggot (*Meromyza americana*), and the Hessian fly (*Cecidomyia destructor*). He recommends the burning of the stubble or deep plowing of the land as a destruction of the flaxseeds of the Hessian fly. The frit-fly is mentioned as a near ally of the Hessian fly and as liable to be mistaken for it. The author describes the habits and appearances of the Rocky Mountain locusts, and recommends the farmer to plow deeply all lands which are suitable to serve as egg-laying ground for the locust. The young are not able to escape from the soil when the eggs hatch if they are plowed under to a depth of 5 in. Another remedy is suggested which has proved successful in many places and which consists in scattering straw over ground infested by the Rocky Mountain locust in the spring when the young are unable to fly. The young congregate under this straw in the evening and may be readily destroyed in that situation by burning. The method of plowing furrows along the side of the field, and spraying the edge of the field with Paris green, and of scattering poison bran in such situations are mentioned as effective remedies. The "hopperdozer" also is described, along with recommendations as to the best way of operating it.

The common red mite parasite and a tachina fly are mentioned among the enemies of the locust. Brief notes are given on a number of plant lice and scale lice.

Proceedings of the Entomological Society of Washington (*Proc. Ent. Soc. Washington, 4 (1899), No. 3, pp. 177–345*).—This number contains notes on a great variety of insects, myriapods, and arachnids, together with the descriptions of new species. A few papers of special interest to workers in economic entomology can be noted.

A dipterous parasite of Lachnosterna, L. O. Howard (pp. 198, 199).—Contains an account of the finding of two May beetles with dipterous eggs fastened upon them.

Some structural points in sawfly larvæ, H. G. Dyar (pp. 218–221).—The larvæ of 8 species of sawflies are described with special reference to their identification.

Classification of the old family Chalcididæ, W. H. Ashmead (pp. 242–249).—The paper contains an analytical table for the classification of the families and subfamilies belonging to this group.

An investigation of applied entomology in the Old World, C. L. Marlatt (pp. 265–291).—The author gives an account of a recent trip in the Old World and of entomological observations made en route. The means of combating injurious insects which are in common use in the Old World are discussed and an explanation is suggested for the fact that insect outbreaks are of less importance in the Old World than in the New. A number of European species of injurious insects are mentioned which are perhaps liable to be imported into this country in the future unless precautions are taken.

Descriptions of the larvæ of fifty North American Noctuidæ, H. G. Dyar (pp. 315–332).—Technical descriptions of species belonging to a number of genera, with an analytical table designed for use in identifying them.

Alfalfa, grasshoppers, bees—their relationship, S. J. HUNTER (*Contrib. Ent. Lab. Univ. Kansas, 1899, No. 65, pp. 152, figs. 59, pls. 12*).—The first part of this bulletin contains a general account of the grasshoppers which are injurious to crops in the State of Kansas. The species which are mentioned as being of especial economic importance are: *Melanoplus differentialis*, *M. atlanis*, *M. bivittatus*, *M. femur-rubrum*, *M. packardi*, *M. spretus*, *Dissosteira longipennis*, and *D. carolina*.

M. differentialis is chosen as the subject of a special study. A detailed account is given of the appearance of its different immature and mature stages, including the egg stage. Its habits of egg laying are recorded, the common food plants of the insect are listed, and an account is given of the natural enemies of this grasshopper. Among the vertebrate enemies are domestic fowls, blackbirds, meadow larks, red-headed woodpecker, catbird, red eyed virio, yellow-billed cuckoo, and the loggerhead shrike. Blacksnakes are also said occasionally to feed upon this insect. Its invertebrate enemies include the locust mite (*Trombidium locustarum*), predaceous beetles, and parasitic flies, among which are mentioned *Sarcophaga cimbicis* and *S. hunteri*. One of the Asilid flies (*Erax cinerascens*) was observed preying upon the young grasshoppers. The locust fungus (*Empusa grilli*) is recorded as being an efficient help in the control of these grasshoppers.

A detailed account is given of the internal and external anatomy of the species. The remedies which are usually recommended for grasshoppers are described and urged upon the farmers for use, including the hopperdozer, spraying with Paris green, and deep plowing of stubble fields, together with the disking of alfalfa fields in the early spring.

A bibliography of articles relating to *M. differentialis* is appended to this discussion.

The second part of the bulletin contains an account of the relationship of bees to alfalfa and various suggestions for the practical and economic rearing of bees. The experiments which were made for that purpose showed that the seed crop of alfalfa upon which bees gathered honey was 66⅔ per cent greater than that from crops of alfalfa which were not visited by the honeybee.

An account is given of the different varieties of bees, of the different forms of bees found in a single colony, and of the various products which are produced by bees. Analyses are tabulated of various kinds of honey made from different plants, and alfalfa honey is pronounced as the one which most nearly approached the standard of excellence.

The author describes the method of fertilization of alfalfa by the honeybee, and reports communications from a large number of correspondents concerning the benefits derived from the keeping of bees in connection with the raising of alfalfa. On pages 102–141 A. H. Duff gives practical directions for the rearing and the management of bees, with advice as to the kinds of hives to be preferred and as to the extraction of honey, the rearing of queens, and the winter care of bees. A brief account is given of the foul brood of bees and of the wax moth, with a suggestion of the usual remedies. A list of the principal honey and pollen producing plants of the State is appended to the bulletin.

The grain aphis; an army cutworm, E. V. WILCOX (*Montana Sta. Bul. 17, pp. 18, figs. 2*).—The grain aphis (*Siphonophora avenæ*) is reported as having caused considerable damage to grain crops in the State during the past year, the aphis being so abundant in some instances as to interfere with the successful operation of binders.

Some observations were made on the natural history of the grain aphis with results which may be stated as follows: "In the early spring the viviparous females which have wintered over on the roots of winter wheat come up on the leaves. Here, and later upon the wheat heads, an indefinite number of generations are passed until the wheat is cut. Then the aphis migrates to oats, clover, various grasses and volunteer oats and wheat, and finally to winter wheat upon which it preferably passes the winter." A cold rainy spring is mentioned as being unfavorable to the rapid multiplication of the aphis.

A number of natural enemies were noticed preying upon the aphis, among them being the ladybugs, syrphus flies, and aphis-lions. Ladybugs were observed to go down upon the roots of grain in the fall in search of the aphis, and to pass the winter in that situation along with the aphis.

Spraying with kerosene emulsion or tobacco water is mentioned as a possible remedy, and it is also recommended that the stubble should be burned soon after the harvesting of the crop; and attention is called to the advisability of rotation.

A species of cutworm (*Chorizagrotis agrestis*) was observed as occurring in unusually large numbers and adopting the army worm habit. It was seen feeding upon a large variety of food plants, including garden vegetables, fruit trees, and especially grain crops.

The remedy which was tried with best results was the running of irrigation ditches between the crop and the advancing army of worms and keeping a stream of water flowing through these ditches. The worms fall into the ditches and are drowned. Another remedy which was tried was the use of poison bait. Clover dipped in a strong solution of Paris green was used as the bait, and destroyed the cutworms very effectively. The natural enemies which were noticed preying upon the cutworms were species of ground beetles (Harpalus and Calosoma) as well as of the whirligig beetles (Gyrinus and Dyneutes). The blackbird, robin, crow, meadow lark, and domestic poultry were observed eating the cutworms.

The San José scale problem in Ohio in 1898, F. M. WEBSTER (*Ohio Sta. Bul. 103, pp. 185–199, figs. 4*).—Among the remedies to be used in controlling the San José scale the author considers 5. The first remedy, or burning, is to be adopted in case of badly infested trees, especially if these trees are young or of little value. The second remedy, or the use of whale-oil soap, in the experience of the writer is very effective. The whale-oil soap is said to injure the fruit buds of the peach if applied during the fall and winter, but when applied in the spring no decided injury was noticed, and the San José scale was thoroughly destroyed and at the same time the peach-leaf curl seemed to be checked. The whale-oil soap had no detrimental effects on fruit buds when applied in the proportion of 2 lbs. to 1 gal. of water, provided the application was made in the spring when the buds were just putting forth. The treatment by this method is said to have increased the fruit yield about 75 per cent and to have increased the growth of the trees and the amount of foliage to a considerable extent. Whale-oil soap does not destroy all of the San José scale, but the results from its use are very encouraging.

The third remedy, or kerosene, was experimented with to some extent, and the results were generally unfavorable. Kerosene, when sprayed on a dark day or in the evening, was almost uniformly harmful, injuring both the bark and the buds. All trees that were sprayed dropped their foliage prematurely. A maple tree, which was sprayed, died; 3 peach trees died from the effects of the spraying; and even apple trees were considerably injured, and one died.

The fourth remedy is applicable more especially to nursery stock, and is the method of fumigation with hydrocyanic-acid gas. This method is recommended for all nurserymen as being much more reliable than the personal examination of an entomologist.

In the line of the fifth form of treatment, or the utilization of natural enemies, the author attempted the importation of the Florida fungus enemy (*Sphærostilbe coccophila*) without much success. It is suggested that perhaps a careful examination of the conditions under which the San José scale lives in Japan would disclose some natural enemies of the scale which might profitably be imported to this country. The author believes that Japan is the home of the San José scale.

The fruit-tree bark-beetle, the common apple-tree and peach-tree borers, J. M. STEDMAN (*Missouri Sta. Bul. 11, pp. 19, figs. 7*).—The fruit tree bark-beetle (*Scolytus rugulosus*) is recorded as attacking vigorous trees as well as those which have become devitalized through other agencies. The ordinary food plants of the beetle are said to be the plum, cherry, apricot, nectarine, peach, pear, apple, and quince. Apple trees are so often weakened by the attacks of the woolly aphis that they are thus made much more susceptible to the attacks of the fruit-tree bark-beetle, and peach trees suffering from the work of the peach-tree borer are thus brought into condition to be ruined by the attacks of the bark beetle. The beetle is described and figured in its various stages. The beetles emerge the last of March in this State, and begin making their tunnels. About 80 eggs are laid by each female. The tunnels are almost entirely confined to the cambium layer. In Missouri the beetle has 3 or 4 broods during the season, each brood requiring about 5 weeks for its development. The most common parasite which preys upon this beetle is said to be *Chiropachys colon*. The best prevention from the attacks of the beetle is to keep the trees in a good, vigorous condition. Mechanical barriers are of little value in keeping off the insect. The author has used a wash made by dissolving 1 lb. of potash whale-oil soap in 2 gal. of water, which was applied about the middle of March and again about April 1 with good results. The best wash, however, in the author's experience, is made as follows: "Dissolve as much common washing soda as possible in 6 gal. of soft water, then dissolve 1 gal. of ordinary soft soap in the above and add 1 pt. of crude carbolic acid and mix thoroughly; 2 lbs. of lime is then slaked in 2 gal. of water and filtered so as to remove all dirt and small lumps; this is now added to the above and mixed, while to all is added ½ lb. of Paris green or ¼ lb. of white arsenic, and all thoroughly mixed together." This wash is to be applied to the trees by means of a spray pump as soon as the beetles emerge in the spring, and other applications may be made as required.

The second part of the bulletin contains descriptions and economic and biological notes upon the peach tree borer (*Sannina exitiosa*), the round-headed apple-tree borer (*Saperda candida*), and the flat-headed apple-tree borer (*Chrysobothris femorata*). As remedies for these borers, the author suggests digging out the grubs with a sharp knife, pouring hot water or kerosene into the burrows, and the use of thin wooden wrappers about the base of the trunks. Besides these mechan-

.ical measures certain washes are recommended, the best of which, in the author's experience, is made in the same way as the one recommended for use against the fruit-tree bark-beetle.

The forest tent caterpillar, C. M. WEED (*New Hampshire Sta. Bul. 64, pp. 75-98, figs. 14*).—The author reports an unusual amount of damage from this insect during the past year, not only to forest and shade trees, but also to fruit trees. A popular account is given of the appearance of the different stages of the insect and of its habits and life history. W. F. Fisk observed that if the young caterpillars were suddenly disturbed while feeding they fell to the ground without spinning threads. This suggested a remedy in the way of banding. Since a large proportion of the caterpillars during their younger stages fall to the ground at some time or other they can be prevented, by the use of tarred bands, from ascending the tree again. The insect is compared with the American tent caterpillar, and various differences in appearance and habit are mentioned which render more easy its identification. A list of food plants is given, which includes the plants previously published as being fed upon by this insect, and also a list of the food plants of the tent caterpillar as observed by Miss Soule in Vermont. The same observer reports a considerable list of plants in the leaves of which she found the cocoons of this insect.

The author reports that the sugar maple has been very seriously damaged by the forest tent caterpillar, and that the sugar makers have observed a different flavor in the sugar made from trees which had been defoliated the year before.

As enemies of the tent caterpillar are mentioned toads and, on the authority of Miss Soule robbins, orioles, chipping sparrows, catbirds, cuckoos, vireos, cedar birds, and nuthatches. The enemies just mentioned feed upon the caterpillars. Chickadees feed upon the cocoons, and a number of birds, including the English sparrow, feed upon the moths.

A disease which seemed to be bacterial in origin is said to have destroyed large numbers of the caterpillars. As artificial remedies the author suggests the gathering and destruction of the egg masses, swabbing the mass of young larvæ when collected together with cotton waste or other substance, spraying the trees with arsenate of lead, killing the older caterpillars when they collect upon the trunk before molting, banding the trees with raupenleim to prevent the caterpillars which have fallen off from climbing up, collecting the cocoons, and the use of lantern traps.

Combating the striped beetle on cucumbers, F. A. SIRRINE (*New York State Sta. Bul. 158, pp. 32, pls. 2*).—The observations published in this bulletin were made largely in the pickle-growing sections of Long Island. Among the food plants of the beetle are mentioned, besides the common ones, golden-rod, sunflowers, apples, chokeberries, and wild cranesbill.

The beetle issues from its winter quarters between the middle of April and the first of June. During the first few days after emerging from the ground both males and females feed actively. Egg laying begins about July 20, and extends over a period of about a month. Eggs are dropped upon the ground or upon the surface of the leaves, and usually roll from the leaves to the ground. The larvæ require for their complete development about a month, but some few seem to require nearly 2 months. The author suggests that the difference in the length of the larval period is dependent upon the food supply. The larvæ were found in the stems of cucumbers and squash, but most abundantly upon the rind of the muskmelon and of the squash and ripe cucumbers where these came in contact with the surface of the ground. The insect passes the winter in the adult stage. A description is given of the egg, larva, and pupa.

Among the parasites of this insect are recorded a tachinid fly (*Celatoria diabroticæ*) and an unidentified nematode worm.

The spraying of cucumber and melon vines with Paris green and water showed that very few beetles were killed by this method, and that the vines suffered too much damage to permit the method to be generally recommended. As trap crops the author recommends beans and squashes to be planted about the edge of the cucumber or melon patches. The beans and squashes may then be dusted with green arsenite preferably or Paris green. The use of Bordeaux mixture, in the proportion of 4 lbs. copper sulphate and 4 lbs. of lime to 44 gal. of water, as a spray upon cucumbers and melons, gives a very efficient repellent for the striped beetle. The Bordeaux mixture was found not to injure the plants to any extent. The cost of three applications did not exceed $2 per acre. Bordeaux mixture was found to be superior as a repellent to air-slaked lime or any of the bad-smelling mixtures which have been recommended for this purpose.

Wire plate covers have been used for the purpose of protecting the young squashes, but these are only serviceable for a few days while the squashes are first starting from the ground. The covers cost 2 cts. apiece or about $10 per acre for the first year.

The author's general conclusions concerning remedies may, perhaps, best be given in his own words:

> "I recommend the use of squashes as a lure and as a poisoned bait, combined with the use of Bordeaux mixture on the cucumber vines and in some cases also combined with the use of covers. I also recommend the planting of squashes or beans in September for the purpose of poisoning as many of the beetles as possible during the fall. Green arsenite and Paris green can be and frequently are used with water for poisoning the squashes and beans, but as the object of the latter is to kill as many of the beetles in as short a time as possible, it is better to use the arsenites dry for the simple reason that they can be applied stronger and not kill the vines as quickly as when used with water."

Inspection and care of nursery stock, W. E. BRITTON (*Connecticut State Sta. Bul. 129, pp. 10*).—The author calls the attention of nurserymen to the necessity of familiarizing themselves with the appearance of the San José scale, and of watching closely in order to avoid importing the scale from other nurseries to their own. Orchardists are urged to dip trees in a solution of whale-oil soap while still bunched at the time of their receipt, and to inspect their orchards carefully at not too great intervals so as to prevent the spread of San José scale.

Three common treatments for San José scale are named and described: Fumigating with hydrocyanic-acid gas, spraying with kerosene and water, and spraying or dipping the trees in a solution of whale-oil soap.

A brief account is added of the appearance of the San José scale and of its effects upon the trees which it infests.

Apiculture (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 365–374*).—Gives hints on the management of bees so as to get profitable returns, and a description of a swarm catcher.

Italian bees, C. DADANT (*Rev. Internat. Apicult., 21 (1899), No. 6, pp. 102, 103*).—The author enumerates the strong points of Italian bees.

Considerations upon the colonial bees, K. SAJO (*Prometheus, 10 (1899), Nos. 486, pp. 280–284; 487, pp. 289–293; 488, pp. 312–316; 489, pp. 321–324*).—In this article the author discusses the relationship of the different members of bee colonies with one another, with the addition of general notes upon the intelligence involved in their various biological activities.

A plea for comb honey, A. GALE (*Agr. Gaz. New South Wales, 10 (1899), No. 5, pp. 406–409, pl. 1*).—Directions as to the time for putting on supers in order to get the best comb honey.

Homemade comb foundation, A. GETAZ (*Amer. Bee Jour., 39 (1899), No. 26, p. 402, figs. 3*).—A description of the necessary apparatus and method of making the comb.

Dead brood, king birds, honeydew, A. J. COOK (*Amer. Bee Jour., 39 (1899), No. 29, pp. 550, 551*).—Dead brood is distinguished from foul brood. King birds were observed eating robber flies near the beehives, but not eating the bees. Popular notes are given on the origin of honeydew.

The effect of temperatures upon the eggs, larvæ, and pupæ of bees, N. KULAGIN (*Illus. Ztschr. Ent., 4 (1899), No. 13, pp. 193–195*).—Adult bees are less affected by cold than the eggs, larvæ, or pupæ.

Poisoning by honey (*Rev. Internat. Apicult., 21 (1899), No. 6, pp. 117, 118*).—Gives a brief historical account of the subject. *Azalea pontica*, *Andromeda japonica*, *Kalmia angustifolia*, *Rhododendron ferrugineum*, and *R. hirsutum* are referred to as plants from which bees may gather poisonous honey.

The color of flowers and its influence on bee life, A. GALE (*Rpt. Australian Assoc. Adv. Sci., 7 (1898), pp. 937–945*).—From observations made by the author, the conclusion is drawn that bees in Australia show a preference for white and yellow flowers.

Classification of the bees of the superfamily Apoidea, W. H. ASHMEAD (*Trans. Amer. Ent. Soc., 26 (1899), No. 1, pp. 49–100*).—The superfamily is divided into 11 families. Analytical tables are given for identifying these families and also for identifying the genera of each family.

Bee paralysis, O. O. POPPLETON (*Gleanings in Bee Culture, 27 (1899), No. 14, pp. 537, 538*).—A brief discussion of the means of transmission of this disease.

Sericulture and silk reeling from the cocoons by machinery (*U. S. Spec. Consular Rpts., 15 (1899), pt. 2, pp. 131-152, pls. 2, figs. 8*).—In answer to a request from the Department of State addressed to the consuls in France and Italy regarding machines for reeling silk from cocoons, reports were made which are published under the above title. Besides descriptions of the process of reeling and the machines used for that purpose in the countries mentioned, the consuls have reported also upon various features of the rearing, care, and life history of the silkworms in the countries where they made their investigations.

The larval stage of Hypoderma bovis, P. KOOREVAAR (*Ann. Mag. Nat. Hist., 4 (1899), No. 19, pp. 69–73; trans. from Tijdschr. Nederl. Dierk. Ver., 2. ser., 1898, pt. 5, pp. 29–34*).—*Hypoderma bovis* larvæ were found in the spinal canal of a calf. Experimentally placed beneath the skin of a dog, they were found later in the peritoneal cavity, in the fat around the kidneys, and in various other tissues.

A contribution to the biology and classification of the Muscidæ, E. GIRSCHNER (*Ent. Nachr., 25 (1899), No. 12, pp. 177–186, fig. 1*).—Gives systematic notes on a number of the genera of Muscidæ.

Changed conditions in the life of mosquitoes, K. SAJO (*Prometheus, 10 (1898), No. 477, pp. 138–141*).—The author observed that in a ditch where water was usually present during the breeding season for mosquitoes no larvæ could be found, although large numbers of them were found in a tub of water which stood in the garden. The author attributes the absence of mosquito larvæ in the ditch to the attacks of various predaceous water bugs and beetles.

Some insects injurious to stock and remedies therefor, G. W. HERRICK (*Mississippi Sta. Bul. 53, pp. 8*).—The bulletin contains brief biological notes and accounts of the most approved methods of prevention of the following insects: Horn fly (*Hæmatobia serrata*), southern buffalo gnat (*Simulium pecuarum*), horse botfly (*Gastrophilus equi*), screw-worm fly (*Compsomyia* (*Lucilia*) *macellaria*), sheep botfly or head magot (*Œstrus ovis*), ox botfly or warble fly (*Hypoderma bovis*).

Insects: Their structure and life, G. H. CARPENTER (*London: J. M. Dent & Co., 1899, pp. XI+404, figs. 184*).—This work is divided into 6 chapters with the following titles: The form of insects, the life history of insects, the classification of insects, the orders of insects, insects and their surroundings, and the pedigree of insects. At the end of the volume is found a bibliography of 11 pages.

A contribution to a knowledge of the faunistic entomology of Ohio, F. M. WEBSTER (*Ent. News, 10 (1899), No. 5, pp. 134–144*).—A short popular account of the manner of distribution in Ohio of a number of economic insects.

Some insects of the year, E. A. POPENOE (*Trans. Kansas State Hort. Soc., 23 (1898), pp. 40–46*).—Contains notes on the apple-leaf crumpler, the lesser apple-leaf folder, the fall webworm, the handmaid moth, two mulberry borers (*Dorcaschema wildii* and *D. alternatum*), the apple curculio, the northern lady bird, *Aspidiotus forbesii*, and the fruit bark beetle (*Scolytus rugulosus*).

Collection, preservation, and distribution of New York insects, E. P. FELT (*Bul. New York State Mus., 6 (1899), No. 26, pp. 31, figs. 29*).—This bulletin contains directions for making the apparatus which is necessary in collecting insects; an outline of special methods in collecting insects of different habits; a discussion of the technique of preserving, mounting, labeling, and preserving insects; and hints on the study of the distribution of insects and on life zones.

Entomological report for the years 1897, 1898, F. SINTENIS (*Sitzber. Naturf. Gesell. Dorpat, 12 (1898), No 1, pp. 74–89*).—Notes on the habits and biological relations of a large number of insects.

Insect attacks in 1898, R. S. MACDOUGALL (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 287–293*).—Notes are given on the habits, occurrence, and remedies to be adopted in case of attacks from the black currant gall mite (*Phytoptus ribis*), pear gnat midge (*Diplosis pyrivora*), the pine sawfly (*Lophyrus pini*), and the fox pine sawfly (*L. rufus*).

Insect and fungus diseases of fruit trees and their remedies, with notes on the treatment of some garden and vegetable pests, ALLEN, BLUNNO, FROGGATT, and GUTHRIE (*Dept. Agr. New South Wales, Misc. Pub. No. 238, pp. 78, pls. 20, figs. 49*).—This publication contains economic notes on the habits and life history of injurious insects and parasitic fungi which attack common fruit trees and garden vegetables. In connection with all the injurious insects and parasitic fungi which are discussed the appropriate remedies are suggested. The fruit trees and vegetables, the enemies of which are treated, are as follows: Apple, pear, quince, almond, peach, apricot, cherry, plum, fig, citrus trees, grapevine, potato, tomato, cabbage, beans, pumpkin, melons, squashes, cucumbers, and strawberry.

Shade-tree pests in New York State, E. P. Felt (*Bul. New York State Mus., 6 (1899), No. 27, pp. 39–60, pls. 5, figs. 8*).—In this paper the author discusses the economic relationship of the following insects: White-marked tussock moth, elm-leaf beetle, elm-bark louse, tent caterpillars, fall webworm, maple-tree borer, elm-tree borer, pigeon tremex, leopard moth, and the cottony maple scale insect. In connection with the discussion of each insect the author mentions briefly those remedies which are especially effective against the species in question. At the end of the bulletin are found general remarks on the subject of spraying, rules for spraying, the most appropriate apparatus, and directions for making and applying Paris green, London purple, kerosene emulsion, and whale-oil soap.

Enemies of the tea bush and other pests. Report of the honorary entomologist of Ceylon (*Planting Opinion, 4 (1899), No. 18, pp. 339, 340*).—Gives economic notes on *Orthezia insignis, Helopeltis antonii, Xyleborus fornicatus, Orygia postica*, and speaks of the introduction of beneficial ladybirds.

How to handle the striped beetle on cucumbers, F. H. Hall and F. A. Sirrine (*New York State Sta. Bul. 158, popular ed., pp. 6, fig. 1*).—This is a popular summary of Bulletin 158 of the station (see p. 269).

Sweet-potato beetles, E. D. Sanderson (*Country Gent., 64 (1899), No. 2422, p. 511, figs. 3*).—Notes on tortoise beetles and flea-beetles, with suggestions of remedies.

The enemies of the potato, E. Roze (*Histoire de la pomme de terre. Paris: J. Rothschild, 1898, pp. 257–263*).—In this section of his work the author gives a brief discussion of *Melolontha vulgaris, Doryphora decimlineata, Bryotropha solanella, Julus guttulatus*, and *Tylenchus devastatrix*.

Combating enemies of potatoes, M. V. Slingerland (*Amer. Agr., (mid. ed.), 63 (1899), No. 20, p. 612*).—Popular notes on the Colorado potato beetle and potato flea-beetle, with a discussion of remedies.

The boll weevil pest—how it may be dealt with and eradicated, F. W. Mally (*Cotton Ginners' Jour., 3 (1899), No. 5, p. 9*).

Fighting the boll weevil, F. W. Malley (*Texas Farm and Ranch, 18 (1899), No. 24, pp. 3, 4*).—Calls attention to the fact that cotton fields are infested in limited areas and urges the immediate destruction of the weevil in these areas.

Luring the grapevine borer, K. Sajo (*Prometheus, 9 (1898), No. 467, pp. 801–801, fig. 1*).—The insect in question (*Rhychites betuleti*) has a habit of making nests by rolling leaves together. The insect has a decided preference for pear leaves. The author found that a few pear trees located in the vineyard, upon which the leaves were unfolded considerably earlier than on the grapevines, served as trap trees in enticing the beetles to make their nests of the pear-tree leaves. It was then an easy matter to jar the beetles from the pear trees into canvas traps and thus prevent their injury to the grapevines.

A pear-tree destroyer (Agrilus sinuatus), M. P. Passy (*Garden, 56 (1899), No. 1443, pp. 35, 36*).—Contains a description of the insect, a brief account of its life history, and suggestions of remedies, among them being the smearing of the trunk and large branches with tar or lime and cutting the larvæ from the branches.

The phylloxera question, A. J. Perkins (*Jour. Agr. and Ind., South Australia, 2 (1899), No. 11, pp. 889–893*).—Discusses the dangers from infestation with phylloxera, quarantine regulations, and the planting of American vines.

Notes on fruit-maggot flies with descriptions and new species, W. W. Froggatt (*Agr. Gaz. New South Wales, 10 (1899), No. 6, pp. 497–504, pls. 3*).—The author gives a technical description with notes on the life history of the following fruit-maggot flies: *Tephrites tryoni, T. psidii, Halterophora capitata, Trypeta musæ*, and *T. pomonella*. *T. psidii* is described as a new species and was reared from guavas. *T. musæ* is also a new species and was reared from decaying bananas. The author recommends the same line of treatment for all of these fruit-maggot flies. Various experiments tried by different fruit growers in spraying with a solution which was distasteful to the insects were without success. A trap which has proved rather successful in catching the adult flies consists of a candle supported in a tin surrounded by a few inches of kerosene and water and placed under the infested trees.

All the late peaches and persimmons should be gathered and boiled in order to destroy the late brood of maggots. Thorough cultivation of the ground in winter will have the effect of exposing the chrysalids to fatal climatic changes and other enemies.

Coccidæ which menace the fruit culture of Europe, A. Berlese and G. Leonardi (*Riv. Patol. Veg., 7 (1898), Nos. 5-8, pp. 252-260, figs. 4*).—A discussion of the distribution of the San José scale, of the possibility of its introduction into Italy, and of scales which might be confused with it.

The more recent literature on the San José scale, K. Sajo (*Prometheus, 10 (1898), No. 480, pp. 186-188*).—The author discusses the problem of kerosene spraying for San José scale as illustrated by the results of recent experiments in America.

Lessons from the year's work with the San José scale, S. A. Forbes (*Trans. Illinois State Hort. Soc., 1898, pp. 50-62*).—This article contains a general account of the extent of distribution of the insect in the State and of the means which have been adopted for holding it in check or exterminating it. Insecticide operations were carried on with whale-oil soap at 21 out of 25 places of infestation. The operations were begun at the time the leaves fell in November and were continued until the leaves began to unfold in the spring. On an average 98 per cent of the scales were destroyed. The author believes that if it should prove to be impossible to eradicate the San José scale, its injuries can be reduced to comparative insignificance by a single insecticide treatment applied every other year.

Some scales of the orchard, P. J. Parrott (*Trans. Kansas State Hort. Soc., 23 (1898), pp. 106-109, figs. 2*).—Notes on *Mytilaspis pomorum*, *Chionaspis furfurus*, *Aspidiotus uvæ*, *A. fernaldi*, *A. ancylus*, *A. ostreæformis*, and *A. forbesii*.

A dangerous European scale insect not hitherto reported but already well established in this country, C. L. Marlatt (*Science, n. ser., 10 (1899), No. 236, pp. 18-20*).—*Aspidiotus ostreæformis* is a well known pest on various fruit trees of Europe. It is widely distributed in Europe, specimens having been received from Germany, England, and Italy. There is considerable evidence that the insect has existed in this country for about 8 or 10 years in Ohio and New York. The insect has repeatedly been identified wrongly, being referred to 2 or 3 other species of the same genus. The earliest material from this country which is definitely to be referred to the species in question bears the date of January 12, 1895, and came from the Geneva Station of New York. It has been reported from this country as occurring on plum, cherry, apple, pear, prune, and currant. The localities from which specimens have been received are Ohio, New York, British Columbia, Ontario, and Iowa. It was found at numerous points in New York and Ohio.

The author believes the species to be the same as the species which have gone under the names of *A. spurcatus* and *A. zonatus*. In Europe the species has been found on *Prunus domestica*, *Populus tremuloides*, and *Platanus orientalis* beside on the common fruit trees.

My experience in spraying in Illinois orchards for scale insects, R. W. Braucher (*Trans. Illinois State Hort. Soc., 1898, pp. 24-30*).—The author was employed under the direction of S. A. Forbes to superintend the spraying of various orchards in the State for the San José scale by means of whale-oil soap. In one test 1,444 trees were sprayed. It required 5½ days to do the work and 682 lbs. of soap. Of these 1,335 were afterward inspected and living scales were found on 107 of them, or on slightly more than 8 per cent.

Some common sources of error in recent work on Coccidæ, C. L. Marlatt (*Science, n. ser., 9 (1899), No. 233, pp. 835-837*).—The author criticises the establishing of species upon mere differences of habit and exterior appearance without reference to their characters or actual experimental demonstration of specific difference.

Seed and soil treatment and spray calendar, W. J. Green et al. (*Ohio Sta. Bul. 102, folio*).

Spraying calendar, L. R. Taft (*Michigan Sta. Spec. Bul. 12, folio*).—This gives the formulas for the more common insecticides, with suggestions as to the time for applying these insecticides for the destruction of common insects and fungus diseases.

Spraying calendar for 1898, L. R. Taft (*Michigan State Hort. Soc. Rpt. 1897, pp. 324–339*).—A reprint of Michigan Station Bulletin 155 (E. S. R., 10, p. 470).

Nurseries and orchard inspection, U. P. Hedrick (*Michigan State Hort. Soc. Rpt. 1897, pp. 147–150*).—An outline of the regulations which were adopted for the prevention of the introduction and spread of the San José scale and other insects in the State of Michigan.

The need of nursery inspection laws, O. E. Fifield (*Michigan State Hort. Soc. Rpt. 1897, pp. 150–165*).—The author discusses the status of nursery inspection laws in Michigan and other States. The article contains a copy of the bill which was adopted by the American Association of Nurserymen to provide rules and regulations for the inspection of trees.

A law for the extermination of locusts, F. Insfran and C. R. Saguier (*Riv. Agr. Cien. Apl., Paraguay, 1 (1898), No. 8, pp. 348–351*).—A statement of the law adopted for the extermination of locusts in Paraguay.

Horticultural legislation, R. D. Graham (*Michigan State Hort. Soc. Rpt. 1897, pp. 30–38*).—A statement of the State law concerning the inspection of nurseries and orchards and a discussion of the necessity for this law and the good results which are to be hoped for from it.

On a fungus disease of the green scale, A. Zimmermann (*Teysmannia, 9 (1898), No. 5, pp. 240–243*).—*Lecanium viridi* is reported as being attacked and destroyed by *Cephalosporium lecanii.*

A fungus disease of Lecanium viride, A. Zimmermann (*Teysmannia, 9 (1898), No. 5, pp. 240–243; abs. in Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 9, p. 323*).—The author describes a fungus that has proved very destructive to the green scale (*Lecanium viride*).

On the distribution in Italy of Entomophthora planchoniana and its importance in horticulture and agriculture, O. Mattirole (*Staz. Sper. Agr. Ital., 31 (1898), No. 3, pp. 315–326*).—The spread of this fungus disease of insects in Italy is described, and an account is given of its effectiveness in destroying insects.

FOODS—ANIMAL PRODUCTION.

The nutritive value of asparagin, B. K. Brutskus (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesov, 11 (1898), No. 11, pp. 145–228*).—The author reviews exhaustively the literature on the nutritive value of asparagin for herbivora, birds, carnivora, and omnivora, including man. In addition, 2 experiments with rabbits are reported.

The general plan was to feed a ration containing no protein in 1 period and to compare this with a similar ration in which part of the nonnitrogenous material was replaced by asparagin.

The first experiment was divided into 2 periods of 22 and 26 days, respectively. In the first period the daily ration consisted of 640 gm. of rice starch, 120 gm. of birch sawdust, 75 gm. of sugar, 30 gm. oil, 20 gm. salt, 20 gm. hay ashes, 10 gm. barley ashes, 34.4 gm. water, and 150 gm. asparagin. In the second period no asparagin was fed, and the amount of starch was increased to 725 gm., the other ingredients remaining the same. In the first period the daily income of nitrogen was 0.815 gm., 0.778 gm. being supplied by asparagin. The outgo in the urine was 0.870 gm. and in the feces 0.068 gm.; that is, there was a daily loss of 0.123 gm. nitrogen. The average amount of sulphur excreted in the urine daily was 0.123 gm. During this period the rabbit lost 195 gm. in weight, or 13.8 per cent of its total weight. Between the first and second period there was an interval of about 4 weeks, during which time the rabbit was fed barley and potatoes. At the beginning of the second period it had regained its original weight. During the second period the average daily income of nitrogen was 0.041 gm. and the outgo in the urine 0.195 and in the feces 0.042 gm.; that is, there was a daily loss of 0.196 gm. nitrogen. The urine contained on an average 0.0161 gm. sulphur daily. During the second period the rabbit lost 250 gm., or 16.7 per cent of its total weight.

In the first period of the second test, which covered 18 days, the rabbit was fed the ration mentioned above which contained no asparagin. The daily food furnished 0.031 gm. nitrogen, the outgo in the urine was 0.328 gm. and in the feces 0.076 gm.; that is, there was a daily loss of 0.373 gm. nitrogen. The average excretion of sulphur in the urine was 0.0215 gm. The rabbit lost 20 per cent of its weight during this period, or 16.1 gm. daily. The second period (in which asparagin was fed) was not completed.

The author concludes that his results confirm those of Bahlmann, showing that the value of asparagin in a diet containing no protein is much higher than that of an isodynamic quantity of starch, and, further, that although asparagin can not replace albumin in a diet, it may prevent the cleavage of about one-fourth of the quantity of protein which would be broken down in the body when no nitrogen was consumed.—P. FIREMAN.

The influence of removal of the large intestine and increasing quantities of fat in the diet on general metabolism in dogs, V. HARLEY (*Proc. Roy. Soc. [London], 64 (1898), No. 407, pp. 77-88*).—A number of experiments are reported with dogs on the effect of removing the large intestine and increasing the amount of fat in the diet. Analyses are reported of the food, urine, and feces. The author summarizes his results as follows: The large intestine has no effect on the absorption of carbohydrates in the diet, but its absence causes a marked decrease in the absorption of proteids, the amount varying from 93 to 84 per cent. Fat is absorbed in practically normal amounts and the breaking up of fat also continues:

> "The water of the feces is increased in total quantity, although the percentage of water increases with an increased fat diet, instead of decreasing as in normal dogs. The total quantity of feces is also increased on the same diet as that in the normal dogs, and the cholesterin is decreased.
>
> "The formation of urobilin in the feces is diminished in the absence of the large intestine; the sulphates vary the same as the normal as regards those combined with alkalis, while those combined with the aromatic substances are markedly diminished, showing that intestinal putrefaction is decreased."

Digestion experiments, F. E. EMERY (*North Carolina Sta. Bul. 160, pp. 187-204*).—In continuation of previous work (E. S. R., 10, p. 667) experiments with sheep are reported on the digestibility of crab-grass hay alone and in combination with cowpea meal, corn bran and rice bran, and first and second growths of green rape. An unsuccessful attempt was also made to feed peanut meal, a coarsely ground by-product.

The usual experimental methods were followed and the same sheep were used as in previous experiments at the station. The tests with rape were made with 4 sheep, the others with 2. The composition of the different feeding stuffs used is reported. The results of the tests are summarized in the following table:

Coefficients of digestibility of various feeding stuffs by sheep.

	Dry matter.	In dry matter.					
		Protein.	Albuminoids (albuminoid nitrogen × 6.25).	Ether extract.	Nitrogen-free extract	Crude fiber.	Ash.
	Per ct.	*Per ct.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per ct.*	*Per ct*
Crab-grass hay	54.9	32.0	28.8	35.6	52.8	64.40	51.8
Crab grass hay and cow pea meal 1:1	70.9	70.5	69.8	54.7	76.5	64.30	45.9
Calculated digestibility of cowpea meal alone	86.6	82.0	82.0	73.9	93.1	64.00	33.5
Crab-grass hay and corn bran	66.1	48.7	48.3	69.1	74.5	59.70	16.5
Calculated digestibility of corn bran alone	70.5	53.4	53.7	72.3	79.6	53.10	....
Green rape	84.8	88.8	86.4	48.5	92.0	87.00	62.7
Green dwarf Essex rape	88.5	90.2	86.6	54.2	93.8	90.00	76.5
Crab grass hay and rice bran	59.7	52.4	52.6	82.3	66.0	56.00	26.3
Calculated digestibility of rice bran alone	64.7	62.9	64.7	88.6	78.2	29.20	2.4

Digestion experiments with steers, G. L. HOLTER and J. FIELDS (*Oklahoma Sta. Bul. 37, pp. 20*).—The digestion experiments summarized in a previous publication (E. S. R., 10, p. 983) are reported in full. The bulletin also contains the analyses of Kafir-corn fodder (whole plant and different parts), corn fodder (whole plant and different parts), alfalfa, sorghum, black rice corn, milo maize, teosinte, and chufas. Fertilizer constituents were also determined in Kafir fodder from the stack, ashes from stable manure, the soil from roots of castor bean plants, and the soil between rows of castor beans.

Skim milk as a food for young growing chickens, W. B. ANDERSON (*Indiana Sta. Bul. 76, pp. 21-28*).—This test, which is regarded as a duplicate of one previously reported (E. S. R., 10, p. 677), was made with 2 lots, each composed of 10 Plymouth Rock and Houdan chickens, to study the value of skim milk as part of a ration. The test began July 16 and covered 42 days. Both lots were fed a grain ration consisting of equal parts of corn meal, shorts, and ground oats, and in addition, rape, cabbage, and lettuce. Lot 2 was also fed skim milk *ad libitum*. All the chickens were fed three times a day, and were given the same care and treatment. At the beginning of the test each lot weighed 259 oz. During the test lot 1 consumed 732 oz. of grain, 4 oz. of rape, and 43.5 oz. of cabbage; lot 2, 912 oz. of grain, 752 oz. of skim milk, and the same amount of rape and cabbage as lot 1. Lot 1 gained 7¾ lbs. and lot 2 14⅜ lbs.

Basing the financial statement on oats at 80 cts., corn meal at 80 cts., shorts at 60 cts., and skim milk at 20 cts. per 100 lbs., the cost of food per pound of gain was found to be 4½ cts. for lot 1 and 3½ for lot 2.

The test is compared with that previously reported. From the present trial the following conclusions are drawn:

"The results of this trial are very similar to those of the previous one, with the single exception that skim milk did not decrease in value as a food for young chickens, as the chickens became older and cooler weather prevailed.

"Green food given to young fowls confined in pens will not keep them in perfect health when getting a fairly balanced ration. This indicates that the young chickens are unable to digest and assimilate all the nutrients from the ground food.

"Skim milk is a valuable food for chickens. Whether fed with a balanced ration or with green food, its influence is very great in securing increased weight and in maintaining the general health of the fowls.

"The addition of skim milk to the ration increases the profits by decreasing the cost of the ration and by securing greater returns from the other foods given, especially when the chickens are young and confined in pens or small yards."

The manufacture of preserved foods and confectionery, A. HAUSNER (*Die Fabrication der Conserven und Canditen. Vienna: A. Hartleben, 1899, 3. ed., ill.; rev. in Oesterr. Chem. Ztg., 2 (1899), No. 7, p. 183*).

Book of diet, P. E. MUSKETT (*Melbourne, Sydney, Brisbane, Adelaide, London: George Robertson & Co., 1898, pp. 301*).—The author discusses the principal foods and their value as nutrients with especial reference to Australian conditions. A number of receipts for preparing food are also given.

The adulteration of flour, W. A. WITHERS and G. S. FRAPS (*North Carolina Sta. Bul. 156, pp. 59-67*).—The adulteration of flour is discussed and the examination of 50 samples purchased in North Carolina reported. Sixteen per cent were found adulterated with corn flour or corn meal, most of the adulterated samples being cheap flour. No clay, soapstone, or similar substance was detected in any of the samples examined. One sample contained alum.

Mineraline, W. A. WITHERS and H. W. PRIMROSE (*North Carolina Sta. Bul. 157, pp. 71-76*).—The attempt of a North Carolina company to introduce mineraline as an adulterant for wheat flour is noted. Judging from analyses this substance consists of ground talc.

Brief notes are also given of the examination of coffee, bread, bran, and cottonseed meal.

Baking powders on sale in North Carolina, W. A. WITHERS and J. A. BIZZELL (*North Carolina Sta. Bul. 155, pp. 51-56*).—In addition to describing baking powders and their principal ingredients, the authors report the analyses of 25 samples of baking powder purchased in North Carolina. Eighty-one per cent of the samples analyzed contained alum and 56 per cent were straight alum powders. Two samples were apparently so old as to be useless for the purpose for which intended.

Sugar as food, MARY H. ABEL (*U. S. Dept. Agr., Farmers' Bul. 93, pp. 27*).—The extent and use of sugar, the sources of cane sugar, the food value of sugar, and the use of sugar in the dietaries of adults and children are treated of. Among the general conclusions drawn are the following:

"One may say in general that the wholesomeness of sweetened foods and their utilization by the system is largely a question of quantity and concentration.

"From a gastronomic point of view it would seem also that in the American cusine sugar is used with too many kinds of food, with a consequent loss in variety and piquancy of flavor in the different dishes. The nutty flavor of grains and the natural taste of mild fruits is concealed by the addition of large quantities of sugar.

"In the diet of the under-nourished larger amounts of sugar would doubtless help to full nutrition. This point is often urged by European hygienists. In the food of the well-to-do it is often the case, however, that starch is not diminished in proportion as sugar is added. That sugar on account of its agreeable flavor is a temptation to take more carbohydrate food than the system needs can not be denied. The vigor of digestion in each particular case would seem to suggest the limit. A lump of sugar represents about as much nutriment as an ounce of potato, but while the potato will be eaten only because hunger prompts, the sugar, because of its taste, may be taken when the appetite has been fully satisfied.

"Sugar is a useful and valuable food. It must, however, be remembered that it is a concentrated food and therefore should be eaten in moderate quantities. Further, like other concentrated foods, sugar seems best fitted for assimilation by the body when supplied with other materials which dilute it or give it the necessary bulk.

"Persons of active habit and good digestion will add sugar to their food almost at pleasure without inconvenience, while those of sedentary life, of delicate digestion, or of a tendency to corpulency would do better to use sugar very moderately. It is generally assumed that 4 or 5 oz. of sugar per day is as much as it is well for the average adult to eat under ordinary conditions."

Preserving eggs, E. F. LADD (*North Dakota Sta. Bul. 35, pp. 330–332*).—Water glass was found to be a satisfactory preservative for eggs. Directions are given for the preparation of a solution for this purpose.

A study of the causes of the red color which is produced in meat by boiling, together with experiments on the effect of sulphurous acid on the color of meat, K. KISSKALT (*Arch. Hyg., 35 (1899), No. 1, pp. 11–18*).

German laws on meat inspection, OSTERTAG (*Ztschr. Fleisch u. Milchhyg., 9 (1899), No. 8, pp. 141–145*).—Brief directions for meat inspectors.

On the determination of the age of beef carcasses, BUNGE (*Ztschr. Fleisch u. Milchhyg., 9 (1899), No. 8, pp. 145–147*).—Contains practical suggestions for the guidance of inspectors.

Commercial feeding stuffs in the Connecticut market (*Connecticut State Sta. Bul. 128, pp. 12*).—Cotton-seed meal, gluten meal, and other products made from a single grain, and feeding stuffs prepared from two or more grains, are discussed. The average composition of feeding stuffs purchased in Connecticut markets is reported. These were examined chemically and microscopically. These were cotton-seed meal, linseed meal, gluten meal, gluten feed, wheat bran, wheat middlings, mixed feed, rye bran, whole oats, corn meal, oat feed, oat chaff, malt hulls, Quaker dairy feed "stock food," "starch feed," provender, standard dairy feed, H. O., H. O. horse feed, Blatchford's calf meal, and Baum's horse and stock food.

Feeding-stuff inspection, C. D. WOODS (*Maine Sta. Bul. 51, pp. 16*).—Analyses, made in compliance with the State feeding-stuff law, are reported of a number of samples of cotton-seed meal, Chicago gluten meal, cream gluten meal, King gluten meal, Buffalo gluten feed, Rockford Diamond gluten feed, sucrene oil meal, Cleveland flax meal, old-process linseed meal, Blatchford calf meal, Victor corn and oat feed, corn and oat feed, ground corn and oats, Lakeside corn and oat feed, Dundee corn and oat feed, Monarch corn and oat feed, H. O. Co. standard dairy feed, H. O. Co. horse feed, H. O. Co. poultry feed, American Cereal Co. poultry feed, Quaker oat feed, Haskell oat feed, Crescent oat feed, Horseshoe brand ground beef cracklings for poultry, Bradley superior meat meal, Bowker pure beef scraps, Bowker animal meal, pure beef scraps, and American poultry meal. The analyses of cotton-seed meal and gluten meal are briefly discussed.

DAIRY FARMING—DAIRYING.

Annual forage plants for summer pasture, T. L. LYON and A. L. HAECKER (*Nebraska Sta. Bul. 58, pp. 57–70, fig. 1*).—In comparison with alfalfa, the following were tested as forage plants for dairy cows: Rye, oats and peas, hairy vetch, corn, millet, sorghum, white Kafir corn, yellow millo maize, soy beans, and cowpeas. The crops were grown on fifth-acre plats for pasturage, and under similar conditions on tenth-acre plats for the purpose of determining the amount of green forage produced. The treatment of the different plats, the number of days each furnished pasturage for one cow, and the amount of green forage cut from the duplicate plats at the most favorable periods of growth are given. In conducting the test with each crop, a cow was pastured (1) on alfalfa for one month, (2) on the test crop as long as it afforded sufficient feed, and (3) on alfalfa for one month. The tabulated data include the gain or loss in weight of the animal during each period and the average daily production of milk and butter fat. Of the plants tested, sorghum furnished the greatest amount of pasturage. It is noted in this connection that the amount of pasturage furnished by each plat could not be accurately judged by the amount of forage produced on duplicate plats and that the waste in pasturing was least with oats and peas and hairy vetch and greatest with corn and Kafir corn.

Comparing the average results from the two periods on alfalfa with those on the different test crops, it was found that with the exception of hairy vetch, soy beans, and cowpeas, the increase in live weight during the time the cows were on the test crops greatly exceeded that made on alfalfa. With the exception of the cow pastured on cowpeas, the yield of milk was slightly decreased in each case. "White Kafir corn, rye, sorghum, and hairy vetch maintained the milk flow excellently well." The production of butter fat increased with rye, soy beans, and cowpeas and decreased in the other cases. Excluding the test of yellow-millo maize as unsatisfactory, millet was considered as making the poorest showing and corn next.

The effect of food on economic dairy production, A. M. SOULE (*Texas Sta. Bul. 47, pp. 1033-1106, figs. 6, dgms. 8*).—Ten grade Jersey and 8 grade Holstein cows were divided into 6 lots of 3 cows each and fed for 56 days, the time being divided into 4 equal periods. In the first period all the lots were given a nearly uniform ration of cotton-seed meal, hulls, and silage. In the 3 subsequent periods, lot 1 had cotton-seed meal and hulls; lot 2, cotton-seed meal and sorghum hay; lot 3, cotton-seed meal and hulls with silage, and lots 4, 5, and 6, cotton-seed meal and silage with bran, corn meal, and oats, respectively. The proportion of cotton-seed meal to the other components of the ration was diminished from the second to the fourth period in the case of each lot.

The data for the experiment, showing the previous record of the cows, composition of the food materials used, computed digestible nutrients in the daily rations, with cost and manurial value, variations in weight of animals during the experiment, amount and character of food consumed, milk and butter produced, variations in fat as influenced by food and temperature, etc., are presented in detail in tables and diagrams and discussed at great length. Some of the tables are difficult to comprehend, as it is not clear whether the data refer to individuals in the same period or to averages for lots in different periods.

The author concludes that the use of some other grain feed with the cotton-seed meal was more effective and economical than the use of cotton-seed meal and coarse food alone. "The use of 6 lbs. of cotton-seed meal (when the only meal fed) gave a larger profit and proved more effective than the use of 7, 8, or 10 lbs. When 4 to 6 lbs. of cotton-seed meal were combined with 6 or 4 lbs. of bran, corn meal, or oats, the best yields of milk and butter were secured."

Of the 19 rations fed, one composed of 6 lbs. of cotton-seed meal, 18 lbs. of cotton-seed hulls, and 35 lbs. of corn silage is said to have been the most economical for dairy production. The best returns were secured when the nutritive ratios ranged between 1.5 and 1.6. The author states furthermore that "when the proportion of protein and fats furnished in the meals was least and the carbohydrates greatest the yields and profits were the highest" and "when one third of the total digestible nutrients consumed per day was furnished by the meals the best financial results were observed. . . . Rations decidedly at variance with the so called standard rations gave excellent returns from a financial standpoint."

A sudden change of temperature from 49 to 19° F. in 24 hours materially reduced the yields of milk and butter fat for several days. The average cost for the 6 groups of 100 lbs. of milk and 1 lb. of butter, including only the cost of feeding materials at the market prices during the experimental periods, varied from 50.4 cts. to 65.2 cts. and from 10.9 cts. to 14.1 cts., respectively. "Cows will eat more food than they can profitably manufacture into dairy products. They may also suffer from lack of a sufficient supply of certain food ingredients. . . . Conformation is of importance in the dairy cow."

The composition of milk and milk products, H. D. RICHMOND (*Analyst, 24 (1899), Aug., pp. 197–201*).—The author summarizes the results of analyses of 14,135 samples of milk brought in by the railroads from different farms, the averages being given of the morning's and night's milk by months; analyses of 50 samples of normal milk, including determinations of sugar, proteids, and ash in addition to the usual determinations; analyses of a number of samples of abnormal milk; average composition of clotted cream; and composition of butters and separator slime. The analyses of normal milk "confirm Vieth's ratio of sugar, proteids, and ash of 13:9:2, to a remarkable degree. The ratio found is 12.8:9.3:2, which is in excellent agreement."

The author discusses the theory of Storch that a slimy albuminous membrane surrounds the fat globules of milk (E. S. R., 9, p. 176), and presents some data bearing on the subject. From a review of the evidence, he concludes that he is "unable to see that there is any justification for the view that each globule in milk is surrounded by a mucoid membrane; certainly the question is far from being settled by Storch's results."

Effect of sesame cake on butter, PFEIFFER (*Ber. Landw. Vers. Stat. Univ. Jena, 1898, pp. 12–14*).—This experiment was made to determine whether any injustice might arise from the German law of

1897 requiring the mixing of at least 10 per cent of sesame oil with oleomargarine as a means of identifying it. Seven cows were fed a basal ration of coarse fodder during a number of periods, to which various oil cakes were added in different periods, the amount of sesame cake being gradually increased from ½ lb. up to 4 lbs. per head daily. The butter was examined for iodin number and for sesame oil by the Baudouin reaction (shaking with furfurol and hydrochloric acid). It gave no reaction for sesame oil in any case, indicating that no transmission of the oil to the butter was to be feared. This result is said to agree with most of the experiments on this point. [See, however, E. S. R., 9, p. 795; 10, pp. 586, 587.] It was found that the iodin number increased regularly with the increase in amount of sesame cake which was fed.

Spongy curd and the effect of sewage, LLOYD (*Abs. in Dairy, 11 (1898), No. 127, p. 197*).—An instance is cited in which cows twice by accident got into a paddock and waded in and drank from a pool of stagnant dirty water. Each time a spongy curd was produced. To make sure that the water was the cause a bacteriological examination was made, and one of the most typical spongy organisms was found in it as well as in the spongy curd. It was found that the sewage from a number of cottages overflowed into this paddock, and as soon as the difficulty was removed the spongy curds ceased.

Ropiness in milk and cream, A. R. WARD (*New York Cornell Sta. Bul. 165, pp. 395–412, pl. 1*).—The literature of this subject is reviewed and an account is given of an investigation of an outbreak in two dairies. The cause of the ropiness was found to be *Bacillus lactis viscosus*, but considerable difficulty was experienced in locating the point at which the infection took place. The first complaint came from a local milk dealer who was losing his customers on account of the milk becoming ropy after standing. All of the milk handled by this dealer was supplied by one dairy of 12 cows. The cream on the surface of cans of milk which stood in water at a temperature of from 45 to 50° F. became viscid in from 24 to 48 hours. No complaint was heard from customers who consumed the milk within a few hours. Samples of the milk taken directly from the cows failed to show the presence of the bacillus or to become ropy. Cultures of the air and filth of the stable and of the feces of the cows gave no evidence of the presence of the bacillus. The milking utensils were then carefully examined and it was found that "the milk did not contain *Bacillus lactis viscosus* when drawn from the udder, nor did it gain access to the milk during any of the processes to which the milk was subjected up to the time that it was taken from the barn." From the barn the evening's milk was brought to the creamery and placed for the night in deep-setting cans surrounded by ice water, while the morning's milk was aerated and brought to the creamery, where it was again strained before delivering. The brass-wire strainer used for straining the milk was found to be in a filthy condition through lack of thorough cleaning, but the deep setting cans were apparently clean.

Samples of milk exposed to contamination on the surface of the strainer became viscid, as well as samples which were taken from the interior of the deep-setting cans, and a bacteriological examination showed the presence of *Bacillus lactis viscosus.*

At another dairy which had suffered seriously from ropiness, the cause of the contamination was located in the utensils used for holding the milk before and during delivery. As a remedy it was suggested that "the smaller utensils be totally immersed in boiling water for three minutes and that the larger cans be filled to the brim with boiling water for a like length of time." This suggestion was carried out, and the trouble immediately disappeared.

The author was unable to determine the source from which the bacillus originally reached the milk cans, but, in view of the work of Adametz, he is inclined to believe that during warm weather these particular bacteria got into the milk from water.

In conclusion a description is given of the bacillus found in the samples of ropy milk, and its behavior in various cultures.

Pure cultures for Cheddar cheese making, J. R. CAMPBELL (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 205–220*).—This is a continuation of previous investigations in this line (E. S. R., 10, p. 996). Experiments were made in the laboratory and in the dairy which demonstrated the purifying effect of the method employed by the dairymen in preparing starters. The method followed in preparing this homemade starter is to allow a quantity of skim milk to sour spontaneously, skim off the surface, and add about a pint to a pailful of skim milk which has been scalded to 155 to 160° F. and subsequently cooled to 65 to 70°. This process is repeated each day, and on the third day the product may be used for the starter, a portion being retained for the starter for the following day. This may be continued throughout the season.

"By starting with an ordinary sample of sour milk, even though it be impure, the operations entailed in preparing what I have designated 'a homemade starter' will, in a very few days, produce a sample of sour milk containing what is for all practical purposes a pure culture of the bacterium required for the manufacture of good cheese. If the cheese maker begins with an absolutely pure culture, in the course of a few days it will be no purer and in no way better for cheese making than the cultivation obtained by the homemade-starter system."

Two series of experiments in July and August were made at 5 different dairies to compare the homemade starter with a number of pure cultures in practical use in cheese making. The cheeses were scored by competent judges who knew nothing of the method of making. The results of these experiments are tabulated.

The sum total from these experiments may be stated as follows:

"(1) First-class Cheddar cheese can be made by using pure cultures of a lactic organism.

"(2) This organism abounds in all samples of sour milk and sour whey.

"(3) The system recommended for the preparation of a homemade starter is one which exerts a purifying influence upon the bacterial content of the starter, and results in the elimination of bacteria which are unnecessary if not harmful to the production of a first-class material.

"(4) The use of a whey starter is attended with results equal in every way to those obtained from a milk starter."

A number of precautions to be exercised in the preparation and use of the homemade starter are enumerated. It is noted that "a starter should never be used where without it the cheese can be made in about the time specified [5½ hours];" and that "when a starter is used the whey must be run at an earlier stage." Technique in cheese making is regarded as much more important than the use of pure cultures, "for no amount of bacterium will compensate for a deficiency of that keenness of sense which is the result only of long and patient training."

A handbook of dairying based on science and practice, W. KIRCHNER (*Handbuch der Milchwirtschaft auf wissenschaftlicher und praktischer Grundlage. Berlin: Paul Parey, 4. ed., pp. X + 654, pls. 8, figs. 153*).—A new edition of this book.

Absence of alcohol in the milk from cows fed on distillery malt, M. A. PETERMANN (*Rev. Chim. Analyt. et Appl., 4 (1899), No. 6, pp. 185, 186*).—By the application of the iodoform test to the distillate from a liter of milk, by the Duclaux viscometer test, and by the Westphal balance, the author was unable to detect any alcohol in the milk.—H. SNYDER.

Importance of feeding roots (*Milch Ztg., 28 (1899), No. 26, p. 407*).—A Danish experiment is reported in which the profits were increased by substituting roots for a portion of the concentrated food in rations for milch cows.

Winter milking rations (*Dairy, 11 (1899), No. 127, p. 200*).—Ten rations are suggested as a result of experiments conducted during 3 winters.

Influence of feed on the quantity and quality of the milk, F. C. CURTISS (*Amer. Cheesemaker, 14 (1899), No. 159, pp. 1–3*).

Value of breeds, G. M. GOWELL (*Hoard's Dairyman, 30 (1899), No. 21, pp. 410, 411*).—A popular discussion.

Official tests of Holstein-Friesian cows, S. HOXIE (*Hoard's Dairyman, 30 (1899) Nos. 21, p. 422; 22, pp. 440, 441; 29, p. 580*).—Reports 102 tests made from January 1 to May 1, 1899.

On the source of milk fat, W. A. HENRY (*Breeders' Gaz., 36 (1899), No. 4, pp. 89, 90*).—A discussion of an experiment conducted at the New York State Station (E. S. R., 9, p. 1083).

Swedish ropy milk, G. TROILI-PETERSSON (*Abs. in Milch Ztg., 28 (1899), No. 28, pp. 438, 439*).—The cause of ropiness was investigated and attributed to *Bacterium lactis longi*, which was studied in pure cultures. This germ is considered very closely related to *B. lactis acidi*, from which it is distinguished chiefly by the kind of fermentation produced in milk.

The Babcock test: Its origin, use, and manipulation, A. M. SOULE (*Hoard's Dairyman, 30 (1899), No. 31, pp. 616, 617*).

The Babcock test for cheese factories, J. W. DECKER (*Hoard's Dairyman, 30 (1899), No. 25, p. 488, fig. 1*).—Cheese was made from milk containing 3.3, 4, and 5 per cent of fat, 100 lbs. of milk yielding 10.1, 11.4, and 13.1 lbs. of green cheese, respectively.

Observations on the use of the Kröhnke milk filter, P. VIETH (*Milch Ztg., 28 (1899), No. 26, pp. 403, 404*).—Tests are reported on the use and purification of this filter.

Contribution to the study of butter fat, VAN ENGELEN and P. WAUTERS (*Ind. Lait., 24 (1899), Nos. 29, pp. 229, 230; 30, pp. 237–239*).—From investigations extending through one year the conclusion is drawn that abnormal variations in the composition of butter fat are not due to food or period of lactation.

Preservation of butter, R. Gouin (*Ind. Lait, 24 (1899), No. 34, pp. 269–271*).—Various well-known methods are discussed.

Producing, retaining, and controlling flavor in butter, G. L. McKay (*Hoard's Dairyman, 30 (1899), No. 25, pp. 498, 499*).—A popular article.

A test of churns, C. S. Plumb (*Nat. Farmer and Stock Grower, 2 (1899), No. 2, p. 21*).—Trials were made of a churn provided with inside paddles and an arrangement for revolving them at high speed. On account of the difficulty in removing the butter this type of churn is not to be recommended over standard box and barrel churns without inside devices.

Cheese bacteriology, status of the science in the European countries, H. W. Conn (*Amer. Cheesemaker, 14 (1899), No. 161, pp. 4, 5*).

Cheddar cheese making, J. A. Ruddick (*Amer. Cheesemaker, 14 (1899), No. 163, pp. 1–3*).

Method of manufacturing Stilton cheese, R. Owens [(*Agr. Jour. Cape Good Hope, 14 (1899), No. 12, pp. 785–788*).—The method of manufacture of Stilton cheese is described and compared with that employed in making Cheddar cheese.

The best form of cow stall, P. McConnell (*Jour. British Dairy Farmers' Assoc., 14 (1899), No. 2, pp. 85–90*).

Dairy buildings, R. Henderson (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 39–115, figs. 11*).

VETERINARY SCIENCE AND PRACTICE.

Thirteenth annual report of the State board of live stock commissioners for the State of Illinois for 1898 (*Springfield, Ill.: Phillips Bros., 1899, pp. 116*).—This report contains a copy of the regulations of the State board of live stock commissioners regarding Texas fever, an account of various outbreaks of Texas fever in the State, and a record of a large number of dipping experiments which were made in connection with the Bureau of Animal Industry of the Department of Agriculture, a part of the results of which have been published elsewhere and are already noted.

The tuberculin test has been applied very generally to the cattle of the State, and extensive tables are given showing the results of tests and post-mortem conditions in cases which reacted.

A report is made upon the cases of actinomycosis discovered by the meat inspectors, and tables are given showing the number of actinomycotic animals coming from the different States.

The report contains a discussion by J. M. Wright of the history and nature of glanders and upon the use of mallein as a therapeutic agent. Tables are also given showing the clinical record of horses which were tested for glanders by means of mallein.

A proposed reform in the nomenclature of veterinary myology, Arloing and Lesbre (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 5 (1897), pp. 135–173*).—The authors call attention to the convenience of having a set of names for use in descriptive veterinary anatomy which shall be recognized by all veterinarians. At the meeting of the Sixth International Veterinary Congress in Berne, 1895, a resolution was passed to undertake the preparation of such a veterinary nomenclature. The authors have prepared a list of names of muscles known in veterinary anatomy and these names are arranged in parallel columns with the names of muscles in human anatomy adopted by the congress at Basel, and with other names which have been used to a greater or less extent by various authors, and which are to be regarded as synonymous.

On the biology of anthrax bacillus, R. WEIL (*Arch. Hyg., 35 (1899), No. 3-4, pp. 355-408*).—The results of investigations reported in this article may be summarized as follows: Anthrax bacilli of normal virulence and considerable power of resistance form spores when subjected to moderate temperatures considerably sooner than has usually been assumed. At a temperature of 31 to 37° C. spores were formed within 16 hours, at 24° C. within 36 hours, and at 18° C. within 50 hours. At a temperature of 12° C. the most resistant individuals of the anthrax bacilli are still able to produce resting conditions even when the spore formation does not take place regularly. The spores which are produced at a temperature of 37° C. have a greater power of resistance than those which are formed at temperatures ranging from 18 to 31° C. Anthrax bacilli in their vegetative condition are quickly killed if they are subjected to high temperatures in fluid. Heated in bouillon at 80° C. they are destroyed in 1 minute; at 79°, in 1½ minutes; at 78°, in 2 minutes; at 75°, in 3 minutes; at 70°, in 4 minutes; and at 65°, in 5½ minutes.

If anthrax bacilli are subjected to low temperatures, they are seen to pass through 3 stages. During the first stage the normal virulence may become reduced to so low a grade that mice do not acquire the disease even when inoculated with large quantities of the bacilli. In the second stage they lose the power of growth, but regain this power and their virulence under favorable conditions. In the third stage the bacteria reach such a condition that they can no longer be revived. Atmospheric oxygen has no specific effect upon the formation of the resting stages. The anthrax bacilli form spores under anaerobiotic conditions.

On the excretion of micro-organisms through the active mammary gland, K. BASCH and F. WELEMINSKY (*Arch. Hyg., 35 (1899), No. 3-4, pp. 205-226*).—As experimental animals, the authors made use of guinea pigs. The first bacteria which were used were nonpathogenic and as negative results were obtained, various pathogenic bacteria were next tried.

The living bacteria were injected subcutaneously and by withdrawing small quantities of blood in an aseptic manner it was possible to determine when the bacteria had entered the blood system. The milk from the animal was tested from that time until death. The milk was also injected into healthy animals as a further check upon the experiments. The results obtained may be summarized as follows: The only pathogenic germs which pass out in milk are those that have the power of producing hemorrhages or similar changes in the mammary gland by means of which the normal structure of this gland is disturbed. In a case of pure septicæmic processes, where the blood contains the germs in large numbers, no bacteria were found in the milk even after death, and animals injected with the milk remained entirely healthful. This was true of animals which were inoculated and which died of typhus, diphtheria, cholera, and anthrax. When, however, the animal was inoculated simultaneously with anthrax and *Bacillus bovis morbificans*, hemorrhagic disturbances were produced in the mammary gland and the anthrax bacillus was found in milk.

A case of poisoning, E. F. Ladd (*North Dakota Sta. Bul. 35, pp. 307-310, fig. 1*).—A bull died suddenly with symptoms of poisoning. The stomach contents were analyzed, with the result that conin was discovered. When the owner was questioned concerning his hay, it was found that the hay contained *Cicuta maculata* in abundance. This is, therefore, considered a well-authenticated case of poisoning from water hemlock. A description and illustration of the plant are given and a brief account of the symptoms of poisoning by this plant. The treatment recommended consists in cleansing the alimentary tract and the use of chloroform or chloral, as indicated by the symptoms. It is recommended that these plants be removed from the hay before it is stacked or placed in the barn.

Studies on the seeds and oil cakes of ricinus, C. Cornevin (*Ann. Soc. Agr. Sci. et Ind. Lyon, 7. ser., 5* (*1897*), *pp. 107-133*).—This paper contains a description of the plant and of the appearance of the seeds of the castor-oil plant. The method of extracting the oil is described and an account is given of the extent of the use of the oil cakes, which are left over as by-products, as food for man and domesticated animals. If the cakes are spread upon the ground or exposed to the air for from 5 to 6 days, the poisonous principles are destroyed. If the seeds and cakes are cooked for at least 2 hours, they are no longer poisonous. If a solution of ricin is subjected to heat for 2 hours, of which at least 1¾ hours is up to the boiling point, it is transformed into a vaccine which, when used as a hypodermic or intravenous injection, immunizes the animal against the intoxication of ricinus. After animals have been vaccinated once, they can eat with immunity any quantity of the cakes or seeds of ricinus. The flesh of animals thus immunized is harmless when taken as food.

Researches on the bacterial flora of the lungs of man and animals, L. Beco (*Arch. Méd. Expér. et Anat. Path., Paris, 11* (*1899*), *No. 3, pp. 317-362*).—This paper gives an account of the bacteria ordinarily found in the normal lungs of the guinea pig, rabbit, cat, dog, foal, horse, calf, cow, and sheep. The pathological condition and pathogenic bacteria of the lungs of these animals and of man are also described. In sound lungs the tubercle bacillus was not found.

Bacteria in street dust that is sprinkled and in that which is not sprinkled, T. Mazuschita (*Arch. Hyg., 35* (*1899*), *No. 3-4, pp. 252-282*).—This article contains a record of a large number of observations made with the object of determining the hygienic value of sprinkling streets during hot weather. It was found that when streets were sprinkled the bacteria contained in the dust were more numerous and were in better condition to multiply. The author strongly urges the flooding of streets in summer to wash away the dust in which the bacteria are contained. A bibliography of the subject is added to the article.

A contribution to the knowledge of the infectious diseases of animals and man which are produced by anaërobic bacteria, E. V. HIBLER (*Centbl. Bakt. u. Par., 1. Abt., 25 (1899), No. 15–16, pp. 513–531*).—An extensive account of experimentation with 10 races of bacteria.

Some diseases of domestic animals communicable to man, J. I. GIBSON (*Iowa State Agr. Soc. Rpt. 1898, pp. 94–101*).—The author discusses the common means of transmission of germ diseases. The following diseases are described and an account given of the means and extent of their transmission to man: Actinomycosis, blackleg, glanders and farcy, hog cholera, and tuberculosis.

Practical notes on influenza, P. P. SANCHEZ (*Vet. Españ., Madrid, 42 (1899), Nos. 1493, pp. 145–149; 1494, pp. 161–166; 1495, pp. 178–183*).—Gives a description of the disease, a differential diagnosis of influenza and contagious pleuro-pneumonia. An account is given of inoculation experiments for rendering immunity and of hydrotherapy in the treatment of the disease.

Two cases of tetanus cured by the use of antitetanus serum, L. CONSTANT (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 340, 341*).—Clinical records and description of method of using the antitoxin.

On the modifications of tetanus poison, E. BEHRING (*Fortschr. Med., 17 (1899), No. 21, pp. 501–505*).—For producing immunity against tetanus, poisons with a high multiple of indirect poison value in comparison with their direct poison value give better results than the equilibrated poisons.

Antitetanus serum and its preparation, L. S. VIZMANOS (*Vet. Españ., Madrid, 42 (1899), Nos. 1499, pp. 241–244; 1500, pp. 257–260; 1501, pp. 279–281*).—A general account of the effect of antitetanus serum when used for the prevention of tetanic contractions, and a description of the method of preparation.

On the quantitative combination relations between tetanus toxin and tetanus antitoxin in living guinea pigs, E. BEHRING (*Fortschr. Med., 17 (1899), No. 22, pp. 521–534*).—This paper contains a record of a large number of experiments upon guinea pigs and a discussion of the nature and quantitative relationship of the chemical union between the toxin and antitoxin.

Zahn's thermometer holder, J. G. VAETH (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 26, pp. 234, 235, fig. 1*).—A new arrangement for holding the thermometer during tuberculin tests.

Anthrax (*Rev. Facult. Agron. y Vet., La Plata, 4 (1899), No. 1, pp. 129–131*).—Discusses the nature of the disease, the value of vaccination, and the burial of carcasses.

Blackleg vaccine, E. P. NILES (*South. Planter, 60 (1899), No. 7, pp. 335–337, figs. 2*).—The Virginia Station has equipped itself for making blackleg vaccine. Directions are given for sterilizing the hypodermic syringe and making the injections. A list of questions is added which will be sent to each farmer who uses the vaccine.

Actinomycosis in Spain, L. DEL RIO (*Vet. Españ., Madrid, 42 (1899), No. 1497, pp. 210–212*).

The so-called actinomycosis musculorum suis, DAVIDS (*Ztschr. Fleisch u. Milchhyg., 9 (1899), No. 10, pp. 181–187*).—Gives an historical account of the subject and descriptions of appearances of the disease from paraffin sections.

Milk fever in the cow, M. IMES (*Agr. Student, 5 (1898), No. 3, pp. 57, 58*).—A description of the symptoms of the disease is given, together with an account of its etiology and preventive measures, such as antiseptic washes.

On the Schmid-Kolding treatment of milk fever, BRÜLLER (*Wchnschr. Tierheilk. u. Viehzucht, 43 (1899), No. 26, pp. 245, 246*).—Gives a clinical record of 4 cases.

Milk fistula, P. LEBLANC (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 332–334*).—An abscess followed by erysipelas of the mammary gland in a goat left a milk fistula which healed after being ligatured.

Concerning contagious vaginitis of cows, A. LUCET (*Jour. Med. Vet. et Zootech, 5. ser., 3 (1899), pp. 338, 339*).—A discussion of the cause and communicability of the disease.

Distomatosis of the abdominal walls of the cow, REPIQUET (*Jour. Med. Vet. et Zootech, 5. ser., 3 (1899), pp. 271, 272*).—Tubercles formed by distomum are distinguished from those of tuberculosis in similar positions.

Preventive inoculation against red water or tick fever, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 11 (1899), No. 7, pp. 415–418*).—Young heifers were injected with defibrinated blood from animals which had recovered from the disease. After they had in turn recovered, which was usually about 6 weeks later, their blood was used for inoculation purposes to produce a mild form of disease.

Preliminary note on bovine malaria, NICOLLE and ADIL-BEY (*Ann. Inst. Pasteur, 13 (1899), No. 4, pp. 337–343*).—The native races of cattle are perfectly immune and can withstand injections of large quantities, even liters of virulent blood. The serum from cattle thus treated, if collected from 2 to 6 weeks after these inoculations, has no preventive or curative power.

Experimental data on the subject of the susceptibility of camels to cattle plague, M. TARTAKOVSKY (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 4, pp. 228–251*).—The article contains records of experimental inoculations of camels accompanied with temperature charts.

A new parasitic disease of cattle in Cochin China (Amphistomosis hepatica) (*Vet. Jour., 48 (1899), No. 287, pp. 347–350*).—*Amphistomum hepaticum* was found in oxen of Cambodia, Indian buffaloes, and zebus. The anatomical characters of the fluke and the pathological conditions caused by it are described.

How an attack of epizootic abortion was dealt with, C. MARSHALL (*Jour. British Dairy Farmers' Assoc., 11 (1899), No. 2, pp. 91, 92*).—Nocard's method of treatment was tried with good results.

The epizootic occurrence of Tænia cœnura in the calf, T. TAVALLAZZI (*Giorn. R. Soc. Accad. Naz. Vet. Ital., 48 (1899), No. 26, pp. 612–615*).

Railroad fever of cows, ESTOR (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 26, pp. 233, 234*).—Outlines the symptoms of this disease, which is frequently observed in cattle after long railroad journeys. The remedies which have been tried are bloodletting, keeping quiet (with chloral hydrate if necessary), strychnin, alcohol, atropin, and potassic iodid. No treatment, however, had much effect except in mild cases.

Water on the joints in cattle, CADÉAC and MOROT (*Jour. Med. Vet. et Zootech., 5. ser., 3 (1899), pp. 202–205, figs. 2*).—Gives a description of the pathological anatomy of the metatarsus from an animal affected with this disease. The appearance is compared with that of ergotism.

On the physiological effect of digitalis and its diagnostic importance in pericarditis traumatica of cattle, GMELIN (*Monatsh. Prakt. Thierh., 10 (1899), No. 9, pp. 385–417, figs. 33*).—In cases of this disease digitalis is found to have great value as a diagnostic agent. As a remedy it is not uniform in action. A number of sphygmographic tracings of blood pressures in the carotid artery accompany the article.

Bovine rumenotomy, S. H. SWAIN (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 4, pp. 223–225*).—The article contains an account of the method of preparing the instruments and animals and of making the operation.

On the causes of the sterility of cattle, E. ZSCHOKKE (*Landw. Jahrb. Schweiz, 12 (1898), pp. 252–272, pl. 1*).—Contains a general discussion and classification of the various causes of sterility, whether from pathological anatomy and physiology or from peculiarities of temperament and constitution of both sexes.

On multiple adenom formation in the lungs of sheep, A. EBER (*Ztschr. Tiermed., 3 (1899), No. 3, pp. 161–172, pls. 4*).—These formations are described and figured with especial reference to their microscopic details. The etiology of the disease is not thoroughly known.

Remarks on the nature and the differentiation of the infectious swine diseases in the United States, V. A. Moore (*Amer. Vet. Rev., 21 (1898), No. 12, pp. 813-829*).—The author here gives an historical account of the development of our knowledge on the subject of hog cholera and swine plague. A synonymy of names is added for this country and Europe, and detailed descriptions of the pathological anatomy of hog cholera and swine plague are given, as well as a list of the characters of the bacilli of these two diseases.

Hog cholera and swine plague, A. W. Bitting (*Reprinted from Farmer's Guide, 1898, Aug.-Oct., pp. 22*).—In this pamphlet are discussed the extent of the swine industry in Indiana and the various questions connected with the diagnosis and treatment of hog cholera and swine plague. The author has made an experimental study of a large number of patent remedies which have been recommended for treatment of swine diseases and concludes that they are all worthless. Stress is laid upon the advisability of maintaining cleanly surroundings as a means of preventing serious outbreaks of swine diseases.

Serum therapy of hog cholera, E. Leclainche (*Ann. Méd. Vét., 48 (1899), No. 7, pp. 367-370*).—A brief discussion of the method to be adopted in preparing the hog-cholera serum and of the technique of its application.

Practicability of serum therapy in the treatment of hog cholera, W. B. Niles (*Iowa State Agr. Soc. Rpt. 1898, pp. 315-318*).—In this paper the author discusses the technique of the application of the serum treatment for hog cholera and gives a brief account of the success which has attended its use.

Results of some vaccinations with Beck's serum against swine diseases, J. Müller (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 26, pp. 235, 236*).—Reports the favorable outcome from vaccination of sows.

Infectious pneumoenteritis of the pig (*Gaz. Méd. Vét., 3. ser., 23 (1899), No. 137, pp. 543-547*).—Gives the history of our knowledge of the disease and a discussion of its cause, distinguishing between hog cholera and swine plague.

The serotherapy of erysipelas of the pig, E. Leclainche (*Compt. Rend. Soc. Biol., Paris, 11. ser., 1 (1899), No. 15, pp. 346-348*).—Inoculations were made with a mixture of immunizing serum and virulent cultures of blood. Sheep proved to be good animals from which to obtain immunizing serum.

Combating erysipelas of hogs, O. Voges and W. Schütz (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 20, pp. 177-179*).—A serum is used which destroys the bacillus when injected into animals already suffering from the disease and also has the power of giving immunity.

Echinococcus veterinorum, S. Stewart (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 4, pp. 215-217*).—In the region of Kansas City, Missouri, it is stated that about 5 out of every 1,000 hogs are infected with the cystic stage of *Echinococcus veterinorum*. A description is given of the post-mortem appearance of the disease.

Projection as a reliable means for demonstrating the presence of trichinæ, H. Kabitz (*Ztschr. Fleisch u. Milchhyg., 9 (1899), No. 10, pp. 187-189*).—Description of a projection apparatus for examining flesh for trichinæ. The instrument is known as a trichinoscope.

A case of malarial fever, H. Taylor (*Vet. Jour., 49 (1899), No. 289, pp. 1-8, figs. 3*).—Gives the symptoms of the disease in a horse. Treatment with potassic nitrate, potassic chlorate, quinin, and iron tonics was of no avail. Post-mortem lesions and microscopic appearances of tissues are described.

The etiology and pathology of endocarditis, Thomassen (*Ann. Med. Vet., 48, (1899), No. 6, pp. 285-29[illegible]*).—A microscopic examination of sections from the sigmoid and mitral valves from the heart of a mare which died of the disease disclosed the presence of streptococci and bacilli.

An experiment in inoculating camels with glanders, E. T. Dshunkovsky (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 4, pp. 255-261*).—A record of experimental inoculations of camels with this disease.

The pathology and treatment of spavin, J. MACQUEEN (*Jour. Comp. Path. and Ther., 12 (1899), No. 2, pp. 119–125*).—The author discusses the anatomical conditions found in cases of spavin and gives a general discussion of the cause of this disease.

Some "inventors'" horseshoes, J. A. W. DOLLAR (*Veterinarian, 72 (1899), No. 859, pp. 479–487, figs. 9*).—A discussion with illustrations of some of the numerous inventions in the line of nailless horseshoes.

Diseases of poultry, G. E. HOWARD (*The American Fancier's Poultry Book. Washington, D. C.: G. E. Howard & Co., 1898, pp. 89–102, ill.*).—The author gives a discussion of the symptoms and treatment for all of the more common diseases of poultry, including apoplexy, black rot, bumblefoot, canker, catarrh, cholera, consumption, crop bound, diarrhea, egg bound, egg eating, feather eating, frost bites, gapes, giddiness, gout, indigestion, leg weakness, lice, liver diseases, pip, rheumatism, roup, scaly legs, soft eggs, ulceration, and worms. Figures are given of the more common forms of parasitic insects which attack poultry.

The tick of the domestic fowl and fowl fever (*Bot. Dept. Trinidad Bul. Misc. Inform., 3 (1899), No. 19, pt. 11, p. 180*).—*Argas americanus* is said to have been introduced into Trinidad, and to be the cause of a fowl fever in that place.

A disease in cattle not distinguishable from rabies, V. A. MOORE (*Veterinarian, 72 (1899), No. 858, pp. 396–416*).—Contains a clinical record and account of post-mortem conditions of cattle which died of a disease closely simulating rabies. Inoculation upon rabbits with virulent cultures gave positive results. The rabbits died with all the symptoms of ordinary rabies. The author concludes that rabies may occur without being traceable to the bites of mad dogs, and recommends that when the disease breaks out the cattle should be removed to higher ground.

On the narcosis of domesticated animals, FRICK (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 25, pp. 225–227*).—A discussion of the relative merits of chloroform, morphin, chloral hydrate, ether, and cocain. The different methods of application are described, and special discussions are given on the choice of the most suitable narcotic for the horse, ox, pig, dog, and cat.

The occurrence of cancer in the lower animals, J. MACFADYEAN (*Jour. Comp. Path. and Ther., 12 (1899), No. 2, pp. 137–141*).—Carcinomata are recorded in the form of primary or secondary tumors in the dog, cat, horse, cow, and sheep.

Discovery of Bacillus alvei, L. STACHELHAUSEN (*Southland Queen, 5 (1899), No. 1, pp. 8–10*).—A history of the work which led to the discovery of the germ, and brief mention of remedies.

Contagious pustulant dermatitis, TRASBOT (*Rec. Méd. Vét., Paris, 8. ser., 6 (1899), No. 8, pp. 163–172*).—Gives a statement of the symptoms and clinical appearance of this disease, which has been called Canadian variola and American variola.

The necrosis bacillus as a cause of disease in our domesticated animals, FRANCKE (*Berlin. Tierärztl. Wchnschr., 1899, No. 25, pp. 299–303*).—An historical discussion of the development of our knowledge of the bacillus and of its activity during the acute stages of certain diseases.

A septicæmia of the guinea pig, C. PHISALIX (*Bul. Mus. Hist. Nat. [Paris], 1898, No. 6, pp. 279–282*).—Gives an outline of culture methods, and a description of the bacillus and of its pathogenic action. The dog resists the action of this bacillus, but rabbits, mice, and pigeons succumb quickly.

Psittacosis, or parrot septicæmia, L. BRUSASCO (*Giorn. R. Accad. Naz. Vet., 48 (1899), No. 19, pp. 434–441*).—Notes on a contagious disease which is said to be frequent among parrots imported from America, and which can be easily transmitted to man.

Contribution to the study of Laverania danylewsky, A. LAVERAN (*Compt. Rend. Soc. Biol., Paris, 11. ser., 1 (1899), No. 24, pp. 603–606, figs. 12*).—This organism is an endoglobular hematozoon which infests pigeons. The author suggests that certain species of mosquitoes probably serve as intermediate host for the hematozoa.

Preventive inoculation, W. M. HAFFKINE (*Jour. Comp. Path. and Ther., 12 (1899), No. 2, pp. 142–156; reprinted from The Lancet*).—This article is in the nature of a general discussion covering the derivations from virus and microbes and their effect, immunity against the attack and resistance against actual symptoms of diseases, the relationship between the two, and records concerning inoculations made as prophylactic remedies against the plague.

The intensification of virulence in sera taken from overimmunized animals, H. VALLÉE (*Compt. Rend. Soc. Biol. Paris, 11. ser., 1 (1899), No. 18, pp. 432, 433*).—There is no bactericide action in the sera of overimmunized animals.

A contribution to the knowledge of sera which have a specific effect upon blood corpuscles, K. LANDSTEINER (*Centbl. Bakt. u. Par., 1. Abt., 25 (1899), No. 15-16, pp. 546-549*).—The agglutination of blood corpuscles by specific sera is to be considered due to the action of the stroma of the red blood corpuscles.

TECHNOLOGY.

Experiments in sirup making, B. B. ROSS (*Alabama College Sta. Bul. 103, pp. 97-105*).—An account is given of experiments in the clarification and manufacture of sirup on a small scale, in continuation and extension of work previously reported (E. S. R., 7, p. 719). It appears that the best results in clarification and evaporation are secured by the use of steam for heating purposes.

"Since the evaporation of juices and sirups is carried out in the sugar factories and refineries upon such a large scale, it was impossible to secure upon the market evaporation apparatus adapted to sirup making upon a small scale, and hence two small evaporators were especially constructed for experimental purposes, the smaller of the two being improvised from an ordinary open-fire evaporator already on hand.

"This evaporator was about 4½ ft. long, 3 ft. wide, and about 6 in. deep, while the large evaporator had a length of about 5 ft , a width of about 3 ft., and a depth of 10 in.

"The sides of the evaporators were of wood as usual, and the bottoms were constructed of sheet copper, but no partitions were employed as in the ordinary evaporators.

"A series of pipes, connected at the ends by return bends, were placed in the bottom of each evaporator, almost the whole surface of the bottom being thus covered, with the exception of a space about 4 or 5 in. in width which was reserved for the collection of the scums from the boiling juice. This unoccupied space should be on the side of the evaporator opposite to the point at which the steam is admitted, and this side should also be slightly lower than the other in order to facilitate the removal of the scums. The piping employed was galvanized iron, three-fourths inch inside diameter, and valves were provided for the proper regulation of the steam used in the evaporation, while another set of valves enabled the operator to prevent the too rapid escape of waste steam from the coil.

"The juice, after sulphuring, is first run into the small evaporator or clarifier, steam is turned on, and the contents of the clarifier brought gradually to a boil.

"The scums and impurities come to the surface quite rapidly, the greater portion of them collecting over the space not occupied by the pipes, where they can be easily removed.

"The clarifier is somewhat more elevated than the evaporator, and when the juice has been well skimmed it is at once run into the larger evaporator and the steam is immediately turned on.

"Fresh quantities of juice are now run into the clarifier, boiled, skimmed, and then run into the evaporator, the evaporation of the juice being conducted all the while.

"Any scums which form in the evaporator can be removed in the usual way, and when the sirup has reached the proper density, the steam is shut off and the evaporator is emptied through the usual outlet."

The process of clarifying by means of sulphur fumes with or without lime, described in an earlier bulletin, has continued to give excellent results.

"When this process is employed, the resulting sirup is much clearer and brighter, and at the same time, it can be preserved much more readily. If it is desired to preserve the sirup for a considerable period of time, the hot liquid, concentrated to the proper strength, is run into a bottle or a well-glazed jug of from ½ gal. to 1 gal. capacity, which has been rinsed out with hot water. The vessel is filled almost up to the mouth with the hot sirup and is then securely sealed and stored away for future use.

"By this process sirup has been successfully preserved at the laboratory for from 1 to 4 years, and crystallization of sugar can also be prevented if care is taken to avoid cooking the sirup to too great a density."

"Clariphos" (a strong solution of acid phosphate of lime) and bisulphite of lime were also tested as clarifying agents. The former is considered valuable for the purpose, especially in sugar houses, "but the increased amount of manipulation required in the way of settling, filtering, etc., interferes materially with its adaptability to sirup making upon a small scale. . . .

"It is believed that under normal conditions the bisulphite can be used to advantage as a substitute for sulphurous-acid gas."

The manufacture of sorghum sirup, A. A. DENTON (*U. S. Dept. Agr., Farmers' Bul. 90, pp. 32, figs. 9*).—In this bulletin "the simplest means only, suited to sirup makers who have limited facilities, are considered." It is stated that the manufacture of sorghum sirup has declined because of the inferior quality of the product. It is claimed that by selecting varieties of sorghum suited to sirup making, employing methods of planting and cultivation favoring the full development of the canes, and by more efficiently clarifying the juice, sorghum sirup can be produced of as good quality as sugar-cane sirup.

"The quality of sorghum sirup is determined by the more or less perfect separation from the juice of the impurities which are solid and of those which are in solution." The removal of the former only is considered in the bulletin.

"The methods recommended are cold settling of raw clayed juice, with or without lime, or settling the heated juice with clay, and with or without lime. The method preferred is to settle cold, limed and clayed juice, draw off and heat the settled juice, clay and settle it, and again draw it off, then evaporate it."

The removal of the soluble impurities is to be further investigated before recommendations are made.

Is maize stored for a long time suitable for the manufacture of starch? (*Ztschr. Spiritusind., 22 (1899), p. 37; abs. in Jour. Soc. Chem. Ind., 18 (1899), No. 3, p. 288*).—Old maize, if stored when thoroughly ripe, is considered as a rule preferable to fresh maize for starch making, because it is drier and yields more starch.

Report of the enological station of Haro, Spain (*Mem. An. Estac. Enol. Haro, 1898, pp. 42*).—This is one of the enological stations established by the royal decree of February 15, 1892. The work reported consists principally of meteorological observations and chemical examinations with reference to the growth of grapes and the production of wine.

How to produce good wine, E. MAUMENÉ (*Comment s'obtient le bon vin. Paris: Société D'Éditions Scientifiques, 1898, pp. 238, figs. 51.*)—This manual is volume 3 in the series Encyclopédie des connaissances pratiques. It is designed to be a ready reference book for wine manufacturers, and as such the practical aspect of the subject is kept always in view. After an introductory chapter on certain physiological processes in the grape, the author discusses alcoholic fermentation, various methods and processes of manufacture, qualities of wine and the ways they may be affected, adulterations, both admissible and inadmissible, and analyses of musts and wines. The book has a complete table of contents, but no index.

Wine making based upon the properties of grape oxydase, A. BOUFFARD and L. SEMICHON (*Ann. École Nat. Agr. Montpellier, 10 (1898), pp. 37–89, figs. 2*).—The authors claim that by the proper use of oxydase and a little sulphuric acid almost any color of wine may be produced. Under some conditions oxydase may prove injurious to wine making.

Recent progress in vinification, A. LOIR (*Rev. Sci., 4. ser., 11 (1899), No. 17, pp. 526–529*).

Washing cider apples, TRUELLE (*Mess. Agr., 4. ser., 10 (1899), No. 5, p. 164*).—If a lot of cider apples are washed and the water filtered, an ill-smelling filtrate is often obtained. This residue would have given a bad taste to cider. In washing, the fruit loses some pectins, a little sugar, traces of tannin, and some of its ferments; hence cider from washed fruits ferments slowly at first, but the rapidity of fermentation accelerates under favorable conditions. It is recommended that baskets of fruit be placed in a stream of water and then be allowed to dry before pressing. The process is much used in Germany, Austria, and Switzerland.

Cost of construction and operation of cotton-seed oil mills; value and uses of oil, meal, and hulls, B. W. KILGORE (*Tradesman, 41 (1899), No. 8, pp. 55, 56*).

Oil seeds and cotton oil, WAGNER (*L'Engrais, 14 (1899), No. 9, pp. 208–210*).

AGRICULTURAL ENGINEERING.

The construction of a stave silo, L. A. CLINTON (*New York Cornell Sta. Bul. 167, pp. 173–188, figs. 7*).—After three years' study and observation the author concludes that the round stave silo "is the most practical and successful silo which can be constructed." The original cost is very slight, as no expert labor is required, and the maximum of capacity is secured with the minimum of material. The bulletin gives a detailed explanation of the construction of a stave silo, based largely upon experience with such a silo built at the station in 1898.

Irrigation in Colorado, J. SHOMAKER (*Irrig. Age, 13 (1899), No. 1, pp. 7–10*).—A brief review of history and present status.

Irrigation in Wyoming, J. SHOMAKER (*Irrig. Age, 13 (1899), No. 2, pp. 41–44*).—A brief review of history and present status.

Market garden irrigation (*Amer. Agr. (mid. ed.), 63 (1899), No. 24, pp. 747, 748*).

Usefulness of reservoirs to agriculture in the irrigated regions, E. MEAD (*Senate Doc. 124, 55. Congress, 3. Session, pp. 14, figs. 2*).—A brief discussion of the subject submitted in response to a resolution of the Senate of the United States.

Unprofitable irrigation works, T. S. VAN DYKE (*Irrig. Age, 13 (1899), Nos. 1, pp. 11–16; 2, pp. 44–50*).—These are the fifth and sixth papers of this series.

Water rights according to the explanations of the civil department of Cassation of the Senate, D. FLEXOR (*St. Petersburg: Min. of Agr. and Imp. Domains, Div. of Land Amelioration, 189–, 2. ed., pp. XII + 151*).

Agricultural machinery in Denmark, 1898, C. V. BIRK (*Tidsskr. Landökon., 1899, No. 4, pp. 223–232*).

Third annual report of the Provincial Instructor in Roadmaking, Ontario, 1898, A. W. CAMPBELL (*Pp. 80, figs. 13*).—Brief notes on a variety of topics.

A cow barn with framework of steel (*Irrig. Age, 13 (1899), No. 2, pp. 64–68, figs. 6*).—An illustrated description of a barn built on the grounds of the Hospital for the Insane at Middletown, Connecticut.

Dairy buildings, R. HENDERSON (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 39-115, figs. 41*).—This article discusses in considerable detail, with numerous illustrations, the arrangement, plan, materials, and construction of cow stables, milk houses, churning rooms, cheese rooms, dairy offices, pig and poultry houses, manure pits, sculleries, etc. Special attention is given to the question of ventilation.

A barn for cattle feeding, J. E. WING (*Breeders' Gaz., 35 (1899), No. 15, p. 451, figs. 2*).

The new poultry house and other buildings at the New York State Station (*New York State Sta. Bul. 153, pp. 316-319, figs. 4*).—Brief illustrated descriptions are given of a poultry house, piggery, and manure shed.

STATISTICS—MISCELLANEOUS.

Thirteenth Annual Report of Alabama Canebrake Station, 1898 (*Alabama Canebrake Sta. Rpt. 1898, pp. 16*).—Brief notes are given on tests of field crops and vegetables, noted elsewhere, and on insecticides and fungicides, together with a financial statement for the year ending December 31, 1898.

Ninth Annual Report of Arizona Station, 1898 (*Arizona Sta. Rpt. 1898, pp. 151-189*).—This includes the treasurer's report for the fiscal year ending June 30, 1898; a report of the acting director on the personnel, equipment, work of the station, and station publications, and reports of the botanist, chemist, and agriculturist and horticulturist, noted elsewhere.

Eleventh Annual Report of Arkansas Station, 1898 (*Arkansas Sta. Rpt. 1898, pp. 100*).—A financial statement for the fiscal year ending June 30, 1898, with a brief report by the director and reprints of Bulletins 19-55 of the station on the following subjects: Preliminary report on Arkansas seedling apples (E. S. R., 10, p. 48); second-crop potatoes for seed (E. S. R., 10, p. 542); methods of combating communicable diseases of farm animals (E. S. R, 10, p. 595); the feeding value of whole cotton seed, crushed cotton seed, and cotton-seed meal and hulls for finishing steers for market (E. S. R., 10, p. 673); a report of progress of investigations in the chemistry of wheat (E. S. R., 10, p. 943); fattening value of certain foods gathered by pigs (E. S. R., 10, pp. 1085, 1089); orchard cultivation (E. S. R., 10, p. 1044).

Eleventh Annual Report of Louisiana Stations, 1898 (*Louisiana Stas. Rpt. 1898, pp. 8*).—This contains a report of the director on the work of the Sugar Station at Audubon Park, the State Station at Baton Rouge, and the North Louisiana Station at Calhoun; the staff of each station; a subject list of bulletins issued during the year, and a financial report for the fiscal year ending June 30, 1898.

Eleventh Annual Report of Maryland Station, 1898 (*Maryland Sta. Rpt. 1898, pp. 169-176*).—This contains a brief outline of the work of each department, a list of the publications issued during the year, notes on the station staff, a meteorological summary for 1897, and a report of the treasurer for the fiscal year ending June 30, 1898.

Fourth Annual Report of Montana Station, 1897 (*Montana Sta. Bul. 16, pp. 53-100, figs. 2, dgm. 1*).—Contains a financial statement for the fiscal year ending June 30, 1897, and reports by the director, horticulturist, chemist, biologist, and agriculturist. The report of the horticulturist is noted elsewhere, and that of the chemist contains an illustrated description of the new chemical building erected at the station.

Director's report for 1898, W. H. JORDAN (*New York State Sta. Bul. 153, pp. 303-332, pls. 12, dgms. 4*).—This includes brief notes on the personnel of the station; descriptions of the new biological and dairy building (E. S. R., 10, p. 401) and the new poultry house (see above), and notes on other building improvements; a discussion of the relation of the station staff to farmers' institute work; a review of the work of the departments of chemistry, horticulture, botany, entomology, and animal industry for the year; and a subject list of Bulletins 143-157 published in 1898.

Proceedings of Agricultural Students' Association, 1898-99 (*Nebraska Sta. Bul. 57, pp. 27-56*).—The constitution and by-laws of the association and the minutes of the first annual meeting held March 10, 1898, are given. Experiments with smooth brome grass are noted elsewhere. Plans for future work in agriculture, botany, entomology, horticulture, etc., are suggested.

Experiment Station Work—IX (*U. S. Dept. Agr., Farmers' Bul. 92, pp. 30*).—The following subjects are treated in this number: Sugar beets on alkali soils, planting and replanting corn, improvement of sorghum, improved culture of potatoes, second-crop potatoes for seed, cold *vs.* warm water for plants, forcing head lettuce, the date palm in the United States, the codling moth, Jerusalem artichokes for pigs, feeding calves, pasteurization in butter making, gassy and tainted curds, and pure cultures in cheese making.

The past and future of Scottish agriculture, A. HUTCHESON (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 121-149*).

Bulletins of Alabama Station (*Index to Vol. VI, Buls. 89-100*).

Wisconsin farmers' institutes, 1898 (*Wisconsin Farmers' Institutes Bul. 12, pp. 270, figs. 76*).—This is a report of the twelfth annual closing farmers' institute held at Janesville, March 8, 9, and 10, 1898, and includes some 37 popular addresses, with discussions.

Address and report read at the annual meeting of the Moscow Agricultural Institute September 26, 1898 (*Moscow, 1898, pp. 136; abs. in Selsk. Khoz. i Lyesov., 192 (1899), Mar., pp. 709, 710*).—There were in the institute at the close of the academic year 1896-97 182 students. Of this number 44 graduated. The cost of maintenance of the institute in that year amounted to 186,000 rubles (about $74,000).—P. FIREMAN.

Agricultural returns for Great Britain for 1898, P. G. CRAIGIE (*London: Wymen & Sons, 1899, pp. LIV+267*).—This report shows the acreage and produce of crops, prices of grain, and number of live stock, with agricultural statistics for the United Kingdom, British possessions, and foreign countries.

Agricultural conditions in the Russian Baltic Provinces, L. FRIIS (*Tidsskr. Landökon., 1899, No. 3-4, pp. 164-194*).

Our foreign trade in agricultural products, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 15, pp. 45*).—A statistical review of the agricultural imports and exports of the United States during the five fiscal years 1894-1898. In 1898 the agricultural imports amounted to $314,291,796, which was over 51 per cent of the total imports, and the agricultural exports to $858,507,942, or about 71 per cent of the total exports. Among the exports showing an increase in 1898 were wheat, corn, oats, rye, bacon, lard, hams, pickled pork, cotton-seed oil, oil cake and oil-cake meal, cattle, and horses, and among those showing a decrease were leaf tobacco, barley, canned beef, salted or pickled beef, hides and skins, and butter. Of the imports coffee, hides and skins, silk, and vegetable fibers showed an increase in 1898, and sugar, wool, tea, leaf tobacco, fruits, wines, vegetable oils, spices, and distilled spirits showed a decrease.

Agricultural imports and exports, 1894-1898, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Circ. 21, pp. 15*).—Statistical tables reprinted from Bulletin 15 of the Section, noted above.

The sugar industry and its requirements, E. DENMAN (*Queensland Agr. Jour., 5 (1899), No. 2, pp. 110-116*).—Paper read by the author before an agricultural conference, dealing with the sugar industry of Queensland and in other sugar-producing countries of the world.

The work of the Imperial Russian Society for the acclimatization of animals and plants, N. F. ZOLOTNITSKY (*Moscow: Min. Agr. and Imperial Domains, 1899, vol. 7, pt. 1, pp. 192; abs. in Selsk. Khoz. i Lyesov., 193 (1899), pp. 713, 714*).

Proceedings of the Portuguese Royal and Central Agricultural Association, 1897-98 (*Travoux executés de 1897-98 par l'association royale et centrale d'agriculture portugaise. Lisbon: Typographie Portugaise, 1899, pp. 111*).

NOTES.

Alabama College Station.—W. B. Frazer has recently been added to the station staff as assistant in horticulture, and A. McB. Ransom has been elected third assistant chemist. The new chemical laboratory, designed exclusively for research work, is rapidly nearing completion. It is a commodious brick structure with stone trimmings, containing one story and basement. It is well lighted and ventilated, and will be furnished with all the appliances of a well-ordered laboratory. As soon as it is completed it will be occupied as the experiment station laboratory, while the older building will be given over exclusively to college work.

Connecticut College.—The name of this institution has been changed from Storrs Agricultural College to The Connecticut Agricultural College.

Connecticut State Station.—A. L. Winton, after 15 years of continuous service, has been given 6 months' leave of absence, which he will spend in travel and study in Europe. W. L. Mitchell has resigned to take a position as chemist in a manufacturing establishment, and Clifford Langley, a graduate of Yale University, has been added to the staff as assistant chemist.

Illinois Station.—The station has recently made an extensive exhibit at the Decatur Corn Carnival of experiments in Indian corn, which attracted much attention and brought the work of the station prominently before a large number of people.

Iowa College and Station.—H. H. Hume, formerly assistant in the departments of botany and horticulture at the station, has recently been elected horticulturist and botanist in the Florida College and Station. C. R. Ball, formerly assistant in botany at the college and station, has been made third assistant in the Division of Agrostology of the U. S. Department of Agriculture.

Kansas Station.—R. B. Mitchell, assistant in the veterinary department of the station, has resigned to accept an appointment in the U. S. Army.

Maryland College and Station.—F. P. Vietch, M. S., has been appointed assistant soil physicist, and will work with Professor Whitney, in Washington, D. C.; Thomas M. Price, a graduate of the college, has been appointed assistant chemist, and H. P. Gould has been appointed assistant entomologist to succeed E. D. Sanderson, resigned. W. T. L. Taliaferro, professor of agriculture in the college, will be connected with the station in the capacity of agriculturist, and C. F. Doane, assistant in dairying and bacteriology at the station, will serve in the college as instructor in dairying during the coming year.

Nebraska University and Station.—R. S. Hiltner, assistant chemist of the station, has resigned to accept a position in the department of chemistry of the university, and R. W. Thatcher has been appointed to fill the vacancy on the station staff. E. A. Burnett, formerly in charge of animal husbandry in the South Dakota College and Station, has been appointed to a similar position in this university and station.

New Hampshire Station.—Arthur Given has resigned his position as assistant chemist, and Roscoe H. Shaw, B. S., and Harry A. Clark, B. S., have been appointed assistant chemists. E. H. Forristall has resigned as assistant in agriculture to become superintendent of the farm and herd of the Walker Gordon Company, of Boston, Mass. He has been succeeded by H. P. Richardson, B. S.

New Jersey Stations.—John B. Williams, of New Durham, has been appointed a member of the governing board, *vice* Abraham W. Duryee, deceased.

New Mexico Station.—P. Moreno, of Las Cruces, and L. Bradford Prince, of Espanola, have been appointed members of the governing board, *vice* J. Armijo, deceased, and H. D. Bowman, resigned. C. H. Tyler Townsend has retired from the station staff. A series of weekly press bulletins prepared by the agricultural and horticultural department are being widely distributed throughout the Territory and seem to be much appreciated.

North Carolina College and Station.—J. A. Bizzell, assistant chemist, has retired from the station work and will devote his whole time to teaching. B. S. Skinner, farm superintendent, has also retired from station work.

North Dakota Station.—W. C. Langdon has resigned his position as veterinarian of the station. His successor has not yet been appointed.

Pennsylvania Station.—M. E. McDonnell, who recently returned from Europe, where he had pursued a course in dairy bacteriology, and was appointed assistant bacteriologist in the college and station, has resigned to become bacteriologist to the Pennsylvania Railroad Company, with headquarters at Altoona. J. D. Huston, fellow in dairy husbandry; W. A. Hutchison, fellow in agricultural chemistry, and A. O. Hiester, special assistant, are no longer connected with the station.

Rhode Island College.—The prospectus for the second special winter course of study and training in poultry culture has been issued. The course occupies six weeks and will commence January 10, 1900.

South Carolina College and Station.—C. C. Newman has been appointed assistant horticulturist, to fill the vacancy caused by the death of J. F. C. Du Pre. During the past summer the board has erected a veterinary hospital at a cost of $750. It is a two-story structure, 30 by 48 ft., with a basement 18 by 30 ft. The latter is divided into dissecting and post-mortem room, 18 by 18 ft., and fireproof room for alcoholic specimens, combustibles, etc., 12 by 18 ft. On the first floor are rooms for office, pharmacy, operating, and horseshoeing. On the second floor is a room for hospital attendant, space for feed bins, dog kennels, and poultry cages. The building is to be supplied with sewerage, water, and electric lights. It will be used in common for college and station purposes. In the agricultural division of the station interesting results are being obtained in cross breeding and hybridizing cotton, melons, etc., and special studies are being made of rice and its products by the chemical and botanical departments.

Tennessee University and Station.—Charles E. Chambliss, entomologist; J. B. McBryde, chemist, and R. L. Watts, secretary and horticulturist, have resigned from the staff. Mr. Watts is now engaged in commercial fruit culture in Pennsylvania. Charles A. Mooers, recently chemist at the North Louisiana Station, and former assistant chemist at the Tennessee Station, has been elected chemist. The agricultural department has been organized into three divisions, with an expert in charge of each, namely: Division of field plats, Phares O. Vanatter; division of feeding and dairy husbandry, George A. Flickinger, and division of practical agriculture, John R. Fain. Experiments are in progress in feeding dairy and beef cattle. Variety tests of wheat and forage crops, and experiments with green manure and artificial fertilizers are being carried on; also pot experiments to study the influence of lime on the Tennessee soils, and plat experiments to show the importance of seed selection. With the aid of the Office of Road Inquiry of this Department a half mile of macadam road is being constructed. A new course has been organized in agriculture, and a short course of twelve weeks will be introduced this winter for the first time. The agricultural department is compiling a handsome handbook for farmers. A new barn has just been completed at a cost of $5,000. This barn, which measures 56 by 88 ft., is provided with cement floors, triple silos, and complete arrangements of all kinds for experiments in feeding, etc. It consists of five distinct departments—the dairy stable, the horse stable, the silos, the storage barn, and the tool and implement sheds.

Texas College.—Charles H. Alvord, B. S., of the Michigan Agricultural College, has been elected to the position of assistant professor of agriculture in the college, vacated by A. M. Soule.

UTAH STATION.—U. P. Hedrick, horticulturist and botanist of the station, has become assistant horticulturist at the Michigan Agricultural College, and has been succeeded by C. P. Close, of the New York State Station.

VIRGINIA COLLEGE AND STATION.—The board of control has been reorganized and is now constituted as follows: C. E. Vawter, of Miller School; John Thompson Brown, of Brierfield; B. R. Selden, of Richmond; D. M. Cloyd, of Dublin, and J. M. McBryde (*ex officio*), of Blacksburg. A. T. Eskridge, assistant chemist, has been transferred to the college and made instructor in analytical chemistry, leaving W. B. Ellett the sole assistant chemist to the station.

WISCONSIN UNIVERSITY AND STATION.—J. A. Jeffery, assistant in agricultural physics in the university and station, has resigned to assume charge of the department in his line at the Michigan Agricultural College. At the September meeting of the board of regents Andrew Robinson Whitson, B. S., a graduate of the University of Chicago in 1894, was elected to succeed Professor Jeffery. He will begin active duties in the department of physics in the agricultural college in May, 1900, the intervening time being spent in special study in preparation for his work. J. W. Decker, instructor in cheese making, has resigned to assume charge of the dairy department of the Ohio State University.

AGRICULTURAL EXPERIMENT STATION AT CHOJNOWO, POLAND.—An association of thirty land holders has been formed to organize an experiment station in Chojnowo. The special objects of the station will be soil studies, including analyses and vegetation experiments, the examination of fertilizers, feeding stuffs, and seeds; field experiments, and seed production. The station will have a field of about 55 acres of land at its disposal, and a revenue of about 4,000 rubles (about $1,600) the first year. The management of the station will be in the hands of a board of five persons, with Dr. Casimir Rogóyski as director.

EXPERIMENT STATION FOR MILLING.—A new departure in the line of experiment stations is one for milling products, recently established at Berlin in connection with the Imperial Agricultural High School. Among the important objects of the station are the examination of flour, mill products, and bran for official purposes and for private parties, the analysis of oil cakes and other feeding stuffs for individuals, the furnishing of advice to millers and bakers, and the testing of implements. Investigations are to be made on such problems as the effect of storage of flour on its baking qualities, cause of differences in baking qualities of flours from different kinds of wheat, occurrence of diastases in flours, fixing of types of flours, etc. The director of the station is Prof. L. Wittmack, professor of agricultural botany in the agricultural high school. The management of the station is in charge of a board, of which Dr. Traugott Mueller, of Berlin, is chairman.

MISCELLANEOUS.—The Sixth International Congress of Agriculture will be held at Paris in connection with the Exposition of 1900 from the 1st to the 8th of July of next year. The congress will comprise the following sections: Rural economics, agricultural education, agronomy, breeding and care of live stock, agricultural engineering, special crops of southern France and the French colonies, and measures against parasites and for the protection of useful animals. Detailed information concerning the congress may be obtained from Henry Sagnier, general secretary of the commission of organization, Rue de Rennes 106, Paris.

An international congress for the rational feeding of animals will be held at Paris June 21-23, 1900, at which the following subjects are to be considered: Milk substitutes for feeding calves for breeding and for veal; influence of food on the fat content of milk; the rôle of saccharine materials in nutrition—use of molasses and sugar in the feeding of animals; importance of relative proportions of nitrogenous and nonnitrogenous materials in the rations of work animals; sale and purchase of feeding stuffs according to analysis—control of feeding stuffs, silage, and methods of desiccation for preserving feeding stuffs having a high water content (beets, potatoes, forage, etc.). Preliminary papers on the above subjects are requested and will be received by a committee, of which G. Gallo, Rue de la Victoire 69, Paris, is the secretary.

The annual meeting of the Association of Agricultural Experiment Stations in the German Empire was held at Munich September 16 and 17, 1899.

PERSONAL MENTION.—J. I. Schulte, editor of the department of field crops of this journal, has taken leave of absence for a year to continue his studies in France, especially with Prof. P. P. Dehérain, at Grignon.

Dr. W. Somerville, professor of agriculture and forestry at the College of Science, Newcastle-upon-Tyne, in connection with the University of Durham, has been elected to the new professorship of agriculture in Cambridge University.

G. Poirault has been appointed the successor of the late C. Naudin as director of the laboratory at Villa Thuret, at Antibes.

Prof. J. Kühn, of Halle, Germany, is making a study of some of the diseases of rye, and requests fresh material of *Tilletia secalis*.

A biographical sketch of the late Dr. E. Lewis Sturtevant, by C. S. Plumb, is given in the Tenth Annual Report of the Missouri Botanical Garden. A list of about 100 titles of articles is appended as a bibliography of his writings.

T. Francis Rivers died at his home in Sawbridgeworth, England, August 17 at the age of 68. He was widely known as the introducer of a large number of new varieties of peaches, nectarines, plums, pears, etc., many of which bear his name. At the time of his death he was chairman of the British Fruit Growers' Association.

Edward Frankland, the eminent English chemist, widely known for his work on water analysis, died recently while traveling in Norway, at the age of 75 years.

Prof. P. Freda, director of the agricultural chemical experiment station at Rome, died June 4, 1899, at the age of 43 years.

Henry Lévêque de Vilmorin, the eminent horticulturist, plant-breeder, and commercial seedsman, died August 23, 1899, at his home at Verrières le Buisson, Seine et Oise, France, at the age of 56. His death was sudden and was due to cerebral congestion.

Dr. G. de Chalmot, of Holcomb Rock, Va., died October 9, 1899. Although for a number of years past engaged in industrial chemistry, it will be remembered that during his connection with the Virginia State board of agriculture as chemist Dr. de Chalmot published a number of valuable papers on agricultural chemistry, notably on the pentoses and other carbohydrates.

EXPERIMENT STATION RECORD.

VOL. XI. No. 4.

An examination of the bulletins and reports of the experiment stations shows something of a dearth of veterinary literature, especially such as relates to investigations. Twenty-seven stations employ veterinarians or persons who are engaged in work on animal pathology related to veterinary science. In four cases the veterinarians are not carried on the rolls regularly but are consulting experts. Of the 4,000 reports and bulletins issued by the stations since their organization only about 325 are upon veterinary subjects, and a considerable proportion of these are largely popular bulletins representing little if any investigation. Nearly one half have been devoted to the subjects of dehorning, anthrax, glanders, hog cholera, swine plague, Texas fever, and tuberculosis. The last-mentioned disease has been discussed in about 60 bulletins. A large part of the work on tuberculosis has been confined to making tuberculin tests and reporting the results. From a practical sanitary standpoint this is very important, and taken as a whole it has taught many valuable facts regarding the proper use of the test and its practical application.

The stations have recently taken much interest in the prevention of such diseases as glanders, hog cholera, Texas fever, anthrax, and blackleg, in cooperation with the Bureau of Animal Industry of this Department, and have materially assisted in demonstrating the practicability of using new means for their prevention in general farm practice. In some cases valuable original work has been done by the station veterinarians along these lines. It is much to be desired that efforts to extend the use of serums, antitoxins, and other new methods for the treatment and prevention of animal diseases shall be accompanied by investigations to increase our knowledge regarding these diseases and their treatment.

With regard to the question as to how far the stations are warranted in undertaking to prepare the various antitoxins and serums for general distribution to stockmen, it would seem that the same rule should apply as in other departments of station work, e. g., that after the matter has passed the stage of experiment and demonstration it should be left to private enterprise, unless State funds are specially provided which can be used for the employment of assistants, so that the regular investigations may proceed without hindrance or interruption. As in other lines of station work, the idea that the veterinary department is for investigation rather than for inspection, general practice, preparation of remedies, etc., should be kept prominent.

There are several lines of work which especially seem to demand more attention than they are receiving at present. Some of these relate to the common contagious diseases of stock. It is perhaps desirable, for instance, to determine by actual experiments as nearly as possible the exact method of transmission of various contagious diseases. The causes of apparently isolated outbreaks of contagious diseases are not well enough understood. Incubation periods can often be determined more accurately. There are local conditions in each State which introduce new factors into the problem of every disease. These factors should be experimentally measured. In the case of milch cows especially there is needed a more definite experimental knowledge of the extent to which pathogenic organisms are transmitted.

The subject of disinfection, so intimately connected with the control and prevention of disease, presents a good field for some extremely useful work. The experimental knowledge bearing on this subject rests too largely on work performed under conditions quite different from those which ordinarily surround the stock farm or even the stables of an experiment station. Effective disinfection under these conditions is far more difficult and uncertain than in operations in human surgery or in the case of human habitations. In stables and barns rough surfaces are always to be found, usually very extensive in area, and various articles which are not easily disinfected. Disinfectants for this purpose should be of particularly high penetrating power and of active germicidal qualities. It is frequently necessary also to disinfect barnyards or paddocks which have become infected. The extent of surface and material to be disinfected requires large quantities of the disinfecting substances, and the expense of the ordinary disinfectant becomes an important practical consideration. It would seem that experiments undertaken with the object of determining the penetrating power and germicidal effectiveness of different disinfectants under different farm conditions might remove considerable of the uncertainty attending their use, and perhaps suggest more effective and practicable methods for the stockman in disinfecting his premises.

In connection with feeding experiments upon animals it is often observed that certain substances used as fodder have a beneficial or other effect upon the animal's health, but such observations are usually merely incidental and are not made in any systematic way. Especially in intensive feeding, the effect of the system of feeding on the general health of the animal may well be studied. In this way the work of the feeder and the veterinarian may often go hand in hand, and may bring forth results of much practical value.

In human medicine the study of the best sanitary methods is perhaps of fully as great importance to the welfare of human beings as the study of pathology and curative agents, and this is equally true when applied to domestic animals. The rules concerning animal hygiene and sanitation found in treatises on the subject of animal diseases are too often based upon conjectures or very insufficient data, and in many cases are drawn from the analogies of human sanitation. The great economical importance of animal industry warrants systematic investigation on this subject of hygiene and sanitation as applied to domestic animals, and the effects of the various factors of temperature, ventilation, food, water, exercise, etc., on the health of the animal and its ability to resist or withstand disease.

There is also a useful field for investigation on poisonous plants, especially in regions where range feeding is practiced and these plants are quite numerous. This is illustrated by the varied and contradictory opinions as to the nature and cause of so-called "loco" poisoning. Large losses of stock occur every year which are usually attributed to the poisonous effects of some plants, and which have not been definitely referred to known diseases. The effects upon stock of the smuts and ergot eaten with grasses and cereals are not clearly understood. Plants reputed to be poisonous are not always dangerous at all stages of their growth. Very few exact experiments have been made on this subject, and the general information is largely a matter of tradition or conjecture. There is good opportunity here for a useful line of experiments, and these experiments can best be made in the region where the trouble exists and where fresh material can be obtained.

Not every station can afford to take up veterinary work, as it involves an expensive equipment, and much of the investigation is in itself necessarily quite expensive. Where it is made a feature of the work, it seems the part of wisdom to devote sufficient funds to the department to make it a strong one and enable it to undertake investigations in a serious way. Some excellent pieces of work have been done by station veterinarians, and they should not be content to have their departments given over largely to the holding of clinics, giving of advice to stock owners, and police work, but should strive to raise the grade of their work. There are many large problems in every State for the solution of which the stockmen naturally look to the station, and in the end the most widespread benefit and the fullest recognition will come from larger devotion to these more fundamental problems.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

A new method of ash determination, A. E. SHUTTLEWORTH (*Inaug. Diss., Göttingen, 1899, pp. 46, figs. 3*). Reported by B. Tollens (*Jour. Landw., 47 (1899), No. 2, pp. 173–200, pl. 1*).—An account of an investigation conducted in the laboratory of B. Tollens. The author found that the ash prepared by careful incineration in a muffle furnace at a low temperature was not completely extracted by hydrochloric acid, as shown by the high and varying percentage of silicic acid. Heated at a higher temperature the substance slagged or the ash smelted, thus preventing the complete action of the hydrochloric acid. A series of analyses of materials containing definite amounts of silicic acid and small portions of potassium and calcium carbonates showed that the residue insoluble in hydrochloric acid ("silicic acid") is frequently too high, the error increasing with the temperature at which the incineration was made.

Experiments were undertaken to prevent this formation of silicates undissolved by hydrochloric acid, which resulted in the adoption of acetate of lime for this purpose. This substance when mixed with the material to be incinerated was found to prevent slagging or smelting, even when the material was incinerated at a high temperature. The lime also hastens the incineration. The acetate of lime is used in the form of a solution containing about 0.2067 gm. of CaO in 20 cc. Usually about 20 cc. of the lime solution is used, although in some cases more is required. An excess does no harm. Data are given showing the advantage from the use of calcium acetate, and the method of preparing it is described.

The loss of chlorids in incinerating by the ordinary method was also studied, and it was found that this may be considerable, increasing with the heat used. For instance, the ash of a sample of oat straw when prepared with the greatest care contained 18 per cent of potash, while the ash of the same straw obtained by heating in a muffle at a high temperature contained less than 6 per cent of potash.

The author describes and illustrates an apparatus which he has devised to simplify the incineration and prevent losses. The apparatus, which is of platinum and weighs 70 gm., allows a current of air to be conducted through it and, in case it is desired, the determination of the carbonic acid directly in the apparatus without transferring the ash to a special carbonic-acid apparatus. In this apparatus, with the use of acetate of lime a substance can be completely incinerated without smelting or volatilization in less than 4 hours. The ash is weighed in the apparatus, so that the danger from absorption of moisture from the air is avoided.

The plan of the apparatus is shown in fig. 1, in which *f* is the deep platinum dish, the principal part of the apparatus; *e*, a tube with arms *e''* for stirring, and *e'* a small flat dish fastened to it. *d* is the cover, to which the cylinder *d'* bearing the outer cylinder *b* is soldered. *c* is a tube connecting at *x* with the tube *e* and carrying a shallow dish above the top of the cylinder *d'*. *a* is a cover fitting tightly over *b*, with a hole in the center for the tube *c*. The tube *c e* conducts air into the apparatus, and serves as a stirrer when rolled between the thumb and finger. The shallow dish at *c* is filled with distilled water to prevent the heating of the tube and to keep the outlet to the apparatus moist. Any portions of the ash which are carried along by too strong an air current are arrested in the cylinder *d'* or at the moist outlet.

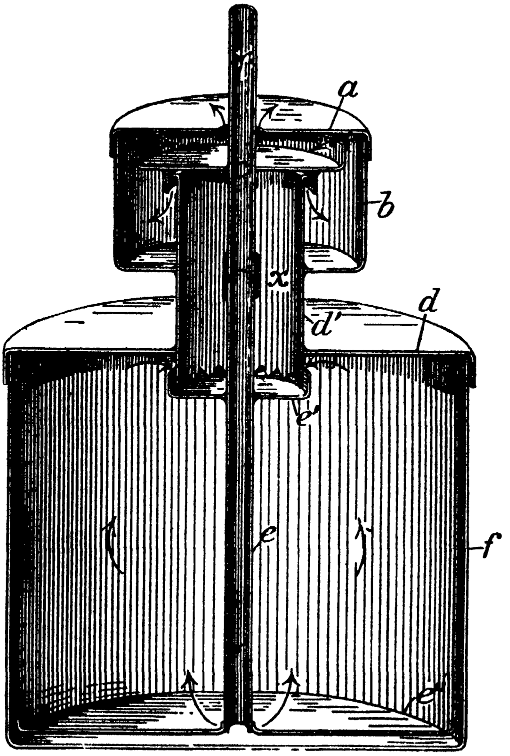

Fig. 1 —Apparatus for ash determination.

An especially constructed oven for the ash apparatus is described, together with the arrangement for carbonic acid determination.

Some notes on the estimation of carbohydrates, F. W. Traphagen and W. M. Cobleigh (*Jour. Amer. Chem. Soc., 21 (1899), No. 4, pp. 369–373*).—The authors present the following volumetric method for the determination of the reduced copper:

"One hundred cubic centimeters of Fehling's solution is diluted with 100 cc. of water and heated in a boiling-water bath. A known amount of sucrose or starch, contained in carefully analyzed samples which are as nearly as possible like the substance under analysis, is inverted. These solutions are used with similar solutions containing approximately known amounts of sucrose or starch. The amounts taken in each case are such that the precipitated cuprous oxid is nearly identical in weight. The precipitated cuprous oxid is collected on a Hirsch funnel covered with asbestus felt. After washing thoroughly with water the top layer of the asbestus carrying most of the cuprous oxid is transferred with a platinum spatula to the beaker in which the precipitation was made. The remaining asbestus is moistened and the cuprous oxid adhering to the side of the funnel is easily rubbed off. Water is added and the mass thoroughly stirred. Fifty cubic centimeters of a saturated solution of ferric sulphate in 20 per cent sulphuric acid is added. After the cuprous oxid is dissolved, filter on the same funnel, thus leaving it ready for another filtration. The solution is then ready for titration with potassium permanganate. The end reaction is clear and definite."

An electrical method for the determination of nitrogen, in organic substances, C. C. L. G. BUDDE and O. V. SCHOU (*Ztschr. Analyt. Chem., 38 (1899), No. 6, pp. 344–348, fig. 1*).—The authors give a preliminary description of an apparatus in which nitrogen is determined as in the Kjeldahl method, but with the aid of electrolysis. The digestion flask is made from a bulb tube (bulb of 50 to 100 cc. capacity) by closing one arm of the tube so as to form a depression of about 10 cc. capacity at the bottom of the bulb. The electrodes are placed in this depression with the substance, the anode being a piece of platinum foil bent into a cylinder, and the cathode a platinum wire hammered out flat. A pair of copper wires, each encased in glass tubing, extend through the neck of the flask nearly to the bottom, and the connections from the electrodes are fused into these tubes, the contact with the copper wires being made with mercury. The substance is mixed with 4 cc. of fuming and 8 cc. of concentrated sulphuric acid, and treated to an electric current for about three-quarters of an hour, when the liquid is usually colorless. At first a weak current is passed, but it is gradually increased to about 10 amperes and the liquid becomes strongly heated. After cooling, the acid is neutralized and the ammonia distilled off as usual in the Kjeldahl method.

The method is believed to possess marked advantages over the ordinary digestion, and does not require the addition of any foreign substance. A table shows that it usually gave results nearer the theoretical than the ordinary Kjeldahl method.

The Kjeldahl method of sugar determination, and the reducing power of cane sugar, G. BRUHNS (*Ztschr. Analyt. Chem., 38 (1899), No. 2, pp. 73–96*).—This is a critical investigation of Kjeldahl's method,[1] especially from the point of the sugar chemist. In this method the required quantity of Fehling's solution and the sugar solution are mixed in an Erlenmeyer flask, diluted to 100 cc., a current of hydrogen conducted through, and the solution heated for 20 minutes on a boiling water bath, after which the cuprous oxid is filtered off and weighed. The method is the same for all kinds of sugar, and does not necessitate the preparation of different Fehling solutions and the observance of special directions for each kind of sugar.

---

[1] Ztschr. Analyt. Chem., 35 (1896), p. 344.

The author found, however, that the method is not suitable when a large amount of cane sugar is present. Whether cane sugar in small quantity was a disturbing factor was not determined, but as it is a very common constituent of foods it will often prevent the use of the Kjeldahl method.

A method of analysis for canned condensed milk, F. S. HYDE (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 439–444*).—A stock solution is prepared by diluting 25 gm. of the condensed milk with 75 cc. of water, which gives approximately 100 gm. of solution of very nearly the consistency of cow's milk. The determinations of solids, fat, and sugar are made in this stock solution by usual methods, weighing out the sample in each case instead of measuring. Citric acid is used for inverting the cane sugar, the author finding that this acid "usually does not produce coagulation in condensed milk solutions even on boiling." The degree of condensation is determined "by dividing the percentage of milk solids in the condensed milk by 12.5 per cent, the average of ordinary cow's milk."

The author gives analyses of a number of samples of condensed milk. "The amount of cane sugar averages between 30 and 40 per cent, and the fat below 12 per cent, which is not surprising in a manufactured article. In the so-called evaporated milks or creams, the cane sugar is usually absent."

On the experimental error involved in sampling crops, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1898, pp. 155–159*).—In connection with an investigation of the influence of fertilizers on the composition of corn and potatoes (see p. 336), a study was made of the experimental error involved in sampling the crops. In 1896, each of the $\frac{3}{7}$-acre plats of corn was divided into two parts, each part being weighed separately, and samples averaging 325 lbs., or over 6 per cent of the crop, taken from each part. These samples were husked separately and the stalks and ears weighed. The sample from one part of each plat was subsampled by taking the ears and stalks separately, and that from the other part by cutting stalks and ears up together and then sampling the mixed mass. Four subsamples of 6 lbs. each were taken from each part, and these were rapidly dried in a fodder drier at 60 to 90° C. Dry matter determinations were made in 4 samples each of the whole plant, stover, and ears from each plat, and analyses were made of the combined samples in each case.

In 1897 the same general plan was followed, except that the entire crop on each part was used as a sample, and a larger number of subsamples was taken.

Each of the 114 rows of potatoes was weighed and sampled separately, great care being taken to make the samples representative. The samples averaged about 12 lbs. each, representing over 10 per cent of the entire crop.

Data of analyses of 184 samples are reported and discussed.

"While on the whole variations between the composition of crops differently fertilized are somewhat more marked than those between different samples from the same plat, yet they are not so pronounced as to admit of safe conclusions being drawn as to the effect of fertilization, unless results are quite positive and several samples are taken from each plat.

"No definite statement of the extent of the experimental error involved in single samples can be made. A careful comparison of the figures [reported] indicates, however, that the mean maximum variation of single samples from truth (average of several samples) lay (with the exception of ether extract) between 10 and 15 per cent. When several samples represent each plat the extent of the experimental error is proportionately minimized."

A contribution to the chemistry of butter fat: I, The physical and chemical constants of butter fat, C. A. Browne, Jr. (*Jour. Amer. Chem. Soc., 21 (1899), No. 7, pp. 612–633*).—The results of the examination of a considerable number of samples of butter fat, together with the methods employed, are given. "Nearly all of the analyses were of samples of butter made at the [Pennsylvania] Station creamery, and representing for the most part the product of a herd of high-grade Guernseys. The figures given in the tables accompanying this article need not be taken, therefore, as typical of butter fats in general, though we believe them to be, on the whole, fairly representative."

The range and means for some of the constants are given in the following table:

Physical and chemical constants of butter fat.

Constant.	Range.	Mean.	Number of samples represented.
Specific gravity, $\frac{40^\circ}{15.5^\circ}$	0.9050–0.9102	0.9073	35
Melting point	31.6°–34.6°	33.2°	35
Acid number	0.20–0.66	0.50	5
Saponification number	224.0–234.9	228.5	40
Ether number [a]	223.5–234.4	228	40
Iodin number	29.36–37.80	33.35	40
Reichert number (2.5 gm.)	15.10–17.50	16.2	40
Reichert-Meissl number (5 gm.)	22.80–32.10	28.3	10
Insoluble fatty acids, per cent	86.03–88.84	87.65	10
Soluble fatty acids, calculated	6.52–8.96	7.20	10
Total fatty acids, calculated	94.72–94.94	94.85	40
Acetyl number	3.5–4.8	4.1	5
Glycerol, calculated [b]	12.24–12.79	12.46	40
Glycerol, by analysis	12.30–12.70	12.45	10

[a] Saponification number less 0.5, the mean acid number.
[b] Calculated from figures given for ether number.

The methods employed in these investigations are described in detail, together with some modifications of the usual method of procedure.

"The determinations of the acid number were made upon samples of fat taken immediately after the butter was churned, so it will be observed that even when fresh, butter fat contains an appreciable amount of free acid. . . .

"The results show that the Reichert process gives a mean constant 10 per cent higher than the Reichert-Meissl method, after calculating the figures both to the same weight of fat. . . .

"The experience in this laboratory has been that only from 75 to 80 per cent of all the volatile acids pass over in one distillation. As a test, 10 distillations were made on 2.5 gm. of fat, the contents of the flask being replaced with 110 cc. of water after each distillation. The first fraction took 15.5 cc. of tenth-normal alkali, the succeeding nine fractions requiring each in their order 2.00, 0.95, 0.60, 0.55, 0.40, 0.35, 0.30, 0.30, 0.25, or together 5.7 cc., giving a total of 21.2 cc., thus making the original Reichert number of 15.5 over 25 per cent too small. . . .

"It is evident that while one treatment is amply sufficient to distinguish a butter from a substitute, the method is of little value quantitatively unless the treatment of washing be repeated until the washings become neutral—a tedious operation at the best. . . .

"Instead of distilling the lower fatty acids, it is possible to remove them from the higher insoluble acids by washing. The process can be carried out in connection with the determination of the saponification number, or with the determination of the insoluble acids."

In drying the fatty acids to a constant weight at 100° C. the use of a flask is preferred to an open dish on account of the continued loss of weight in the latter due to partial volatilization of the insoluble acids.

An apparent relation between certain of the constants is illustrated by tables.

"We notice that with an increase of the saponification number a quite uniform increase of the Reichert number takes place, while the iodin absorption decreases; these are such variations as one would expect. . . .

"It would seem as if the percentages of oleic and of the soluble acids in different butter fats bore a ratio somewhat complementary to one another. It must be remembered that the relations are only general and by no means fixed; there are butter fats which show constants bearing relations different from those expressed above, and from isolated cases a table might be constructed showing exactly opposite tendencies. As regards specific gravity and melting point, no definite relation could be discovered, though the latter showed a tendency to diminish as the saponification and Reichert numbers increased."

In conclusion the author mentions briefly some work by others on abnormal butter fats and on the influence of the ration upon the chemical composition of butter fat.

Egg albumin, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 21 (1899), No. 6, pp. 477–485*).—The author prepared a quantity of crystallized egg albumin by the use of acetic acid and of a molecularly equivalent quantity of hydrochloric acid, obtaining from 1,500 cc. of egg white 80 gm. of wholly crystallized albumin with the use of acetic acid and 73.2 gm. with hydrochloric acid. The latter acid is preferred. The crystallized albumin was found to be a compound of a protein substance with an acid, and the indications were "that the acid is mostly, if not wholly, organic."

The composition and properties of a number of fractionally crystallized preparations are given.

"The composition, rotation, heat-coagulation points and reactions of the crystallized egg albumin obtained by aid of hydrochloric or acetic acids show this to be the same substance as that which has in the past been regarded as egg albumin.

"My results, those of Bondzynski and Zoja, and of Panormoff, make it plain that there are two protein substances in the egg white, which are commonly obtained admixed when preparing egg albumin by the usual processes. Whether the extremes of my fractional precipitations of these two albumins consist wholly or even largely of each one of these bodies requires further investigation of large quantities of egg white. This work we now have well under way."

On some definite compounds of protein bodies, T. B. OSBORNE (*Jour. Amer. Chem. Soc., 21* (*1899*), *No. 6, pp. 486–493*).—"The object of this notice is to state briefly some results of an investigation which leads to the conclusion that protein bodies, as hitherto prepared, are, in fact, definite chemical compounds of protein substance with common mineral acids, or contain such compounds in admixture.

"A large number of the purest protein preparations that it has hitherto been possible to make in this laboratory, including egg albumin several times recrystallized, edestin, legumin, excelsin, amandin, corylin, phaseolin, gliadin, hordein, and zein, are, without exception, acid to phenolphthalein, slightly acid or neutral to litmus, and decidedly alkaline to lacmoid."

Investigations with edestin compounds and derivatives are reported.

Xanthin bases in sugar cane, E. C. SHOREY (*Jour. Amer. Chem. Soc., 21* (*1899*), *No. 7, pp. 609–612*).—The author reports finding guanin in cane juice, the average of 6 samples of juice of approximately the same purity and composition showing 0.0012 per cent of guanin nitrogen. equivalent to 0.0025 per cent of guanin. The average of 4 samples of refuse molasses showed 0.0308 per cent of guanin nitrogen, equivalent to 0.066 per cent of guanin.

"The small amount of guanin present in cane juice is of little technical importance. The amount present in refuse molasses may, however, be worthy of note in considering the fertilizing or feeding value of the same.

"In the analysis of sugar cane and its products the presence of guanin may introduce an error in some cases unless its presence be recognized."

Proceedings of the fifteenth annual convention of the Association of Official Agricultural Chemists (*U. S. Dept. Agr., Division of Chemistry Bul. 56, pp. 140*).—This is a brief account, edited by H. W. Wiley, of the convention held at Washington, D. C., November 11, 12, and 14, 1898, which has already been briefly reported (E. S. R., 10, p. 504).

Methods agreed upon by the Belgian and Holland experiment stations, A. F. HOLLEMAN (*Landw. Vers. Stat., 51* (*1899*), *No. 4–5, pp. 357–365*).—This is very similar to an account of these methods already noted (E. S. R., 10, p. 304).

A step toward international cooperation in the methods used by the agricultural experiment stations, A. MAYER (*Landw. Vers. Stat., 52* (*1899*), *No. 1–2, pp. 165, 166*).—The author urges the importance of uniform methods, and mentions the recent union of the Holland, Belgian, and Luxemburg stations in this respect.

A common error in recorded results of proximate plant analysis, L. F. KEBLER (*Amer. Jour. Pharm., 71* (*1899*), *No. 1, pp. 25, 26*).—This relates to pharmaceutical analysis, and not to methods of fodder analysis.

The preparation of standard solutions of sulphuric acid, A. MARSHALL (*Jour. Soc. Chem. Ind., 18* (*1899*), *No. 1, pp. 4–6*).

Indicators for use in alkalimetry, F. GLASER (*Ztschr. Analyt. Chem., 38* (*1899*), *No. 5, pp. 273–278*).

A study of the relative value of lacmoid, phenacetolin, and erythrosin as indicators in the determination of the alkalinity of water by Hehner's method, J. W. Ellms (*Jour. Amer. Chem. Soc., 21 (1899), No. 4, pp. 359-369*).—From the data presented "it is quite apparent that any one of the indicators offers but little superiority over either of the other two. Erythrosin gives more uniform results and a larger percentage of the carbonates actually present with low amounts than with high amounts, while the reverse seems to be true of lacmoid and phenacetolin."

Determination of small quantities of sulphur in volatile organic materials, R. Lucion (*Bul. Assoc. Belge Chim., 13 (1899), No. 6, pp. 290-293*).—The use of potassium chlorate and other oxidizing reagents is discussed. The use of the bomb calorimeter, in order to obtain complete oxidation of the sulphur, is reported. The bomb used was not platinum lined, but enameled. No results are given. It is stated that the method of V. Tieftrunck is probably the best to follow, but it can not be used in many laboratories because of the want of a long heavy platinum tube.—H. SNYDER.

On a possible error in the determination of nitrogen in nitrates due to impurities in reduced iron, B. L. Hartwell and H. J. Wheeler (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 468, 469*).—"Recently in making blank determinations with a new lot of so-called chemically pure reduced iron it was found that, by the modified Ulsch method, much less ammonia was required for neutralizing the acid than in the case of blank tests formerly made. The error from this cause in determinations involving half a gram of commercial sodium nitrate would amount to from 0.30 to 0.35 of a per cent. By direct distillation, without first allowing the iron to dissolve in the acid, no difficulty was experienced."

The authors refer to a similar observation by L. Brandt (E. S. R., 10, p. 819).

The determination of carbon and hydrogen in organic substances containing nitrogen, O. F. Tower (*Jour. Amer. Chem. Soc., 21 (1899), No. 7, pp. 596-605*).—The work reported shows that in burning amido compounds, the use of the copper spiral at the exit end of the combustion tube may be safely omitted —L. H. MERRILL.

The general usefulness of the Kjeldahl method for the destruction of organic substances previous to the determination of mineral matter, O. Gras and W. Gintl, Jr. (*Centbl. Physiol., 12 (1899), No. 11, pp. 308, 309*).

On the determination of albumoses and peptones, J. Effront (*Bul. Soc. Chim. Paris, 3. ser., 22 (1899), No. 14, pp. 680-683*).

The influence of temperature on the specific rotation of sucrose and method of correcting readings of compensating polariscopes therefor, H. W. Wiley (*Jour. Amer. Chem. Soc., 21 (1899), No. 7, pp. 568, 569*).—The results of readings at wide range of temperature are given, together with tables and formulas for corrections.

Rotatory power of sugar, E. Mascart and H. Bénard (*Ann. Chim. et Phys., 17 (1899), pp. 125-144; abs. in Sci. Abs., 2 (1899), No. 21, p. 627*).

Detection and determination of sucrose in the presence of lactose, E. Dowzard (*Jour. Chem. Soc. [London], 75 (1899), Apr., pp. 371, 372*).

Determination of sugar in molasses feed, O. Foerster (*Chem. Ztg., 23 (1899), No. 19, p. 196*).

Determination of the molasses content of molasses feeds, H. Neubauer (*Landw. Vers. Stat., 51 (1899), No. 6, pp. 421-439*).—A method is described.

Detection of corn starch in wheat flour, K. Bauman (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 1, pp. 27-29*).

Determination of the quality of sugar beets, L. Sempolowski (*Landw. Vers. Stat., 51 (1899), No. 4-5, pp. 341-349*).—This article treats of the sampling in the field and the laboratory and the determination of sugar. Usual methods are employed.

Investigations on the aerometric method for determining fat in milk, H. Timpe (*Chem. Ztg., 23 (1899), Nos. 41, pp. 436, 437; 43, pp. 455-457*).—Investigation of Soxhlet's method and its application to milk unusually rich in fat.

Note on butter analysis, W. L. Gadd (*Chem. News, 80 (1899), No. 2076, p. 113*).—The author finds that "the change undergone by alcoholic potash on keeping has a serious effect upon the accuracy of Reichert's test, and in extreme cases probably renders the estimation valueless. On the other hand, by using fresh alcohol and solid potash concordant results are obtained, even with fat several weeks old."

Contribution to the study of the fatty acids of butter, VAN ENGELEN and WAUTERS (*Bul. Assoc. Belge Chim., 16 (1899), No. 6, pp. 282-290*).—A short study of the influence of different foods upon the composition of butter. The density, melting point, index of refraction (Abbé), fixed and volatile acids of butter are given when cows were fed 40 kg. of second-growth rape and straw and allowed to graze for an hour, and also when 2 kg. each of cotton-seed meal and wheat bran formed a part of the ration.—H. SNYDER.

On the detection of butter adulteration, A. J. SWAVING (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 3, p. 274*).—Remarks on the limit for the Reichert-Meissl number.

An acoustical method for the determination of the melting point of fats and waxes, E. DOWZARD (*Chem. News, 79 (1899), No. 2053, pp. 150, 151, figs. 3*).

A new test for formaldehyde, N. LEONARD and H. M. SMITH (*Analyst, 24 (1899), Apr., p. 86*).—Milk containing formaldehyde is said to give a violet color when heated with 3 to 5 times its volume of concentrated hydrochloric acid, even when as little as 0.0001 per cent of formaldehyde is present; with over 0.1 per cent a yellow color is produced.

Tests for boric acid, V. LENHER and J. S. C. WELLS (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 417-420, fig. 1*).

The detection of saccharin in foods, A. HASTERLIK (*Chem. Ztg., 23 (1899), No. 25, pp. 267, 268*).

Detection of sesame oil, A. BÖMER (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, pp. 705-709*).

On some points in the analysis of water, G. H. BAILEY and J. H. JOHNSTON (*Jour. Soc. Chem. Ind., 18 (1899), No. 5, pp. 455-457*).

Determination of ammonia, nitric and nitrous acids in water, L. W. WINKLER (*Chem. Ztg. 23 (1899), Nos. 43, pp. 454, 455; 51, p. 541*).

On the use of hyposulphite for titration, especially for the estimation of oxygen in water and sewage effluents, B. W. GERLAND (*Jour. Soc. Chem. Ind., 18 (1899), No. 4, pp. 340, 341*).

Determination of oxygen in water, L. MUTSCHLER (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 6, pp. 481-484, fig. 1*).

Determination of oxygen in water, F. ZETSCHE (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, pp. 696, 697*).

Researches on moorland waters: I, Acidity, W. ACKROYD (*Jour. Chem. Soc. [London], 75 (1899), Mar., pp. 196-200*).—The article includes a description of the method of estimating acidity.

Measurements of turbidity in water, W. P. MASON (*Jour. Amer. Chem. Soc., 21 (1899), No. 6, pp. 516, 517, fig. 1*).—Describes the use of a brass tube 2½ in. in diameter and 2 ft. long, closed at the ends by disks of glass. The turbidity is determined by comparison with standards made with distilled water and exceedingly fine kaolin.

On rapid methods for the estimation of the weight of the suspended matters in turbid waters, C. L. PARMELEE and J. W. ELLMS (*Tech. Quart., 12 (1899), No. 2, pp. 145-164*).—Results are reported of comparisons of the following: Gravimetric method, standard clay solutions, photo-comparator, wire method, and diaphanometer. Any of the four last-named methods "gave fairly reliable results" when carefully standardized against the gravimetric method.

Analysis of commercial vinegar, F. G. RYAN (*Amer. Jour. Pharm., 71 (1899), No. 2, pp. 71-73*).—Analyses of 3 samples by the usual methods, "with a view of illustrating a class of analytical work that may be undertaken by graduates in pharmacy."

Detection of caramel in spirits and vinegar, C. A. CRAMPTON and F. D. SIMONS (*Jour. Amer. Chem. Soc., 21 (1899), No. 4, pp. 355-358*).—The authors suggest the use of fuller's earth, which extracts the caramel used in coloring but has very little effect upon natural coloring matter. "By means of Lovibond's tintometer the difference in color before and after treatment may be determined with a considerable degree of accuracy, and in this way more than twice as much color was found to have been absorbed from artificially colored spirits as from the natural."

Determination of fusel oil in alcoholic liquids, E. BECKMANN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, pp. 709-714, figs. 2*).

The analysis of human urine, W. CAMERER and SÖLDNER (*Ztschr. Biol., 38 (1899), No. 2, pp. 277-290*).—A large number of experiments on the analysis of urine are reported.

The estimation of arsenic in Paris green, T. SMITH (*Jour. Amer. Chem. Soc., 21 (1899), No. 9, pp. 769-772*).

A method for carrying out chemical reactions under high pressures, B. H. HITE (*Amer. Chem. Jour., 22 (1899), No. 1, pp. 80-86, pl. 1, figs. 5*).—A description of an apparatus in which substances can be subjected to intense pressure. As high as 400,000 lbs. to the square inch has been obtained; and other forms of cylinders are described in which pressures of from 50,000 to 200,000 lbs. to the square inch can readily be exerted.

New form of condenser, F. W. ASTON (*Chem. News, 79 (1899), No. 2059, p. 217, fig. 1*).

An electric drying oven, T. W. RICHARDS (*Amer. Chem. Jour., 22 (1899), No. 1, pp. 45-49, figs. 3*).

A simplification of Beckmann's boiling-point apparatus, S. L. BIGELOW (*Amer. Chem. Jour., 22 (1899), No. 4, pp. 280-287, fig. 1*).

A new form of potash bulb, W. C. ANDERSON (*Jour. Soc. Chem. Ind., 18 (1899), No. 2, p. 119, fig. 1*).

An improved apparatus for the estimation of carbonic acid in minerals, etc., A. MARSHALL (*Jour. Soc. Chem. Ind., 17 (1898), No. 12, pp. 1106, 1107, fig. 1*).

New laboratory apparatus, A. GAWALOWSKY (*Ztschr. Analyt. Chem., 38 (1899), No. 4, pp. 237-242, figs. 7*).—Descriptions of a burette tip, float, holder, and pinch cock, and apparatus for making distilled water on a large and on a small scale.

Apparatus for rapid analysis of milk, G. D. MACDOUGALD (*Jour. Soc. Chem. Ind., 18 (1899), No. 3, pp. 237-238, figs. 13*).—"The process is virtually the Leffmann-Beam, but the method of manipulation and apparatus are more or less novel." Special tubes, delivery apparatus for adding the acid, mixing apparatus, and a reading lantern are described. The apparatus is arranged for rapid work on a commercial scale, and the author explains that one of his assistants, with the aid of a boy, can easily make 120 to 140 determinations in 6 hours.

A new apparatus for determining solids and fat in milk, S. SONN (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 8, pp. 655, 656, fig. 1; Ztschr. Analyt. Chem., 38 (1899), No. 6, p. 353, fig. 1*).—An aluminum boat with cover is used, in which about 20 cc. of milk is evaporated with about 2 gm. of fat-free cotton, and the solids weighed. The fat is determined in the residue by placing the open boat on end in a wide Soxhlet extraction apparatus, or in a nickel capsule with inside siphon tube, and this in turn in a glass jacket similar to that of an extractor. The fat is then extracted as usual.

A new filtering medium, G. W. SARGENT and J. K. FAUST (*Amer. Chem. Jour., 21 (1899), No. 3, pp. 287, 288*).

A new slide for the microscopical examination of water, foods, and feeding stuffs, A. HEBEBRAND (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, pp. 694-696*).

Miscellaneous analyses, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1898, pp. 176-181*).—These include analyses of 56 samples of water with reference to sanitary condition (see p. 328), 31 samples of sugar beets, 3 samples of muck, 2 samples of vinegar, and 1 sample each of whey, casein, and condensed milk.

Miscellaneous analyses, C. W. MCCURDY and T. SMITH (*Idaho Sta. Bul. 19, pp. 55-76*).—Analyses are reported of 36 varieties of strawberries (sugar content), 65 varieties of peas (sugar content), 6 samples of wines, 2 of vinegar, 2 of black pepper, 1 each of English breakfast tea, cream of tartar, breakfast food, baking powder, washing fluid, "silver" ware, and sunflower seed, 2 of lye, 7 of Paris green, 2 of sulphur, 3 of coal, 2 of hops, the ash of Wyoming coal, sage brush, yellow pine, white pine, red fir, tamarack, and box elder, and 21 samples of water (see p. 327).

Report of the senior analyst, Cape of Good Hope, 1898, C. F. JURITZ (*Cape Town: W. A. Richards & Sons, 1899, pp. 77, pl. 1*).—Contains a report of the analyses of foods, water and beverages, soils, fertilizers, sheep dips and disinfectants, prickly pears (young leaf, older leaf, stalk, inner portion of stalk), minerals, sea water, etc.

Report of the division of chemistry, A. M. PETER (*Kentucky Sta. Rpt. 1897, pp. XIII-XXX*).—This includes analyses of butter, cane juice, sugar beets, dried distillery feeds, tobacco sprayed with arsenic, Paris green and "laurel green," niter earth, hog manure, marls, wood ashes, phosphatic rock, kainit, potassium sulphate, by-product of manufacture of tobacco extract, dissolved bone, Damaraland guano, mineral waters, wine, coal, and coke.

BOTANY.

Report of the botanist, C. S. CRANDALL (*Colorado Sta. Rpt. 1898, pp. 138-141*).—A brief statement is made relative to the cooperative experiments conducted with the Division of Forestry of this Department in testing the relative hardiness of forest-tree seedlings grown from seeds produced in different sections of the country. Experiments were begun in 1897 and continued in 1898, and although the records thus far made are not considered conclusive, they show that in the matter of hardiness seedlings from northern seed have a decided advantage over those from southern seed.

Notes are given on the work of collecting the flora of the State, and numerous additions to the herbarium, made by exchanges, are reported.

The Colorado orchards have in the past been considered remarkably free from fungus diseases, but some of the more troublesome ones are beginning to be observed. In addition to the blight of apple and pear, already reported (E. S. R., 10, p. 266), the leaf spot of raspberries and blackberries has been observed in three counties and is doing considerable damage. The orange rust of blackberries and the leaf blight of strawberries are reported from several localities, and the powdery mildew of the cherry as well as a blight of cantaloupes is reported from the Arkansas Valley.

Report of the botanist, C. E. BESSEY (*Nebraska Sta. Rpt. 1898, pp. XXV-XXXIII*).—Some of the problems which presented themselves during the year are reviewed, and the opinion is expressed that it would be well for the station soon to take up the study of the physiology of plants with especial reference to the practice of irrigation.

Attention is called to the asparagus rust, which so far has not been reported from Nebraska, but should be watched for. The carnation rust has made its appearance in the greenhouse at the station. The stinking smut of wheat and the loose smut of wheat, oats, and barley are said to be quite common and require some attention.

A disease was found on potatoes which at first was thought to be downy mildew, but proved not to be. It appeared to be due to a fungus the exact nature of which was not determined on account of lack of material.

Specimens of wheat received from several localities were found affected with the wheat scab.

Notes are given on some poisonous plants and weeds which have attracted attention. Several cases of poisoning due to species of larkspur have been reported, and specimens of plants were obtained, but not sufficient to determine exactly the species of plant causing the trouble. "The Russian thistle has attracted but little attention the past season, and it is certainly not as threatening a weed as it was a few years ago." *Rumex acetosella* and the wild four o'clock (*Allionia nyctaginea*) are spreading throughout the State and in some localities becoming quite troublesome. A note of warning is also given concerning an annual mustard (*Erysimum repandum*) which has been reported from the northern part of the State and is likely to become troublesome if it secures a foothold.

Notes are given on various grasses and forage plants. A list of the titles of the principal papers which bear more or less directly upon agriculture published by the author during the year is reported.

A contribution to the knowledge of physiological constants, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 263-272*).—This report consists principally in a discussion of the theories of some of the earlier investigators upon this subject, the theories of DeCandolle, Linsser, and Hoffmann being discussed at considerable length. A number of American investigators are mentioned, among them Clarke, Waldo, Robertson, Bailey, and Irish, but no mention is made of the extensive investigations of C. H. Merriam in this line. After discussing the various theories, the author attempts to test some of them from data relative to the physiological constant of 6 varieties of plums at Geneva, N. Y. From the tabulation it appears that the sum temperatures at 32° are fairly constant for each variety, and the other constants are found to apply with a fair degree of accuracy.

The author concludes that the factors presented by various authors to explain modifications of physiological constants, although subject to exceptions, are applicable in certain circumstances, and that the determination of some physiological constants is possible. The various factors to be taken into consideration will be found useful, in proportion to their accuracy, in the scientific explanation of many puzzling variations in the periods of blooming, or maturing of fruits, flowers, and vegetables.

Concerning the temperature of plants, W. SOUTTER (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 572-575*).—The author briefly reports upon a number of experiments on the internal temperature of plants, the subjects of his experiments being young growing shoots of bamboo and banana, the fruit of a pumpkin, the flowers of *Cereus grandiflora*, and the fruits of cocoanut. Incidental to these investigations he reports notes made on the growth of bamboo. In 37 observations the total growth of the shoots in 24 hours was a little in excess of 19 in., in 69 cases it was 14 in., and in 111 others over 12 in. The maximum growth observed during 24 hours was 25 in.

In the temperature experiments, the maximum and minimum temperatures of the air with both wet and dry bulb thermometers are given, and the maximum and minimum temperatures within the growing tissues. Observations during 6 consecutive days are given of the internal temperature of bamboo shoots, on the last day the wet bulb thermometer showing a maximum of 76.5° F. in air, 89.3° in the bamboo shoots, with a minimum of 72.8° and 75.8°, respectively. In the banana stem the temperatures were as follows: Wet bulb in air—maximum, 86.6°; minimum, 63.8°; while in the banana stem the maximum registered was 90°, and the minimum 75.4°. In the experiments with the pumpkin the maximum air temperature was 78.4° and the minimum 64°; while in the fruit under investigation the temperatures were 81.2° and 66.6°, respectively. The experiments with the cactus flower gave readings from 10 to 15° higher than the air temperature.

In the experiments with cocoanuts 2 nuts were selected and placed in a box without soil and kept for 10 days in a room. A thermometer was inserted in one of them which registered 6.3° lower than the surrounding temperature. On the eleventh day the nuts were planted in the shade and germination begun. For 18 days there was no perceptible rise in temperature, after which time the temperature of the germinating nut began to rise rapidly. The experiment was terminated after 28 days, on which date the temperatures read as follows: Soil, 56.6°; atmosphere, 70.6°; interior of cocoanut, 83°.

Investigations on the nutrition of plants with organic nitrogenous compounds, L. LUTZ (*Ann. Sci. Nat. Bot., 8. ser., 7 (1899), Nos. 1, pp. 1–80; 2–6, pp. 81–103*).—The author reports a series of experiments in which about 20 different kinds of organic nitrogen were added to nutrient solutions in which a number of plants were grown. Most of the experiments with phanerogams were conducted with seedlings in sand cultures. The flowering plants experimented with were *Zea mays*, *Cucumis melo*, *C. prophetarum*, *Ipomœa purpurea*, *Cnicus benedictus*, and *Helianthus annuus*. Among the algæ were *Protococcus viridis*, *Mesocarpus pleurocarpus*, and *Oscillaria* sp., and among the fungi, *Penicillium glaucum* and *Aspergillus niger*. Especial precautions were taken to eliminate the action of bacteria, fixation of nitrogen by soil, and all forms of fermentation.

The results of the experiments showed that under as exact conditions as were possible to be obtained, the phanerogams were able to obtain their necessary nitrogen from organic nitrogenous compounds of the amin class, and this assimilation could take place without transformation into nitric or ammoniacal nitrogen.

The assimilation of organic nitrogenous compounds is confined to those of comparatively simple radicals. The methyl amins are readily assimilable, while benzyl amin and pyridin are not. The phenol amins act as strong poisons, and the compound ammonium salts and alkaloids are unable to supply the plants with the nitrogen, all samples after a while showing some loss in their initial nitrogen.

In the experiments with algæ and fungi similar results were obtained, the plants assimilating compounds of the simpler amin radicals with the same ease as nitric or ammoniacal nitrogen.

These results, the author claims, have a practical bearing in the practice of composting. In the case of beet or fruit refuse, shellfish and fish refuse, the organic nitrogen may be made available for plants without the transformation into ammonia or nitrates, the process of fermentation being checked when the lower amins are secured. In this way the frequently rapid action of manures may be explained.

The results obtained with alkaloids are thought to shed some light upon their rôle in plants. Alone they are entirely unassimilable, but when in conjunction with some assimilable form of nitrogen large quantities of them may be taken up, and it is thought possible in this way to explain the migration and disappearance of alkaloids in plants at certain times.

The assimilation of carbohydrates and elaboration of organic nitrogen in higher plants, Mazé (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 3, pp. 185-187*).—The author quotes briefly the opinions of a number of investigators relative to the transformation of nitrates and the assimilation of carbohydrates by plants, and gives an account of experiments in which vetches, which had been sprouted in darkness and kept free from bacteria, were grown in sterilized nutritive solutions containing a variable quantity of glucose. The plants were placed in these sterilized solutions when they were from 8 to 10 cm. in length, and were grown in darkness for different periods of time. The following table will show the results obtained in one series of cultures:

Assimilation of carbohydrates by plants.

Lot.	Time of experiment.	Glucose.	Dry weight of seed.	Dry weight of plant.	Gain (+) or loss (—).
	Days.	*Per cent.*	*Mgs.*	*Mgs.*	*Mgs.*
No. 1	50	1	202. 8	269	+ 66. 2
No. 2	39	2	202. 8	276 7	+ 73. 9
No. 3	92	4	202. 8	838. 2	+635. 4
No. 4	92	6	202. 8	710	+507. 2
No. 5	53	0	202. 8	161. 6	— 41. 2
No. 6 [a]	53	0	202 8	133. 4	— 69. 4

[a] No nitrogen in culture solution.

The above table shows that these plants were able to transform the glucose into their necessary carbohydrates, and also to elaborate albuminoid material. The plants grown in the glucose solutions were much more vigorous than those in the check. Their taproots were strong and well branched. and the stems attained a much greater length.

amounting to as much as 1.3 meters, with branches extending 1.65 meters. The nitrates were found throughout the stems to the last internode, the meristomatic tissue being the center of the most active transformation of nitrates.

Sap pressure and flow in the sugar maple, L. R. JONES and W. A. ORTON (*Vermont Sta. Rpt. 1898, pp. 234–236*).—Preliminary investigations upon this subject were conducted by W. J. Morse during the season of 1897, which was a notably poor and quite short one for sap flow. The problems presented will require the observations of a series of years. After describing the methods, the authors state that a close relation exists between sudden rises of temperature and of sap pressure, and also that the line of pressure is somewhat more tardy in its general rise and fall than is that of temperature.

The direction of the sap flow during the sugar season is a matter of considerable difference of opinion, and, to test this, lithium chlorid was injected into the tree. The results obtained show conclusively that in ordinary conditions there is an almost equally rapid movement of the sap current both upward and downward in the vicinity of the spout. Similar methods were used to determine the existence or nonexistence of lateral flow, but the results were entirely negative. The conclusion seems clear that the sap moves freely in both directions with the grain of the wood, but very slowly across it. An unexpected result obtained was the rapid decrease in the amount of the lithium, ending in some cases in its total disappearance in the sap within 24 hours.

How can the efficiency of Nitragin be increased? F. NOBBE and L. HILTNER (*Landw. Vers. Stat., 51 (1899), No. 6, pp. 447–462*).—The authors reply to various criticisms on the efficiency of Nitragin, and suggest methods whereby its activity may be increased. The principal thing to be observed is to have the bacteria present at what is termed the critical period, between the time of inoculation and the time when the young roots are capable of being infested. It is considered of prime importance that this period should be as short as possible, and in seed inoculation the authors now recommend the addition of the cultures to the seed after they have been soaked from 12 to 24 hours, or, in the case of seed which are long in germinating, after 3 or more days.

Where soil inoculation is practiced, it is advised that the bacteria cultures be mixed with finely cut leguminous hay and sown over the field after the first plants begin to appear. The authors state that this method adopted some weeks after the seed were sown gave greatly increased results over their checks.

The evolution of plants, D. H. CAMPBELL (*New York: The Macmillan Co., 1899, pp. VI+319, figs. 60*).—In this book, which is expanded from a course of lectures in Leland Stanford Junior University, the author has sought to give an accurate though not strictly technical statement of the present state of our information regarding the genealogical history of the plant kingdom. While primarily designed for botanists, its untechnical character commends it to every student of evolution. All sources of information have been freely drawn upon, and the result is one of the most orderly arrangements of the plant kingdom of which we have any knowledge. Exceptions may be taken to the position of certain disputed groups, but until more is positively known concerning them their true position can only be doubtfully assigned. The chapters on geological and geographical distribution and the influence of environment are very suggestive of reasons for many apparent anomalies in nature.

Foreign seeds and plants imported by the Section of Seed and Plant Introduction, O. F. Cook (*U. S. Dept. Agr., Division of Botany Inventories 1, pp. 81; 2, pp. 94; 3, pp. 14; 4, pp. 9*).—These contain lists of the seeds, plants, cuttings, etc., secured by the special agents of the Section of Plant Introduction, through exchanges and by other means. The first consists principally of lists of seeds and plants which have been secured by N. E. Hansen during a trip to Russia, Central Asia, and Siberia. Inventory No. 2 continues the list secured by Mr. Hansen, and gives lists of materials collected by W. T. Swingle, and other miscellaneous collections. Inventory No. 3 gives a list of the improved varieties of sorghum which have been developed by the Division of Chemistry of this Department, and now made available to the experiment stations through this section. Inventory No. 4 enumerates and describes the cereals and forage plants secured by M. A. Carleton in Russia for distribution through this section.

Notes on grasses of Nebraska, South Dakota, and Wyoming, L. H. Pammel (*Proc. Davenport Acad. Sci., 7 (1899), pp. 229–245, pls. 7*).—Ecological and economic notes are given of the grasses of this region, and the following new species described: *Phleum alpinum scribnerianum*, *Melica pamelii* Scrib., *Poa wyomingensis* Scrib., and *Hordeum cæspitosum* Scrib.

Secale africanum, O. Stapf (*Hooker's Icon. Plant., 7 (1899), No. 1, Plate 2601*).—The author describes as new this species of rye, which is said to be so abundant as to lend its name to the region. It is considered a very distinct species and not a degenerate variety of *S. cereale*.

Observations on the denudation of vegetation, M. Manson (*Pacific Rural Press, 58 (1899), No. 8, p. 116*).—Suggests remedies for Californian conditions.

The opening lecture of the course of vegetable physiology applied to agriculture at the Museum of Natural History, P. P. Dehérain (*Ann. Agron., 25 (1899), No. 5, p. 212*).—An outline is given of the proposed work, which was to be principally concerned with studies of natural and artificial meadows.

On the occurrence of lignin in the vascular cryptogams, K. Linsbauer (*Oesterr. Bot. Ztschr., 49 (1899), No. 9, pp. 317–323*).

The relation between the color of daffodils and the composition of the soils in which they are grown, A. P. Aitken (*Trans. and Proc. Bot. Soc. Edinburgh, 21 (1898), pt. 2, pp. 113–116*).—Marked differences having been noted in daffodils grown in different places, analyses of the soils were made. It was found that the intensity of color increased with the percentage of organic matter, phosphoric acid, lime, and peroxid of iron. Whether all or some particular item is the cause of the increased intensity of color is to be investigated further.

The biology of pollen, B. Lidforss (*Jahrb. Wiss. Bot. [Pringsheim], 33 (1899), pp. 232–312; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, p. 411*).—The author claims that moisture is not generally destructive of the germinating power of pollen grains, and that the resistance of pollen to moisture is often greatly influenced by external conditions, it being greatly enhanced in moist air. As a rule, those pollen grains which are unable to resist moisture germinate very rapidly. The pollen grains of anemophilous plants are, as a rule, characterized by their comparatively small size. While containing a larger proportion of starch, they have less nitrogenous matter than those of entomophilous plants.

Causes of the direction of the lateral branches of trees, J. Baranetzky (*Sitzber. Bot. Sec. Naturf. Ver. Kiew, 1898, Aug. 28; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, p. 412*).—The development of the lateral branches of trees is said to present two different types. In one, represented by the maple, ash, chestnut, etc., the physiological properties of the lateral branches are the same as those of the erect main stem, their oblique direction being due to the angle at which they branch from the main stem. In others, as in the linden, elm, etc., the lateral branches are physiologically bilateral even in the bud. In pines, all the first year's shoots are erect, the subsequent bending down of the lateral branches being due to the unequal growths of the tracheids.

Downward growth of rhizomes, A. RIMBACH (*Beitr. Wiss. Bot., 1. Abt., 3 (1898), pp. 117-204; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, pp. 412, 413*).—The power of rhizomes or other underground organs to rise or sink deeper into the soil is attributed to changes in the direction of the growth in length due to the shortening or elongation of the internodes of the stem, rarely to the lateral extension of the underground organ itself. It is influenced by the depth of covering of the soil, a slight covering inducing descent, while a deep covering will cause an ascent of the rhizome, etc. The author claims that this phenomenon can not be explained by heliotropism or aerotropism.

Seedless grapes, MÜLLER-THURGAU (*Landw. Jahrb. Schweiz, 1898, p. 71, pls. 4; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, p. 407*).—The author attributes the absence of seeds in some grapes to two causes, namely, the pollen grains may be well developed, but the ovules incapable of impregnation; either the pollen tubes do not reach the ovules or the ovule itself is sterile. To this class belong the Sultanas and currants of commerce. In the second class the ovules are capable of impregnation, but the pollen grains are degenerated; either the pollen tubes do not germinate or are incapable of impregnating the ovule cell. Grapes which do not contain seeds are always smaller than those of the same variety containing them.

The effect of various substances upon the respiration and assimilation of submerged plants, B. JACOBI (*Flora, 86 (1899), No. 3, pp. 289-327*).—The effect of carbon dioxid, potassium nitrate, potassium chlorid, sodium chlorid, quinin, antipyrin, thyroidin, and iodin on *Elodea canadensis* and *Myriophyllum verticillatum*, as shown in their respiration and assimilation, was investigated and reported upon. Different effects were sometimes noted for equal strengths of solution on respiration and assimilation, the one being stimulated and the other retarded.

On the absorption of nutrient substances by roots, L. KNY (*Ber. Deut. Bot. Gesell., 16 (1898), pp. 216-236; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, p. 296*).—The author conducted experiments upon maize, peas, and *Hydrocharis morus-ranæ*, in which the absorption of methyl violet and of nitrates was demonstrated. The results were by no means uniform, individuals of the same species showing great variation. The absorption of nutrient substances by roots is said to take place not only through the root hairs but through the epiderm in a zone of varying length on the apical side of the root-hair region.

Hydrocyanic acid in plants, A. HÉBERT (*Bul. Soc. Chim. [Paris], 3. ser., 19 (1898), pp. 310-313; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, p. 405*).—The presence of traces of hydrocyanic acid is reported in red and black currants, young green shoots of *Ribes aureum*, the embryo of *Eriobotrya japonica*, and in the leaves, stalks, and buds of *Aquilegia vulgaris* at the commencement of the period of vegetation. The quantity present is not considered sufficient to act as a means of defense.

Hydrocyanic acid in the Amygdaleæ, A. J. VAN DE VEN (*Arch. Neerland Sci. Exact. et. Nat., 2 (1899), pp. 383-396; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 4, p. 405*).—The author states that the quantity of hydrocyanic acid in the branches of cherry-laurel decreases with increase of age. There is little evidence of the presence of this acid in the roots of this plant. In the youngest leaves the acid occurs only in isolated groups of cells along the principal veins, the proportion reaching in early summer as much as 2.4 per cent. The amount of the acid in the leaves may be decidedly increased by insolation. The author claims to have been unable to find any trace of hydrocyanic acid in *Vicia sativa* or in other species of the genus, or in *Aquilegia vulgaris*, where it has been stated to exist.

On the digestion of starch in plants, LECLERC DU SABLON (*Compt. Rend. Acad. Sci. Paris, 127 (1898), No. 23, pp. 968–970*).

The presence and function of silica in plants, B. VON SWIECICKI (*Halle, 1898, pp. 45; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 3, p. 292*).—The author claims that in the case of cereal crops the upper portion of an internode is always stronger than the lower in consequence of its containing a larger amount of silica. The greatest strength was found in the first and fifth internodes, and the upper part of the fifth internode in particular contains much more than the average proportion of silica.

Formation of sugar in beets, M. GONNERMAN (*Ztschr. Ver. Deut. Zuckerind., 1898, pp. 667–689; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 3, p. 301*).—It is stated that the formation of sugar in the leaves of the beet can take place only through the action of an enzym. There are present in beet leaves two enzyms, an invertase and a diastase, both of which are distinct from the corresponding enzyms of barley. By their action starch is transformed by hydrolysis into products which are then changed into saccharose partly in the leaves and more completely in the parenchyma of the root.

The physiological importance of the furfuroids in the organism of the sugar beet, J. STOKLASA (*Ztschr. Zuckerind. Bohmen, 23, p. 291; Neue Ztschr. Rübenz. Ind., 42 (1899), No. 19, pp. 204–207*).

Anatomy and physiology of sugar-beet seed, A. NESTLER and J. STOKLASA (*Bul. Assoc. Chim. Sucr. et Distill., 16 (1899), No. 10, pp. 972–980, figs. 2*).

Protein destruction and regeneration in plants, N. PRIANISCHNIKOW (*Ber. Deut. Bot. Gesell., 17 (1899). No. 4, pp. 151–155*).—A preliminary report of experiments with *Pisum sativum*, *Vicia faba*, and *Lupinus luteus* to determine the process of destruction and regeneration of protein. Investigations by various authors on *V. sativa*, *V. faba*, *Pisum sativum*, *Phaseolus multiflorus*, *L. luteus*, and *Cucurbita pepo* are quoted.

The ecological relations of the vegetation on the sand dunes of Lake Michigan, H. C. COWLES (*Bot. Gaz., 27 (1899), Nos. 4, pp. 281–308; 5, pp. 361–391, figs. 26*).

Influence of external agents on the anatomical structure of maritime plants, J. SCHMIDT (*Bot. Tidsskr., 22 (1899), No. 2, pp. 145–168, figs. 7*).—Experimental investigations upon *Lathyrus maritimus* as influenced by saline solutions and light.

Some observations on the effect of distilled water on the roots of plants, N. SCHOULTZ (*Compt. Rend. Soc. Imp. Nat., 28 (1897), pp. 217, 218*).

Effect of Roentgen rays on plants, G. TOLOMEI (*Rend. Accad. Lincei, Rome, 7. ser., 5 (1898), No. 1, pp. 31–39*).

Lichens on plum trees, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 289–290, pl. 1*).—While engaged upon pollination experiments with plums the author noted the occurrence of a number of species of lichens, especially on old trees. A quantity of material was collected and at least 12 species were determined. As has already been shown by Waite,[1] the application of Bordeaux mixture is a specific for the removal of these unsightly if not injurious plants.

Influence of light on the development of fungi, F. GRAEWITZ (*Ueber den Einfluss des Lichtes auf der Entwickelung einiger Pilze. Leipsic, 1898, pp. 74; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 4, p. 420*).—From a series of experiments made chiefly on *Pilobolus microsporus* and *Coprinus stercorarius*, the author claims that the ripening of sporangia is not necessarily dependent on an entire absence of light although normally it takes place at night. On the other hand, the sporangia of Pilobolus and the pileus of Coprinus are not differentiated in perpetual darkness. The rapidity of the development of the receptacle increases with the intensity of the light.

A statistical enumeration of Australian fungi, D. MCALPINE (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 482–488*).—Notes are given on a number of species of fungi and their distribution in Australia, tables being given showing the proportion of species in the different colonies and comparisons made with the known species occurring in Great Britain. At the end of 1897 there were known to occur in Australia 12 groups of fungi containing 2,480 species. Of these about 31 per cent are common to Great Britain.

---

[1] Jour. Myc., 7 (1893), p. 265.

The biology of parasitic fungi, M. NORDHAUSEN (*Jahrb. Wiss. Bot. [Pringsheim], 23 (1898), pp. 1–46; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, pp. 310, 311*).—*Botrytis cinerea* ordinarily a saprophyte may become parasitic, forcing entrance into the tissues of the host plant. Culture experiments seem to indicate that the fungus secretes two substances, one of which is poisonous to protoplasm and the other destroys the cellulose of the cell wall. These substances are probably enzyms. By this means the fungus is able to attack almost any plant in nearly any part. Somewhat similar results were secured with *Mucor stolonifer* and *Penicillium glaucum*, although in general the last species does not appear to secrete a poisonous enzym.

On the biology of wood-frequenting fungi, F. CZAPEK (*Ber. Deut. Bot. Gesell., 17 (1899), No. 5, pp. 166–170*).

The modification of characters in the Uredineæ, P. MAGNUS (*Ber. Deut. Bot. Gesell., 17 (1899), No. 5, pp. 178–184, pl. 1*).

Spore formation in Dematium pullulans, F. WELEMINSKY (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 9, pp. 297–303, figs. 9*).—The author figures and describes the method of spore formation in this fungus.

The decomposition of glucosids by fungi, K. PURIEWITSCH (*Ber. Deut. Bot. Gesell., 16 (1898), pp. 368–377; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, p. 301*).—The mycelium of *Aspergillus niger*, *A. glaucus*, and *Penicillium glaucum* is said to have the power of decomposing glucosids in the same way that emulsin acts upon them. The spores have the same power when germinating. The substances resulting from the decomposition are glucose and some benzol derivatives. The glucose is taken up by the mycelium, while the other may be absorbed or remain in solution.

A contribution to the knowledge of endotropic mycorrhiza, J. BERNATZKY (*Termesz. Füz. Budapest, 1899, pp. 23, pls. 2*).

Biological species and races, E. ROSTRUP (*Bot. Tidsskr., 20 (1898), pp. 116–125; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, p. 301*).—The author distinguishes between these two terms as applied to fungi. In the case of biological races the capacity for one form to pass over into another has been only partially lost, while in biological species it has entirely disappeared. Biological races are said to occur in *Lophodermium pinastri*, and biological species in the genera Coleosporium and Melampsora. In *Puccinia graminis* there are a number of biological races, each of which is limited to a definite host plant, while biological species also occur in the same genus.

Three edible species of Coprinus, G. F. ATKINSON (*New York Cornell Sta. Bul. 168, pp. 491–516, figs. 15*).—In continuation of his studies and illustrations of mushrooms, the author describes 3 edible species of Coprinus, namely, the shaggy mane (*Coprinus comatus*), ink cap (*C. atramentarius*), and the glistening Coprinus (*C. micaceus*).

METEOROLOGY.

Lightning and the electricity of the air, A. G. MCADIE and A. J. HENRY (*U. S. Dept. Agr., Weather Bureau Bul. 26, pp. 71, pls. 4, figs. 21*).—This bulletin contains two parts.

"Part I deals with the electrification of the atmosphere and the best method of protecting life and property from lightning stroke, being in large part a revision of Bulletin 15, Protection from Lightning [E. S. R., 8, p. 31]. Part II gives statistics of actual losses of life and property, including live stock in the fields, sustained in the United States during 1898.

"The aim of the paper is to furnish information of practical value to all persons, especially those who may have occasion to seek protection from lightning."

The statistics collected show that during the 9 years, 1890–1898, 2,496 deaths due to lightning occurred in the United States—or about 5 per million of the population. During 1898, 1,866 buildings were struck and damaged, the total estimated loss being $1,441,880. The number of fires due to lightning during 1890–1897 was 7,558, the estimated loss from this cause being $17,672,772. The recorded loss of live stock by lightning stroke in 1898 was, cattle 964, horses 306, mules 30, pigs 116, and sheep 436, valued at $48,257.

"The order of frequency of lightning stroke on the various soils in percentages, deduced from 380 reports, is as follows: Loam, 26 per cent; sand, 24 per cent; clay, 19 per cent; prairie, 19 per cent; scattering, 12 per cent."

Meteorology, L. G. CARPENTER (*Colorado Sta. Rpt. 1898, pp. 174–176*).—A brief account is given of the work of the station in this department, especially of observations on rainfall, sunshine, and soil moisture. "To determine our rainfall normal at this place, we now have 20 years' observations for most months. The normal thus obtained for the whole year is 13.26 in." Ten years' sunshine records have been secured but have not been measured and reduced.

Meteorological record (*Minnesota Sta. Rpt. 1898, pp. 561–566*).—Tables of normal monthly and annual temperatures and precipitation for some 35 stations in Minnesota having records for 5 or more years, with annual and monthly temperatures and precipitation at 69 stations during 1897.

Report of the division of meteorology, V. E. MUNCY (*Kentucky Sta. Rpt. 1897, pp. XXXVI–XL*).—A tabular summary of meteorological observations during 1897 on temperature, pressure, precipitation, sunshine and cloudiness, wind, thunderstorms, snow, hail, and fogs. The mean temperature for the year was 55.7 F, the highest 96°, September 14, and the lowest —6, January 25. The total rainfall was 49.19 in.

Explosions to prevent hailstorms, E. OTTAVI (*Chron. Agr. Canton Vaud, 12 (1899), No. 14, pp. 331–334*).—Refers to what purport to be successful experiments in Styria.

On the blue color of the sky, J. M. PERNTER (*Wiener Akad. Anz., 1899, p. 193; abs. in Naturw. Rundschau, 14 (1899), No. 30, pp. 383, 384*).

WATER—SOILS.

Study of evaporation, J. E. PAYNE (*Colorado Sta. Rpt. 1898, pp. 212–215*).—Observations on the rate of evaporation from water surfaces and from different types of soil are reported.

"[In the first case] two galvanized iron cans 18 in. in diameter and 52 in. deep were set close together in the ground so that the tops of the cans were on a level with the surface. These were filled with water. During July the evaporation was 11.38 in. Both were exposed equally to the action of the sun and wind during this time. August 1 one was screened from the direct rays of the sun and the other was left uncovered. From August 1 until September 24 the one in the shade lost 14.75 in., while the one in the uncovered can lost 18.43 in.

"The can which was uncovered was left until October 3, when it was found that it had lost 35 31 in. during the time from July 1 until October 3, or 95 days."

For the observations on evaporation from the soil 4 different kinds of soil were used: (1) an upland soil of a mulatto color, containing a small amount of clay, considerable sand, and enough lime to cement it, so that it is quite hard when in its natural condition; (2) a very fine black soil from a hilltop; (3) a rich clay soil of dark color, and (4) a fine light-colored soil, commonly called gopher clay. Cans 18 in. in diameter and 52 in. deep were filled with these soils, a layer of subsoil being placed at the bottom of each can. The cans were placed in a trench so that their tops were on a level with the surface of the ground. Water was added from time to time through a piece of gas pipe which extended 2½ ft. below the surface, the total amount added being equal to 3 in. of rainfall for each can. The soils were kept bare and uncultivated. At the end of 85 days the loss in weight was determined. This was found to be for soil No. 1, 1,038 tons per acre; for soil No. 2, 527 tons per acre; soil No. 3, 435 tons per acre, and soil No. 4, 600 tons per acre.

> "Four other cans just like the ones described were filled with subsoil and soil of type No. 1. In two of these millet was planted, while two of them were left bare. After 85 days it was found that the average loss from the bare soils was 905 tons per acre, while the average loss of the two upon which millet was growing was 1,056 tons per acre. The millet grew to be only 4 to 6 in. high before it formed heads. Three inches of water besides the rainfall was added to each of these cans also."

Other observations on evaporation from the soil were made in connection with a study of the influence of a wind-break. The wind-break was a sod wall and close board fence 4 ft. high, running east and west. Twenty galvanized-iron buckets, 11½ in. in diameter, were filled to the same level with soil No. 1 and sunk in the ground, at distances of from 1 to 10 ft. from the wind-break, so that their tops were on a level with the surface. Ten of the buckets were in buffalo grass sod and 10 in a millet field. Water was added to each bucket occasionally by means of glass tubes reaching nearly to the bottom. During 62 days, beginning July 13 and ending September 13, the average loss of water per acre from the soil in the buckets was 705 tons. As in the previous experiments the soil was uncultivated and bore no vegetation.

The influence of the wind-break is shown in the following table:

Evaporation during 62 days, July 14 to September 14, from buckets of soil at different distances from a wind-break.

	Water evaporated per acre during 62 days.	
	North of wall in sod.	South of wall in millet.
	Tons.	*Tons.*
Buckets 1 rod from wall	677	647
Buckets 3 rods from wall	633	686
Buckets 5 rods from wall	700	738
Buckets 7 rods from wall	703	704
Buckets 8 rods from wall	....	761
Buckets 10 rods from wall	712	....

Electrical instruments for determining the moisture, temperature, and soluble salt content of soils, L. J. BRIGGS (*U. S. Dept. Agr., Division of Soils Bul. 15, pp. 35, figs. 12*).—These methods have been described as they have been developed (E. S. R., 9, p. 535; 10, p. 30).

"It is the object of this bulletin to describe the instruments and methods at present employed by this Division in investigating the moisture and temperature of soils in the field, together with a convenient field apparatus for investigating the soluble salt content of soils. Several important modifications in the instruments and methods, as previously described in other bulletins of the Division, have been made. A special instrument is now used for each of the three classes of determinations, instead of a single instrument as heretofore. This change greatly simplifies the instruments, makes them easier to operate, materially lessens their cost, and in the case of the moisture and temperature instruments permits the use of direct reading scales, thus avoiding, except in cases where more than ordinary accuracy is desired, the necessity of any reduction of the results obtained."

Moisture determinations, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Bul. 38, pp. 396–402, 405, 406, 409–411, fig. 1, dgms. 2*).—In connection with the comparative tests of methods of culture of wheat, noted elsewhere (see p. 338), determinations of the moisture content and temperature of the soil at different depths were made and observations on the temperature and humidity of the air and on evaporation were recorded.

"Three complete determinations of the moisture content of each plat were made during the season. The first set of samples was taken May 3 to 12, a short time after sowing and before much of the grain was up. A second set of samples was taken July 5 to 9, when the wheat was heading, and the third set was taken August 10 to 15, just after harvest. Part of the first set of samples, including all of the fall-plowed plats except three, were taken with a soil tube made after the pattern of the tube used by Prof. F. H. King, of the Wisconsin Experiment Station. The remaining samples of the first and second sets were taken with a common wood auger.

"Samples were taken with the auger and with the tube from the same plat and the percentage of moisture was compared. The auger samples showed the higher percentage of moisture. The auger method of sampling is preferable with our soil when it is moist and sticky.

"Each sample taken is a triplicate or is a composite from 3 holes made in the same plat. An inch and a quarter auger was used for the first foot and an inch auger for the second and third feet. The samples thus obtained were found to be more nearly equal in bulk and weight than when the larger auger was used for each foot.

"Favorable weather prevailed during the taking of each set of samples. Check samples taken on the last day of sampling from the first plat samples showed very little change in moisture content. The greatest change or loss occurred between July 5 and 9, the time the second set of samples was taken. This was at a time when the grain was using a large quantity of water and a check sample showed a decrease of moisture as follows during the 4 days' interval:

	Per cent.
First foot	1.31
Second foot	1.81
Third foot	No change.

"The soil samples were dried in a large vertical oven over a free gasolin flame. The temperature was maintained at about 110° C. The drying was continued for from 20 to 24 hours, or until the weights were practically constant. It was found that after a sample was thoroughly dry continued heating caused a gradual slight increase in weight. All percentages of moisture are calculated on the dry weights of the soil."

Observations on evaporation were made with a modified Piche evaporometer.

> "The essential features of the instrument are a graduated glass tube which is filled with water and allowed to rest upon a base covered with filter paper into which the water feeds and from which the evaporation takes place. By a comparison of the results given by this evaporometer with those obtained from a freely exposed water surface it was found that the evaporation recorded by the evaporometer exceeded that from the free water surface in the ratio of 1.2:1."

In a special study of the moisture and temperature of the soil under the Campbell and ordinary methods of culture of wheat, daily observations from May 13 to the end of August were made on fall-plowed plats at depths of 3 to 6 and 21 to 24 in., with the electrical apparatus devised by the Division of Soils of this Department.

> "The results seem to be slightly in favor of the Campbell treatment. Under this treatment the 3 to 6 in. depth has maintained more water than the ordinary treatment through the whole season. The drought seems to have been about 2 weeks later in reducing the moisture at 21 to 24 in. under the Campbell treatment than under the ordinary. . . .
>
> "The average moisture content for the whole season shows a difference in favor of the Campbell treatment of 1.84 per cent in the first 6 in. and 0.43 per cent at the 21 to 24 in. depth. . . .
>
> "The temperature at the 3 to 6 in. depth was highest through the whole season in the Campbell plat, the greatest difference, 13°, occurring May 17. The greatest and most rapid changes of temperature also occur in the Campbell ground.
>
> "At the 21 to 24 in. depth . . . the temperature of the 2 plats seldom varies more than 2 or 3°, but the general average for the whole season is in favor of the ordinary treatment. At this depth the soil given ordinary treatment shows greater and slightly more rapid changes of temperature than the Campbell ground. The loose earth of the cultivated plat is subject to great and rapid changes of temperature, but it seems to act as a blanket to keep the heat more uniform in the firmer soil below. . . .
>
> "The mean of the daily temperature for the whole season shows a difference of 7.84° in favor of the Campbell ground at the 3 to 6 in. depth, while at the 21 to 24 in. depth the difference is 1.53° in favor of the ordinary treatment. . . .
>
> "The cultivated ground gets warmer near the surface during the day but cools off more rapidly during the night than does the ground receiving ordinary treatment, while the latter allows more heat to penetrate deep into the soil than does the former."

On the injurious effect of sea water on soils, A. J. SWAVING (*Landw. Vers. Stat., 51 (1899), No. 6, pp. 463–471*).—This is an account of examinations of Holland soils which had been overflowed by the sea. It was found that the soils to a depth of 25 cm. contained from 0.5 to 6.2 parts of chlorin per thousand. In the course of a year the amounts were greatly reduced. The injury to crops on the flooded land was apparently partly due to washing of the soil and the deposition of mud, forming a crust which retarded the washing out of the chlorin and in some cases prevented the germination of seeds.

Salt-water flood of November 29, 1897, T. S. DYMOND and D. HOUSTON (*Jour. Essex Tech. Lab., vol. 3, pp. 173–182*).—Analyses of soils from the coast of Essex flooded by sea water during different lengths of time (6 hours to 8 days) showed the presence of about 0.2

per cent of salt (NaCl) in the surface soil as against 0.01 per cent in unflooded soil, an amount considered insufficient to account for the injury to the crops, since "it has been found that in soil containing as much as 1.6 to 2 per cent of salt, i. e., 20 tons per acre diffused through the first 6 in., barley and annual grasses are able to grow, while the latter will produce a full crop in land containing 1 per cent and that clover will flourish in land containing 0.5 per cent of salt."[1] The injury is believed to be due to the action of the salt on the mechanical condition of the soil.

The removal of the salt from the soil by means of washing and by the growth of crops is discussed, the results of some experiments in these lines being briefly referred to.

The soils of Dorset, D. A. GILCHRIST, C. M. LUXMOORE, and A. M. RYLEY (*Jour. Reading College, 1899, Sup. VIII, pp. 40*).—This is a preliminary report "issued under the terms of an agreement with the Technical Instruction Committee of the Dorset County Council, by which the agricultural department of Reading College has undertaken to analyze 20 samples of soil annually during the 5 years commencing January 1, 1898, making in all 100 samples of soil. Preliminary reports will be published annually, and a full report will be issued at the end of the 5 years."

Analyses of 22 samples of soil from Dorset, besides 2 from Oxon and 1 each from Hampshire and Berkshire, are reported.

> "The districts from which the samples of soil are taken are carefully selected so that the various geological formations in Dorset may be well represented, and also that each may be, as far as possible, typical of a considerable area of land.
>
> "The principal objects of the work are (1) to place in the hands of Dorset agriculturists information as to the composition of the soils of the county, and (2) to make suggestions for the manuring of the principal farm crops on the different classes of soils. The samples of soil are collected by the agricultural lecturers, who note the geological and agricultural characteristics of the soils and subsoils, as well as their suitability for different crops."

The samples were taken in boxes which preserved the soils in their natural condition to a depth of 18 in. The soil and subsoil were separately subjected to mechanical and chemical analysis by the usual methods. The phosphoric acid and potash soluble in citric acid by the Dyer method were also determined. "There is no simple relation yet apparent between the richness or poverty of a soil in potash or in phosphates, total or soluble, and the geological formation on which it lies." Lime in state of carbonate is distinguished from that in other combinations.

The results are discussed with reference to "the manuring of the principal farm crops on the different classes of soils."

Potable water, C. W. MCCURDY and T. SMITH (*Idaho Sta. Bul. 19, pp. 67-76*).—The importance of a pure water supply is briefly discussed, directions are given for taking samples of water for analysis, and analyses of 1 sample of artesian water

---

[1] Proc. Inst. Civil. Eng., 101 (1890), pp. 189-204.

(with reference to sanitary condition and mineral constituents) and 20 samples of well water (with reference to sanitary condition) are reported, with notes on interpretation of the results of analysis.

The industrial sterilization of potable water by means of ozone (*Rev. Sci. [Paris], 4. ser., 12 (1899), No. 14, pp. 432-435*).—A review of work on this subject.

Drinking water—city, town, and rural supplies, A. W. BLAIR (*North Carolina Sta. Bul. 161, pp. 207-223, fig. 1*).—This bulletin reports analyses with reference to sanitary conditions of 88 samples of drinking water and discusses in a popular manner the purity and solvent properties of water; sources of drinking water; the construction and care of wells; the relation of drinking water to disease, and the value of chemical analysis in determining the sanitary condition of water. Directions for sampling drinking water are added.

Drinking water, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1898, pp. 177, 178*).—Analyses, with reference to purity, of 56 samples classified as follows: Springs, 20; wells, 27; reservoirs, 5, and pond ice, 4. "The analyses show that 25 per cent of the spring water, 30 per cent of the well water, 40 per cent of the reservoir water, and all of the ices were either impure and unfit to use or else were of doubtful purity. There have been 231 samples of water analyzed at this station during the past 5 years. The proportions of questionable samples in the various groups have been found to be, spring, 22 per cent; well, 50 per cent; pond, etc., 41 per cent. It is but fair to say, however, that in several cases there was reason to believe that the sample was made impure by the use of a dirty jug, bottle, or can."

Essential soil constituents, T. S. DYMOND (*Jour. Essex Tech. Lab., vol. 3, pp. 11-15, dgm. 1*).—A table and diagram show the total and available amounts of lime, magnesia, potash, phosphoric acid, sulphuric acid, and nitrogen in average Essex soils, and the amounts absorbed by crops, lost in drainage, and applied in fertilizers and manure.

Soils of Mississippi—texture and water conditions, W. L. HUTCHINSON (*Mississippi Sta. Bul. 58, pp. 14*).—A popular general discussion of this subject.

Analysis of soils, C. F. JURITZ (*Rpt. Senior Analyst Cape of Good Hope, 1898, pp. 36-50, chart 1*).—Results of examinations of some 50 samples of soil are reported and the available plant food in grain soils of 3 different divisions of the province is shown in a colored chart. The results of studies of hillock and level soil here reported have been previously noted (E. S. R., 10, p. 827).

The presence of zinc in the soil and the products of the soil, from different parts of the province of Liege, JOURISSEN and PROST (*Bul. Assoc. Belge Chim., 16 (1899), No. 6, pp. 272-278*).—Notable quantities of zinc were found in both the soil and vegetation, even at a distance of 22 kilometers from zinc works. The methods employed for the separation and determination of zinc are given.—H. SNYDER.

FERTILIZERS.

The availability of organic nitrogen in fertilizers as measured by the alkaline-permanganate method, C. H. JONES (*Vermont Sta. Rpt. 1898, pp. 160-171*).—Nine modifications of the permanganate method were tested on 18 nitrogenous materials. "The results of these preliminary trials with the various acid, alkaline, and neutral permanganates indicated that comparisons of the nitrogen availabilities of different substances would probably be more reliable if equivalent amounts of nitrogen were used than if a gram of substance, be it rich or poor in this element, was taken." The experiments on this point, using acid and alkaline-permanganate solutions, gave results more comparable with each other than those obtained by using 1 gm. of material for each determination.

"A consideration of the results obtained, rapidity and ease of handling, led to the selection of the alkaline-permanganate method (using 16 gm. potassium permanganate and 150 gm. sodium hydrate to a liter) for further work on a nitrogen equivalent basis of about 4.50 per cent (0.045 gm.)."

The results obtained were as follows:

Nitrogen availabilities as shown by the alkaline-permanganate method.

	Materials.	Total nitrogen.	Using 1 gm. of substance.		Using 0.045 gm. nitrogen.			
			Nitrogen available.	Availability of nitrogen.	Substance used.	Nitrogen equivalent.	Nitrogen available.	Availability of nitrogen.
		Per cent.	*Per cent.*	*Per cent.*	*Gms.*	*Per cent.*	*Per cent.*	*Per cent.*
1	Ground bone	3.33	2.42	72.6	1.333	4.44	2.94	66.2
2	Dried fish	6.93	3.15	45.5	.666	4.62	3.16	68.5
3	Tankage	5.18	2.31	44.6	.900	4.66	2.61	56.0
4	Cotton seed meal	6.90	1.81	26.4	.666	4.60	2.13	46.3
5	Dried blood	13.71	3.95	28 8	.333	4.57	3.12	68.3
6	Castor pomace	5.70	2 52	44.2	.800	4.56	2.73	60.0
7	Leather	7.51	1.16	15.6	.600	4.50	1.47	32.7
8	Hoof meal	13.65	4.55	33.3	.333	4.55	3.11	68.3
9	Horn meal	14.53	4.49	30.9	.310	4.50	2.67	59.4
10	Horn shavings	14.39	4 65	32 3	.310	4.46	2.88	64 6
11	Leather refuse	7.29	1.43	19.5	.610	4.45	1.33	30.0
12	Philadelphia tankage	7.07	1 23	17.4	.620	4.38	1.30	29.7
13	Felt refuse	4.55	2.24	49.2	1.000	4.55	2.31	50.8
14	Wool waste	4.94	1.71	34 5	.900	4.45	1.82	41.0
15	Casein	12.36	3.30	26.7	.360	4.45	2.59	58.2
16	Flax meal	6.41	2 17	33.8	.700	4.49	2.03	45.2
17	Gluten meal	6.55	1.76	26.5	.680	4.52	2.09	46.0
18	Muck	1.57	.52	33.0	2.800	4.40	.94	21.3

"It would appear from the table that 1 gm. of highly organic materials is too large an amount to subject to the disintegrating effect of a solution containing 1.6 gm. of potassium permanganate and 15 gm. of sodium hydrate under the specified conditions [digesting below boiling 1 hour and distilling 1 hour]. Its use gives low and obviously unsatisfactory figures. Thus the nitrogen of cotton-seed meal and of dried blood, which is known to be readily available in the soil, ranks lower in apparent availability than that of wool waste and muck, which is actually relatively inert. Indeed it does not rise far above that of the leather products. When, however, equal quantities of nitrogen rather than of the crude material are treated, a different and more rational story is told.

"Grouping the crude stock according as it falls one side or the other of 50 per cent availability when thus tested, the following showing is made:

"*Above 50.*—Dry ground fish, dried blood, hoof meal, ground bone, horn shavings, castor pomace, horn meal, casein, tankage, felt refuse (68.5 to 50.8).

"*Below 50 and above 40.*—Cotton-seed meal, gluten meal, flax meal, wool waste (46.3 to 41.0).

"*Below 40.*—Raw leather. leather refuse, Philadelphia tankage, muck (32.7 to 21.3).

"The only questionable stock in the first group is the felt refuse.

"All the materials in the third group are well known to be of inferior availability.

"The second group is an anomalous one. The nitrogen of cotton-seed and linseed meals is, as a matter of fact, readily available in the soil, yet 8 samples of cotton-seed meal tested on the 4.50 per cent nitrogen basis show low availabilities ranging from 46 to 49 per cent.

"It seems probable that these low figures are caused by the relatively large amounts of nonnitrogenous organic matter which these goods contain. This theory is borne out by the similarity of the results obtained with other vegetable ammoniates (flax and gluten meals), although castor pomace is an exception. It is also confirmed by the lowered results obtained on dried blood, dry ground fish, etc., when nonnitrogenous organic matter (filter paper, starch, etc.) were digested with them in the permanganate solutions. . . .

"The shortcoming of the permanganate method does not seriously impair its usefulness, inasmuch as pepsin-digestion methods accord to materials like unacidified cotton-seed meal their just dues. Doubtful samples should not be condemned on the testimony of a single method. Any fertilizer containing nitrogen with low availability by permanganate, but ranking relatively high by pepsin, may be passed with a fair degree of safety."

The alkaline-permanganate method and the pepsin-digestion method were compared on 118 brands of commercial fertilizers and on the average goods of each of 18 manufacturers selling fertilizers in Vermont. Of the 118 samples 11 showed an availability below 50 per cent and 1 below 40 per cent. Of the 18 average samples 2 seemed to be open to question as regards the quality of the nitrogenous matter.

In conclusion it is stated that—

"The alkaline-permanganate method (16 gm. potassium permanganate, 150 gm. sodium hydrate to 1,000 cc.; 100 cc. used in 600 cc. flask; digestion for an hour below boiling, followed by an hour's distillation) has shown broad distinctions between materials of animal origin of high and low nitrogen availability, provided amounts of substance equivalent to 0.045 gm. of nitrogen are used.

"It is simpler and far more rapid than the pepsin-digestion method, and should prove particularly useful in eliminating quickly from a long list of fertilizers a large share of goods which would surely show high availabilities by the longer and more tedious processes. Its failure to show a sufficient availability with unacidified vegetable ammoniates may be overcome by the use of the pepsin method in doubtful cases.

"Materials falling below 50 per cent nitrogen availability by this method are open to suspicion; those falling below 40 per cent are surely of little value for the production of crops. All such, however, should be likewise tested with pepsin, and, if opportunity admits, may be subjected to vegetation tests.

"The alkaline-permanganate method should be considered an aid to vegetation tests rather than a substitute for them."

The use of ammoniacal fertilizers on calcareous soils, E. Giustiniani (*Ann. Agron.*, *25* (*1899*), *No. 7*, *pp. 325-335*).—This is the first of a proposed series of articles on this subject and deals with experiments made with sand. The experiments were made in 250 cc. bottles containing 200 gm. of sand mixed with varying amounts of calcium carbonate. For purposes of comparison one bottle contained pure sand; another, pure calcium carbonate. A known quantity of ammonium sulphate solution was added and the amount of ammonia which escaped was determined by drawing a current of air through the soil and passing it through acid. In one series of experiments moist air was used; in another, dry air. Experiments of the same character, using only moist air, were made with Thomas slag as a substitute for the calcium carbonate. In the first case the bottles were allowed to stand closed and at rest for 48 hours; a current of moist air drawn through them during 48 hours removed about ½ of the ammoniacal nitrogen added. The amount of calcium carbonate present was practically without effect on the amount of ammonia removed. With dry air, however, nearly the whole of the nitrogen was given off. With Thomas slag the evolution of ammonia was more rapid. In the case of the sand containing 3 per cent of slag, nearly all of the nitrogen was removed in 20 hours.

The preservation of manure, M. Maercker (*Landw. Wohnschr. Sachsen, 1899, No. 1; Neue Ztschr. Rübenz. Ind., 42 (1899), No. 15, pp. 161–163*).

Fertilizers—a guide for instruction in agricultural schools, H. Balster (*Düngerlehre, ein Leitfaden für den Unterricht in der Düngerlehre an landwirtschaftlichen Lehrenstalten. Stuttgart: Eugen Ulmer, 1899, pp. 82*).

A review of the present knowledge of sodium nitrate, together with the origin, production, and destruction of nitrates in the soil, J. A. Myers (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 455–468*).—This is an extended résumé of the subject, treating especially of the agricultural features.

Wiborgh phosphate, L. F. Nilson (*Landw. Vers. Stat., 51 (1899), No. 6, pp. 401–420*).—This article has already been noted from another source (E. S. R., 10, p. 32).

The phosphates of Gard, J. Pellissier (*Jour. Agr. Prat., 1899, II, No. 40, pp. 496–499*).—A description of the deposits and of the nature of the phosphates.

Arsenic in superphosphates, E. Haselhoff (*Landw. Wchnbl. Schleswig-Holstein, 49 (1899), No. 34, pp. 637–639*).

Influence on plants of potassium perchlorate in nitrates, A. Pagnoul (*Belg. Hort. et Agr., 11 (1899), No. 16, pp. 249, 250*).

Fertilizers and fertility, L. A. Clinton (*Amer. Gard., 20 (1899), No. 249, p. 670*).—A discussion and attempt at explanation of the results obtained in certain fertilizer tests on field crops in which the fertilized plats gave decreased yields as compared with control plats which received no fertilizers.

FIELD CROPS.

Crop report for 1898, J. H. Shepperd and A. M. Ten Eyck (*North Dakota Sta. Bul. 39, pp. 413–458, figs. 3*).—The work here reported consists of variety tests and a study of the thickness and depth of planting of grain, forage, and root crops; a test of changing seed wheat; and a series of experiments in crop rotation. Work along this line has been previously reported (E. S. R., 8, p. 214). No results have been published for 1896 and 1897. This report deals mainly with crops grown in 1898. The results are given in tables and discussed.

Among 39 varieties of wheat tested this season, Select Haynes Blue Stem and Select Rysting Fife, both originated from selected plants, stood highest in grade and yield. For a series of 5 years Bolton Blue Stem gave the largest average yield, and for a series of 7 years Experiment Station Fife 66 stood first in yield and grade.

Experiments in changing seed indicated that the practice is beneficial only when a better variety or a better strain of the same variety are obtained.

Sowing wheat at the rate of 5½ pk. per acre gave the best average results for 4 seasons. This season, sowing at different depths had but little effect on the yield. Sowing from 2 to 3 in. deep is considered best.

Of a number of varieties of oats, Tartarian gave the best yields in the 5 years' test. Sowing from 5 to 10 pk. of oats per acre influenced the yield but little during this season.

The results of 4 years' tests showed that Mansury barley was the most prolific of the varieties tested. The results of a single trial showed that sowing barley at a depth of 3 in. gave the best yield.

Tests with spelt indicated that it produces as large a yield as barley, and analyses showed that it is equal in feeding value to barley or oats.

Corn did not mature at the station this season, and Kafir corn has not matured in any season. Gehu, Will Acme, Will Dakota, Mercer, and Northwestern Dent are considered as some of the best varieties for that locality. Sowing corn broadcast gave smaller yields than sowing it in drills. Corn sown in drills 24 in. apart gave better yields than at greater or less distances. Planting in drills 3½ ft. apart produced the largest yields of grain and fodder when single plants stood 6 in. apart in the drill. This season planting from 2 to 4 in. deep gave the best results.

Owing to the short season only the earliest varieties of potatoes ripened in 1898. In a single trial Early Andes gave the best yield and was found to equal Early Ohio in quality and earliness. Planting in hills 10 in. apart with rows 3½ ft. apart resulted in best yields in a series of distance experiments carried on this season. Doubling the amount of seed in the hill was not found profitable. A single trial indicated that planting potatoes from 4 to 5 in. deep gave the best results at the station.

Rotation experiments carried on for 6 years showed that continuous wheat culture is unprofitable and that growing wheat in rotation increases the yield and improves the quality. Land producing 3 crops of wheat and 1 cultivated crop in 4 years gave almost as much wheat and more profitable returns than land producing 4 crops of wheat in succession.

Rye has not proved a profitable crop at the station. Early varieties of buckwheat are considered valuable for the eastern part of the State.

Report of the experiments in the manuring of oats, hay, turnips, and potatoes, R. P. WRIGHT, J. W. PATERSON, and J. R. CAMPBELL (*Glasgow and West of Scotland Tech. Col. Agr. Dept. Rpts. 1897, pp. 116*).—It is concluded from tests on the residual value of manures applied to the turnip crop, as shown in the effect of succeeding oat and hay crops, that applications of the common phosphatic fertilizers and barnyard manure extend their influence over several crops. Superphosphate gave better returns than basic slag or bone meal, considering both the immediate and subsequent effects. Bone meal was inferior to basic slag. Better yields were obtained from an application of 10 tons of barnyard manure and 4 cwt. of superphosphate than from an application of 20 tons of barnyard manure alone.

The results of experiments on the manuring of turnips in 1897 indicated that barnyard manure should be applied with superphosphate. The nitrogen and phosphates of dissolved bones were less effective than the same substances supplied in mineral superphosphate in conjunction with sulphate of ammonia and nitrate of soda. Kainit gave better results than sulphate of potash when applied with superphosphate and nitrate of soda.

From results in manuring hay fields the author concludes that the relative proportion of grasses and clovers in the hay can be largely controlled by the fertilizers applied. Better results were obtained from the barnyard manure when a nitrogenous fertilizer was applied with it.

The results of fertilizer experiments with oats during the season of 1897 showed that the application mixed in the proportion of 1 cwt. nitrate of soda and 2 cwt. each of superphosphate and kainit was most effective. Omitting potash from the application or doubling the amount of kainit in the formula given above was found to be detrimental. The results further indicate that the quantity of superphosphate might be increased with advantage, and that sulphate of ammonia could be wholly or partially substituted for nitrate of soda.

In experiments on the manuring of early potatoes the best results were obtained from a fertilizer containing 17 per cent soluble phosphate, 4.75 per cent ammonia, and 9.75 per cent potash. From the data obtained, the author concludes that potatoes require a complete fertilizer.

A rotation experiment has been in progress for 2 years and is to be continued another season. The object of the work is to determine the relative merits of large quantities of slow-acting fertilizers applied only once in the rotation and of smaller dressings of quick-acting fertilizers applied to each successive crop. The results so far are in favor of the quick-acting fertilizers.

The growth of alfalfa in Kansas, G. L. Clothier (*Kansas Sta. Bul. 85, pp. 1–13*).—This is a report upon observations on the growth of alfalfa in 27 counties of northwestern Kansas. A synopsis of interviews with 51 farmers concerning the raising and use of alfalfa is given.

> "The ideal conditions of soil and moisture for the growth of the plant are found in the valleys of streams where sheet water is obtained at the depth of 20 ft. or less and where the soil is a porous, sandy loam with a permeable subsoil. I am convinced, however, that alfalfa will grow and give remunerative returns upon as many varieties of soil as any other cultivated plant. . . . It will produce a fair crop . . . upon poor land if not water-soaked. . . . Sufficient moisture in the soil is the one condition indispensable to a good crop of alfalfa."

The feeding value of green alfalfa and alfalfa hay is discussed. The author notes that alfalfa hay, even when well cured, is liable to become moldy. As a remedy it is recommended that the hay be stacked with alternate layers of straw in the proportion of 2 loads of alfalfa to 1 of straw. The dangers attending pasturing animals on alfalfa are discussed, as well as the profits from feeding this crop.

The grafting of beets, M. H. Sagnier (*Bul. Soc. Nat. Agr. France, 59 (1899), No. 7, pp. 520–523*).—The grafting of sugar beet for the purpose of increasing the seed yield of desirable varieties is described. A beet from which it is desired to obtain a large yield of seed is sprouted. As soon as the offsets at the crown of the beet have reached 2 or 3 cm. in length they are removed, along with a small portion of the flesh, and grafted on another beet. This is done by inserting the offset on a new beet just below the crown in a cut corresponding to the form of the piece of flesh taken from the mother beet. It is reported that in one experiment 48 offsets were obtained from one mother beet in this manner, 31 of which, when grafted on other beets, grew and produced first-class plants, each plant yielding a normal amount of seed.

Cassava—cultural notes and fertilizer experiments, H. E. Stockbridge (*Florida Sta. Bul. 49, pp. 5–19, pls. 2, fig. 1*).—Notes are given on the origin, habitat, and characteristics of the cassava plant and the soil and climatic conditions it requires. Methods of preserving and planting the seed, preparing and fertilizing the soil, and cultivating and harvesting the crop are described.

The fertilizer experiment was conducted on 9 fifth-acre plats. A fertilizer mixture consisting of 125 lbs. acid phosphate, 150 lbs. cotton-seed meal, and 75 lbs. muriate of potash per acre, which has given good results at the station, was considered a normal application, and in this test the fertilizer applications were modifications of one or more of the constituents of this normal fertilizer.

Yield of cassava roots per acre with different fertilizers.

	Pounds.
Check plat—no fertilizer	7,420
250 lbs. acid phosphate, 300 lbs. cotton-seed meal, and 150 lbs. muriate of potash	10,430
187½ lbs. acid phosphate, 225 lbs. cotton-seed meal, and 112½ lbs. muriate of potash	11,480
125 lbs. acid phosphate, 150 lbs. cotton-seed meal, and 75 lbs. muriate of potash	13,510
125 lbs. acid phosphate, 150 lbs. cotton-seed meal, and 37½ lbs. muriate of potash	15,050
125 lbs. acid phosphate, 75 lbs. cotton-seed meal, and 75 lbs. muriate of potash	15,080
62½ lbs. acid phosphate, 150 lbs. cotton-seed meal, and 75 lbs. muriate of potash	12,250
250 lbs. acid phosphate, 300 lbs. cotton-seed meal, and 150 lbs. muriate of potash	13,475
250 lbs. acid phosphate, 300 lbs. cotton-seed meal, and 150 lbs. muriate of potash	12,740

The average yield of cassava on the 8 fertilized plats was 12,979 lbs., the smallest yield being 10,430 lbs. and the largest 15,080 lbs. As the experiment covers only a one-year trial, the author draws no definite conclusions.

Field experiments with corn, W. C. LATTA and W. B. ANDERSON (*Indiana Sta. Bul. 77, pp. 29–34*).—These experiments are in continuation of work formerly reported (E. S. R., 9, p. 237). This is the seventh year of the experiments. A summary of the average results is here given.

In general, planting corn early in May gave the best returns. The greatest average yields of ears and stalks were obtained when single stalks stood 12 to 14 in. apart in rows 3½ ft. apart. Thick planting reduced the size of the ears and the percentage of grain, but in dry seasons it produced the heaviest yield of stalks. Cultivating 1, 2, and 3 in. deep gave about equal results, and cultivating 4 in. deep considerably reduced the yield. There was practically no difference in planting corn in hills or drills.

The fertilizer tests showed that in continuous corn culture heavy applications of manure and commercial fertilizers were not profitable. A "heavy" application of commercial fertilizers consisted of 250 lbs. of acid phosphate, 432 lbs. ammonium sulphate, and 105 lbs. muriate of potash, and a "heavy" application of horse manure of 14,500 lbs. per acre. It was noticed that the effect of a heavy dressing of fresh horse manure was not exhausted after 15 years of continuous corn culture.

A number of different cultural implements have been under trial for several years, but their use has given nearly equal yields of corn. The spring-tooth cultivator is preferred for the station farm, which has a dark compact loam soil with natural drainage.

Culture of corn forage in Princes Park, L. GRANDEAU (*Jour. Agr. Prat., 1899, II, No. 36, pp. 333–335*).—A record is given of experiments made to determine the effects on corn of fertilizing at seed time with large amounts of potash salts, and also to determine the relative values of different forms of nitrogen for corn.

The experimental field was divided into 16 plats and the whole planted to corn in rows 0.40 meter apart and at the rate of 95 kg. per hectare, May 4. Two plats were used as checks. Each of the remaining plats was divided into 2 equal parts, one-half receiving potash salts at the rate of 200 kg. per hectare and the other half at the rate of 400 kg. per hectare in each instance. Phosphatic fertilizers of different origin were added to some of the plats, while others received nitrogen in the form of nitrate of soda, sulphate of ammonia, or dried blood.

The yields of the different plats are tabulated and compared. In every instance the yield was less with potash at the rate of 400 kg. per hectare than with half that amount, the average difference for all the plats being 3,287 kg. per hectare. On the portions receiving the smaller amount of potash, nitrate of soda gave 6,200 kg. per hectare of forage more than sulphate of ammonia and 12,800 kg. more than dried blood. This work, carried on in 1897, is being continued in 1899.

Effect of fertilization upon the composition of crops, J. L. Hills, B. O. White, and C. H. Jones (*Vermont Sta. Rpt. 1898, pp. 145–155, 182–188*).—The results of investigations on this subject with corn and potatoes during 1896 and 1897 are reported.

The experiments with corn were made on $\frac{2}{7}$-acre plats of fairly uniform medium clay loam soil which had been in grass and had not been fertilized for many years prior to the experiment. Three plats were left unfertilized. One received a liberal application of barnyard manure; and four others were fertilized with mixtures of nitrate of soda, tankage, and acid phosphate with muriate of potash and sulphate of potash, and of bone meal with muriate of potash and sulphate of potash.

"The design of the test was to compare the yields and composition of corn grown for a series of years without fertilization after the first year, noting the effects—and particularly the residual effects—of phosphoric acid from acid phosphate and from bone meal, and of potash from muriate and from sulphate. As nearly as might be, equal quantities of nitrogen, phosphoric acid, and potash were used on each plat."

The crop on each plat was carefully sampled and analyzed with reference to food and fertilizer constituents. The results which are reported in detail show that the composition of the crop was slightly but not materially affected by the fertilizers applied. The crop liberally fertilized with barnyard manure contained less dry matter and nitrogen-free extract and more ash, protein, and potash than those otherwise fertilized or left unmanured. The barnyard manure apparently increased the yield but retarded maturity more than the commercial fertilizers.

"In 1896 the crops from fertilized areas were richer in protein and potash than those from unfertilized plats. No such difference (except with the crop grown on barnyard manure) was noticeable the second year. There was a tendency toward high phosphoric acid figures in the crops on the plats to which bone meal had been applied. The plats receiving acid phosphate, tankage, nitrate and potash salts grew crops containing more ash and protein but less nitrogen-free extract than did those receiving bone meal and potash salts. No differences were noted which might be ascribed to the use of sulphate instead of muriate of potash."

In the experiments with potatoes, 3 sets of plats ($\frac{1}{60}$, $\frac{1}{30}$, and $\frac{1}{20}$ acre in size) were used; 2 sets on sandy loam soil which had been well manured in previous years, and 1 on greensward which had not been fertilized for many years. Three plats received no fertilizer; 2 received acid phosphate and muriate of potash; 2 acid phosphate and sulphate of potash; 2 acid phosphate, muriate of potash, and nitrate of soda; 2 acid phosphate, sulphate of potash, and nitrate of soda; and 2 barnyard manure. The product of each crop was carefully sampled and analyzed, the results of the analyses of 114 samples being reported. The results are summarized as follows:

"The unfertilized crops carried the most dry matter and nitrogen-free extract.

"The crops grown on barnyard manure contained notably more phosphoric acid than did the others.

"The muriate-grown crops contained less dry matter and less nitrogen-free extract than those grown with sulphate of potash.

"The nitrate-grown crops contained less dry matter and more protein than those not thus fertilized.

"The minor constituents fluctuated within narrow limits, and were unaffected by changes in manuring.

"In general, fertilization tended to depress the percentages of dry matter and of starch, and, to a slight degree, to raise those of ash."

Culture experiments with potatoes and beets at Grignon in 1898, P. P. DEHÉRAIN (*Ann. Agron., 25 (1899), No. 7, pp. 336–350*).—The work reported comprises variety and fertilizer tests. Of 5 varieties of potatoes tested, Dr. Lucius was richest in starch, containing 21.9 per cent. Seed of Richter Imperator obtained from 2 different sources produced tubers which varied 2 per cent in starch content. The results for all varieties are given in the following table:

Yield of tubers, dry matter, and starch per hectare of different varieties of potatoes.

Variety.	Tubers.	Dry matter.	Starch.
	Kgs.	*Kgs.*	*Kgs.*
Dr. Lucius	28, 400	7, 845	6, 183
Prof. Maercker	28, 250	7, 484	5, 844
Richter Imperator (Vilmorin)	27, 900	7, 475	5, 857
Richter Imperator (Grignon)	25, 450	6, 359	4, 906
Variété Poulet	18, 550	4, 968	3, 892
Géaute Bleue	17, 300	2, 646	1, 857

Two varieties of forage beets were grown with about equal results. The beets contained 12.4 per cent of sugar and over 19 per cent of dry matter. With the results in view the author suggests that the large coarse growing forage beets be replaced by a beet smaller in size and containing less water and potassium nitrate and more sugar.

Sugar beets in Colorado in 1898, W. W. COOKE (*Colorado Sta. Bul. 51, pp. 43*).—This gives the results of culture experiments, of variety and seed tests, and of competitive tests in growing sugar beets on a commercial scale. The general result of the season's work has demonstrated the ability of Colorado to produce sugar beets profitably, and further work along these lines will be confined to cultural problems and to special features of the industry.

Samples of all the beets grown in 1898 were taken the last of September and again October 22. These showed an average sugar content of 15.43 per cent in the beet and a purity of 78.6 for the first samples, and 16.38 per cent sugar and 78.1 per cent purity for the second samples.

The data for the different experiments including analyses of the beets are given in tabular form and commented upon. At the home station beets planted June 15 produced less than half as much sugar per acre as beets planted May 10, 13, or 27; and beets planted at the Rockyford Substation April 18 gave a larger yield of pure sugar per acre than those planted May 2, 16, or June 1, though the quality of the beets from the latter planting was somewhat better than from the first. Beets planted in ground freshly plowed gave better results as regards germination, sugar, purity, and yield than when planted 3 days after the ground had been plowed. Irrigation of the seed at time of planting did not show any special benefit on heavy ground, but is believed desirable and even necessary on light soils. Soaking beet seed in water for 24 hours before planting resulted in neither advantage nor disadvantage from the practice. In an experiment on planting seed at different depths, results were practically the same whether the seed was planted ½, 1, or 1½ in. deep. Beets planted with a hand drill at the bottom of a 3-in. furrow showed no advantage over level culture. Transplanting beets resulted in every instance in producing fibrous and ill-shaped roots, although the yield and quality of the beets did not seem to be materially affected. The method, however, was not financially profitable. Thinning beets to distances from 4 to 10 in. in the row seemed to have but little effect on the quality of the crop, but the yield was greater with beets less than 8 in. in the row than over this distance. Different dates of thinning had but little influence on the crop, and the author believes that the work of thinning can be extended over a period of 2 weeks without injury to the beets. Heavy rains rendered the test of different numbers of irrigations inconclusive.

Beet seed grown in Utah and New Mexico was compared with seed grown in France and Germany. The experiment was made on small plats and under commercial conditions in coöperation with farmers in different parts of the irrigated districts of Colorado. The American-grown seed was of the Kleinwanzlebener variety. This was compared with Vilmorin seed from France, Mangold from Saxony, and Kleinwanzlebener from Germany. The results, which are shown in tables, were in favor of the Utah-grown seed as regards the percentage of sugar and purity, while the yield per acre was equal to that from the other seed. New Mexico seed gave as good results as the French seed, but not as good as the German seed. The author states that "in the light of these experiments there can be no doubt that sugar-beet seed can be grown in the United States fully equal to the best imported seed."

During the campaign of 1898, 9 carloads of beets grown on a commercial scale by different growers in the vicinity of Loveland, Colorado, were shipped to a sugar-beet factory at Grand Island, Nebraska. The average yield of the beets, as shown by available data, was a little less than 19 tons per acre, and the sugar yield about 5,300 lbs. per acre. Data for shipment of sugar beets from Grand Junction, Colorado, to the sugar factory at Lehi, Utah, in 1893 and 1894 are also recorded, as is data for sugar beets grown in different parts of the State in competition for cash prizes offered by various organizations in 10 counties.

Cultivation experiments with wheat, J. H. SHEPPERD and A. M. TEN EYCK (*North Dakota Sta. Bul. 38, pp. 383–396*).—A record of the second season of this experiment (E. S. R., 9, p. 931). Three fourth-acre plats were added this year, making a total of 63 plats in the series.

The results are given in tabular form, and the weather conditions and crop growth during the trial are described.

The author gives the following summary of results, which are in most cases the average of two seasons, and which are not given as absolute conclusions:

"Wheat sown in drills and cultivated gave a yield of 10 bu. and 12 lbs. less per acre than wheat sown in the ordinary way.

"Fall-plowed land gave 1 bu. per acre heavier yield than spring plowing, as an average for 7 years' trial. Deep plowing gave 43 lbs. greater yield per acre than shallow, and 37 cts. greater net profit. Ground plowed with the Secretary disk gang plow yielded 50 lbs. less per acre than that plowed with an ordinary moldboard plow. Subsoiled land gave an increase of 54 lbs. per acre, but at greater cost, making the net profits 42 cts. less per acre upon subsoiled land. Land subsurface packed gave 1 bu. and 6 lbs. greater yield than land not packed, and 61 cts. greater net profit per acre.

"Rolling and harrowing land after seeding gave an increase of 3 bu. and 11 lbs. per acre in yield and $1.25 in net profit, as a result of a single trial in the season of 1898. Harrowing wheat 1 week after seeding caused an increase in yield of 2 bu. and 1 lb. and an increase in net profit of 72 cts. per acre. Harrowing land immediately after plowing gave an increase of 39 lbs. per acre in yield and an increase in net profit of 25 cts. per acre."

Report of the agricultural section, W. W. COOKE (*Colorado Sta. Rpt. 1898, pp. 143-159, pls. 2*).—This report reviews the work for the season of 1898, and is devoted mainly to the cooperative work with sugar beets carried on in those sections of the State which seem adapted to the crop. The results of the work are given in tables by counties. The average results showed a yield of over 20 tons of beets per acre, with a sugar content of 15.43 per cent and a coefficient of purity of 80.8.

Field experiments at the Arkansas Valley Experiment Station, H. H. GRIFFIN (*Colorado Sta. Rpt. 1898, pp. 220-224*).—The results of experiments with field crops, comprising culture and variety tests with wheat, corn, and grass and other forage crops during 1898, are briefly summarized in a popular manner.

Field tests at the Rainbelt Experiment Station, J. E. PAYNE (*Colorado Sta. Rpt. 1898, pp. 206-211*).—California barley, *Bromus inermis*, alfalfa, nonsaccharine sorghums, cowpeas, Canada field peas, Idaho peas, and a number of varieties of corn were grown experimentally, and the yields are here reported. Gypsum applied at the rate of 1,000 lbs. per acre gave a large increase in the yield of Early Amber cane. The Campbell method of soil culture was tested in connection with growing cereals, sorghums, corn, and potatoes, and in the majority of cases the results were favorable to ground packed according to this method.

Florida beggar weed, J. G. SMITH (*U. S. Dept. Agr., Division of Agrostology Circ. 13, pp. 5, figs. 2*).—This circular gives a brief description of the Florida beggar weed (*Desmodium tortuosum*), discusses its value as a fertilizer and as a hay and forage crop, and gives directions for its culture.

Grass and forage crops, J. H. SHEPPERD (*North Dakota Sta. Bul. 40, pp. 459-470*).—This bulletin summarizes briefly the results of growing various forage crops in North Dakota and in adjoining States and provinces. In connection with the notes cultural methods are described and recommended. Awnless brome grass, timothy, redtop, the native prairie grasses, field peas, hairy or sand vetch, and rape gave promising results, while the experiences with orchard grass, alfalfa, melilot, cowpeas, spurry, and the different varieties of clover were not encouraging.

Experiments on pasture, E. K. (*Agr. Students' Gaz., 9 (1899), No. 4, pp. 111-113*).—Tabulated record of 20 fertilizers used on twentieth-acre pasture plats and the yields of fertilized over unfertilized plats. Phosphatic manures encouraged the growth of clovers. Sulphate of ammonia proved superior to nitrate of soda. "The plat fertilized with superphosphate and nitrate of soda gave the highest yield, but all the plats receiving superphosphate with either nitrate or sulphate of ammonia gave good crops, the increase being from 15 to 19 cwt. over the unmanured."

Results of two years' experiments on the Kemp meadows, near Novo-Alexandri, in the Lublin Government, M. P. SOLONENKO (*Zap. Novo-Alexandri Inst. Selsk. Khoz. i Lyesov., 11 (1898), No. 3, pp. 43-50*).—The influence of fertilizing on the yield of meadow grasses was studied.—P. FIREMAN.

The manuring of hops, H. H. COUSIN (*Agr. Gaz. [London], 50 (1899), No. 1343, pp. 216, 217.*)—Popular discussion of the value and use of phosphates as hop manures.

Mangel-wurzels and the cost of production, H. E. VAN NORMAN (*Indiana Sta. Bul. 77, pp. 35-37*).—Two acres of mangel-wurzels were grown experimentally and the cost of growing the crop determined. The methods of culture and storing are described. Giant Yellow Intermediate yielded 25.25 tons; Champion Yellow Globe, 24.5 tons; Golden Tankard, 17 tons; and Mammoth Long Red, 16.5 tons per acre. The average cost of growing mangels was found to be $1.04 per ton, while the cost of the largest yield was only 85 cts. per ton.

Potato culture, Z. QUINCEY (*Pacific Rural Press, 58 (1899), No. 15, pp. 228, 229*).—A paper read before the University Farmers' Institute, in which the subjects of soil, soil preparation, seed, planting, and cultivation are discussed.

Manuring of potatoes, W. L. SUMMERS (*Jour. Agr. and Ind. South Australia, 3 (1899), No. 1, pp. 11-14*).—Brief summarization of the results of recent fertilizer experiments on potatoes in New York, Georgia, and the Victorian Department of Agriculture.

Large amounts of complete fertilizers for potatoes (*Bul. [Min. Agr. France], 18 (1899), No. 3, pp. 469, 470*).—The profitableness of heavily fertilizing potatoes with commercial fertilizers on soil somewhat exhausted by having borne a crop of potatoes the preceding season without manure was investigated. The results are not entirely satisfactory owing to the fact that somewhat larger amounts of fertilizers were applied than were necessary. They seem to show, however, the harmful effects of applying potash salts on potatoes near planting time, and the more injurious effects of silicate over sulphate of potash when applied at this time.

Ramie, or China grass, W. SOUTTER (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 380-382, figs. 2*).—This fiber plant is figured and described, the Gomess process for separating the fibers and eliminating the resins noted, and suggestions given as to propagation, culture, and the application of fertilizers.

Rape as a forage crop, T. A. WILLIAMS (*U. S. Dept. Agr., Division of Agrostology Circ. 12, pp. 6, fig. 1*).—This circular contains brief popular notes on the culture requirements and feeding value of rape. The plant is described, the most important varieties re mentioned, and the different ways of utilizing the crop are suggested.

Sugar-beet investigations in 1898, C. W. MCCURDY and T. SMITH (*Idaho Sta. Bul. 18, pp. 31-52*).—This bulletin contains a report on culture experiments carried on at the station and in various sections of the State. Directions for the culture of sugar beets, the destruction of insect pests, and instructions for taking samples for analysis are given. Results of 472 analyses show an average sugar content in the beet of 15.53 per cent and an average purity of 82.76. The cost of producing an acre of beets at the station was $32. The profits in beet and wheat raising are compared.

Experiments in the growth of sugar-beet roots in Great Britain (*Jour. Bd. Agr. [London], 6 (1899), No. 1, pp. 45-55*).—A circular of inquiry was addressed to 400 experimenters with sugar beets as to results obtained in 1898. Replies were received from 143 different growers as to methods of planting, soil, yield, sugar content of beet, etc. The data are tabulated for 47 of the most reliable tests. The average quantity of sugar in 100 parts of juice was 15.65 per cent; average purity quotient, 85.19 per cent; average per cent of sugar in 100 parts root, 14.48. The average yield without tops was 16.3 tons per acre.

Fermentation of tobacco, G. DE WAMPE (*Jour. Agr. et Hort., 3 (1899), No. 6, pp. 138–140*).

Cultivation of tobacco on the Sochinsk Agricultural Experiment Station, V. SHCHERBARCHEV (*St. Petersburg, 1898, pp. 10; rev. in Selsk. Khoz. i Lyesov., 192 (1899), Feb., p. 475*).

The velvet bean, J. G. SMITH (*U. S. Dept. Agr., Division of Agrostology Circ. 14, pp. 5, figs. 3*).—Brief popular notes are given on the origin, culture, yield, value, and uses of the velvet bean (*Mucuna utilis*).

Wheat culture in the future, O. MOSZEIK (*Fühling's Landw. Ztg., 48 (1899), No. 15, pp. 595–598*).—An article discussing the world's wheat supply and the condition of wheat culture in various countries.

The production and cultivation of wheat in Portugal, L. DE CASTRO (*La production et la culture du blé au Portugal. Lisbon, 1893 (Portuguese), pp. 67*).

Yield of wheat at the Cappelle Experiment Station for the harvest of 1899, F. DESPREZ (*Jour. Agr. Prat., 1899, II, No. 36, pp. 341–343*).—Notes on 37 varieties tested experimentally and data for the yields of grain and straw of 7 varieties tested on a larger scale for the years 1896–1899. Yellow-Bearded Desprez has given the best results for each of the four seasons, the average yield being 4,705 kg. of grain and 11,302 kg. of straw per hectare.

HORTICULTURE.

Horticultural experiments at Southern Pines, 1896 (*North Carolina Sta. Bul. 159, pp. 97–171, figs. 30*).—This is the second annual report of the operations of the North Carolina State Horticultural Society Experimental Farm at Southern Pines. The organization of the board of control, preliminary work of getting the experimental plats in suitable condition, and general plans of the experiment have been previously described (E. S. R., 8, p. 693) and are only briefly noted here.

The object of these investigations is to determine, by a series of experiments extending over a period of years, the best quantities and relative proportions in which to use the various fertilizing substances for the best growth of fruit and vegetables at the least cost. Incidentally, the best insecticides and fungicides for use on the different crops will be studied. No commercial brands of fertilizers are used, but fertilizing ingredients are employed in different combinations, and green manuring practiced in some instances.

The experiments are conducted on tenth-acre plats for orchard fruits and nuts, fortieth-acre plats for small fruits, and twentieth-acre plats for vegetables. The kinds, combinations, and amounts of fertilizers applied to each plat, and the chemical analyses of each are shown in tabular form. The growth and yields of different crops are illustrated by photographs.

Vegetables were included in the list of crops experimented with in 1896; Station Hybrid sweet corn, White Southern Queen potato, Early Wakefield cabbage, Palmetto asparagus, Livingstone Beauty tomato, Valentine snap bean, White Spine cucumbers, and White Bliss Irish potatoes being employed.

The results of the season's work with fruits are summarized and tables given which show the vigor of growth and air-dried weight of prunings of peaches, plums, apples, and grapes; the height in inches of peach, plum, and apple trees, and the analyses (fertilizer constituents) of grape prunings and strawberry runners on each of the plats differently fertilized. These data are compared with the results obtained in control plats. In the estimation of the writers the data thus far obtained places the agricultural value of different forms of potash for young fruits in the following decreasing order: Sulphate, muriate, double manure salt, carbonate of potash-magnesia, and kainit. Little or no benefit has as yet been shown by the use of green manure. This is thought to be due to the heavy draft on the soil moisture made by the growing legumes.

The data for work with vegetables are given in detail, but no conclusions are drawn. These data show the yield and chemical analysis (fertilizer constituents) of the vegetables grown with different fertilizers, and in addition the starch, sucrose, and glucose of the sweet potatoes.

Ants were again the most serious insect pests in 1896. They were combated entirely by tillage. Some 14 other species of insects were more or less prevalent during the year, and a few of the more usual fungus diseases made their appearance. Bordeaux mixture, with the addition of Paris green and molasses, has formed the main combative measure against these injurious agents.

Plant growing with commercial fertilizers, W. STUART (*Trans. Indiana Hort. Soc., 1898, pp. 105–113, dgm. 1*).—This paper briefly describes the Indiana Station vegetation house and its equipment, and presents the results of 3 series of experiments with fertilizers on lettuce.

The first of these experiments has already been reported (E. S. R., 9, p. 1048). The general plan of the second experiment was similar to that of the first. The bed there described was used in the second test but was divided into 7 instead of 6 sections. Two sections were used as checks. Of the remaining sections, one received dissolved boneblack, one dissolved boneblack and muriate of potash, one dissolved boneblack and sulphate of potash, one dissolved boneblack and nitrate of soda, and one dissolved boneblack, nitrate of soda, and muriate of potash, at the following rates per acre: Dissolved boneblack 1,450 lbs., muriate of potash 658 lbs., sulphate of potash 564 lbs., and nitrate of soda 732 lbs. Grand Rapids lettuce was grown as in the previous experiment. The average weight of the individual plants grown with the different fertilizers was as follows: Control sections, 87.4 gm.; dissolved boneblack alone, 120.8 gm.; dissolved boneblack and muriate of potash, 133.7 gm.; dissolved boneblack and sulphate of potash, 123.4 gm.; dissolved boneblack and nitrate of soda, 134.6 gm.; and dissolved boneblack, nitrate of soda, and muriate of potash, 139.2 gm.

The third experiment was conducted in the station vegetation house in zinc pots, to further test the 2 forms of potash, and phosphoric acid from other sources. "Twenty-one pots, about 10 in. in diameter and of the same depth, were used in this trial, 3 pots being used for each combination." Raw bone meal alone and in combination with sulphate and muriate of potash and with nitrate of soda was used in 5 series, acidulated bone and nitrate of soda in one series, and one series was used as a check. Two plants were grown in each pot and each series was harvested when at its best. The average weight of the individual plants in each series, and percentage increase in weight of plants in the fertilized series over the checks, are tabulated. The data shows a gain in weight of plants over the checks of from 132.1 per cent with raw bone meal alone, to 232.9 per cent with raw bone meal, muriate of potash, and nitrate of soda mixed. The complete fertilizer gave increased yields over combination by twos of 74.7 per cent. But little difference was noticeable in the effect of raw and acidulated bone. Muriate of potash gave slightly better results than the sulphate.

The yields of the 3 sets of experiments are tabulated side by side and compared graphically. The author believes the experiments show that "the addition of phosphoric acid in some form is highly essential to successful lettuce culture;" and that "the addition of potash and nitrogen to phosphoric acid produces a considerable increase over that of phosphoric acid alone."

Notes on the winterkilling of twigs and buds, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 302–306*).—This article is an abstract of a thesis by L. W. English. A study was made of the minute structure of twigs of various trees and shrubs to determine whether hardiness depends on any anatomical peculiarities, but with negative results. Observations were made confirmatory of the theory that "twigs best stored with reserve materials will be best prepared to stand freezing weather." Observations were also made upon the losses by evaporation from apple twigs in winter, which were in practical agreement with others already reported (E. S. R., 8, p. 311; 10, p. 152). It was also found that buds of apple, cherry, and plum trees in Burlington, Vermont, lost from 2.9 to 7.9 per cent of their total weight by evaporation between December 20, 1897, and January 29, 1898. It is believed that "the drying out of fruit buds, if excessive, would be even more disastrous than the desiccation of twigs."

Twigs of various trees were covered with whitewash, others blackened with lampblack, still others coated with wax, and some left as a check. These were started together in the greenhouse. The blackened twigs were earliest in opening and the whitewashed twigs latest. The waxed twigs started slowly and irregularly and were evidently injuriously affected.

Variation in the graft and transmission of acquired characters, L. DANIEL (*Ann. Sci. Nat. Bot., 8. ser., 8 (1898), Nos. 1–6, pp. 226, figs. 19, pls. 10*).—In this article the author demonstrates the existence of a reciprocal action of stock and scion, inducing a direct or indirect variation of the grafted plants.

Variations in the graft may be due to changes in nutrition or may be specific; that is, they may appear in the particular characters of the stock and scion more or less independently of environment. The latter has been, however, a much debated question and the arguments of previous writers for and against it are briefly reviewed.

The article is in two parts. The first part is devoted to a study of the variations produced by grafting directly on the associated plants. A large number of experiments are reported and discussed, developing the facts of variation, after which the attempt is made to give a theoretical explanation of them. The effect of grafting on the general nutrition may be shown in four ways:

(1) The size of the vegetative organs of stock and scion may be modified. If an herbaceous plant is grafted on itself, the general nutrition is interrupted in inverse proportion to the activity of the cambium layer at the time the operation is performed. The same principle applies in the case of grafts between different plants of the same variety. In the case of grafts between plants of different varieties, species, or genera, the reciprocal reactions are much complicated by imperfect functional adaptations. In herbaceous grafts the callus has the same effect on the scion as would placing it in arid soil—it is dwarfed. In determining what species of the same order may be successfully grafted, similarity of habitat is of more importance than relationship. In the case of ligneous plants, the author shows that geotropism is a cause of variation, although this has generally been denied heretofore. It is also shown that a branch that has lost its negative geotropism does not always regain it if grafted on the main axis of the stock, at least in the case of the pear.

(2) The flavor of edible parts, their size, chemical composition, or season of development, may be modified. If the union is perfect, grafting in general produces a change of flavor in the edible parts of vegetative organs. This change may be either in the nature of an improvement or deterioration in quality. There is almost always a reduction in the size of the part which sometimes fails entirely to develop in edible form. For the operation to have practical interest, the diminution in size must be compensated by increase in quality. When the edible parts belong to the reproductive organs, grafting herbaceous plants may or may not cause the enlargement of the pericarp of fleshy fruits or of the seeds in dry fruits. There is no known principle of general application. The flavor of the fruit depends principally on the completeness of the union and the quantity of sap that the scion receives. This principle applies to ligneous and herbaceous plants alike.

(3) The development of the reproductive organs of the scion may be accelerated or retarded. The flowering season of the scion may be affected very differently, according as the plant is annual, biennial, or perennial; according to the time the graft is made; according to the age and nature of the scion, and according to the kind of graft

employed. Grafting may induce variation in the arrangement of flowers, in the season of opening or falling of the petals, or in their color.

(4) The relative resistance of stock and scion to parasites and other injurious organisms or substances may be modified. The principal parasites that attack grafts before the union is complete are mollusks, worms, saw bugs, insects, and molds. These parasites may affect the stock and scion differently. The parasites that attack grafted plants after the union is complete are, in the order of the extent of their ravages, insects, myriapods, fungi and other vegetable parasites, and mollusks. The more imperfect the union of stock and scion the more serious are the attacks; so much so that their extent and severity may be said to be a criterion of the degree of perfection of the symbiosis.

The theory by which the author undertakes to explain these facts is developed at much length. In brief, the nutrition of stock and scion is modified by two causes which may act in the same or contrary directions. These are (1) the callus consequent on the operation, and (2) the difference between the peculiar functional capacities of stock and scion, such as differences in structure, special diastases, differences in composition of the crude or elaborated saps, etc. The phenomena produced are dependent not only on the nature of the plant, but intimately so on environment.

From this theory certain conditions of success in grafting may be deduced. The protoplasm of stock and scion must not, as a result of the operation, be modified beyond that definite point at which poisoning sets in or at which the essential properties of the living substance, as nutrition and motility, are destroyed. Destruction of the protoplasm may result from either of two causes: (1) From the action of plastic or waste products which are brought together suddenly, causing immediate poisoning or gradually causing slow poisoning. These products may give rise through mutual reactions to other injurious products. (2) From deficiency or excess of water in stock or scion, consequent upon grafting.

The author demonstrates the insufficiency of the hypothesis of relationship and that of similarity in composition of elaborated saps to account for the success of a graft or to explain its variations.

A large number of experiments are reported, each illustrating a different variation, all referred by the author to the category of variations produced directly by a mutual reaction of stock and scion. Specific variations differ much in degree, according to the nature of the plant and even according to the part of the scion. This principle applies alike to herbaceous and woody plants. Specific variations result in a more or less complete blending of the characters of stock and scion, or more strictly, these characters appear side by side but separate and distinct. The explanation of the effects of variation in the graft by the hypotheses of xenia and of mutual reaction of the protoplasm are discussed at length. The author believes that the latter hypothesis is sufficient to explain all cases that have arisen, and shows that the former is not.

A method has been devised for the partial differentiation of variations due to nutrition and specific variations by the mixed graft (E. S. R., 9, p. 945). Experiments are reported showing that specific variations may be augmented by mixed grafting to the extent that asexual hybridization is induced.

The second part of the article discusses the inheritance of characters acquired through grafting. Variations due to nutrition were in some cases transmitted by seed collected from the scion, even when no morphological changes were apparent in the scion itself. Such a case shows that the immediate influence of the stock on the scion may be less than its indirect influence on the offspring of the scion. Seed grafts of wild carrot on the cultivated half long red variety showed clearly such a mixture of the characters of stock and scion that the resulting plants might be considered true crosses or graft hybrids produced by the influence of the stock on the embryo. These and similar experiments show also that by grafting a wild on a cultivated plant the former may be made to acquire definite qualities which can be improved by selection. Experiments showed also that these variations which the author classes as specific are at least in certain cases transmitted by the seed. A preliminary report is made of experiments on the inheritance of characters acquired as a result of mixed grafting. No general conclusions are drawn.

In conclusion, the graft may have an influence on the somatoplasm, though this is not always the case. In many plants the effect is often very slight, especially in woody plants, in which the ligneous framework gives to the plant a much more fixed form than herbaceous plants possess. When this influence exists it most often affects characters of little taxonomic importance, as height, vigor, etc., and then its influence is similar to that of environment; but it may sometimes affect the essential characters of varieties or species, such as external form, structure, etc., which become more or less blended into graft hybrids or may disappear, giving place to entirely new characters. Not only may the influence of the graft on the somatoplasm show itself directly in the grafted plants themselves, but it may produce an indirect reaction either parallel or not parallel to the direct reaction, and new characters may develop in the offspring, demonstrating that in the vegetable kingdom acquired characters can, contrary to the theory of Weismann, be transmitted.

From these theoretical considerations certain practical conclusions may be deduced. When grafting does not modify the peculiar characters of a variety, but merely produces certain slight variations of nutrition, it may be employed to perpetuate varieties, races, or accidental forms of perennial plants; but if the influence of the graft on the somatoplasm is very marked and proves to be specific, which experiment alone can determine, it may be applied to the creation of new varieties. Thus a new field of operations is opened up to seedsmen.

Hardiness of plums, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 273–279, dgms. 3*).—The approximate northern limit of successful culture of each group of plums is investigated and discussed. The limits of Lombard and Bradshaw (Domesticas), Burbank and Kelsey (Japanese), and the Wildgoose group are graphically represented. The Americana and Nigra groups are said to be the hardiest of all plums, thriving about as far north as any permanent form of agriculture is found. The Wayland group is believed to be about as hardy as the Wildgoose, and the Miner group slightly hardier. The northern limit of the Chicasaws has not yet been satisfactorily determined.

Problems in plum pollination, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 238–262, figs. 1*).—This is a continuation of work already reported (E. S. R., 9, p. 837). Experiments to determine the self-sterility of plums were continued. The results further substantiated the conclusions reached in 1897. "In all the tests which we have made in 3 years in Maryland and Vermont, practically all varieties of [native and Japanese] plums have proved to be absolutely self-sterile. The only positive exception to this rule is the Chicasaw variety Robinson."

Reliability of experimental method (pp. 240–244).—Certain objections are discussed that have been made to the reliability of the method of testing self sterility by covering blossoms with paper sacks, as used by the author in common with other experimenters. "(1) It is said that blossoms covered with paper sacks are not pollinated, or, at most, the experimenter has no assurance that they are. (2) The paper cover introduces an unnatural condition, which may interfere with the development of the young fruits, even after pollination is properly effected." To these objections the following considerations are opposed:

"(1) As to uncertainty of pollination. (a) In the experiments of 1897 . . . 6,365 [covered] blossoms set only 3 fruits. . . . It seems incomprehensible that [such a small proportion of blossoms] should have been able to pollinate themselves. (b) The circumstances are not unfavorable to pollination. . . . [Covered clusters of blossoms] furnished an abundance of pollen within the sack, so much that, in many instances, when a sack was removed, a considerable quantity of the yellow dust could be shaken out into the hand. The agitation of the sacks full of blossoms in the wind seemed to insure an effectual distribution of the pollen to all or nearly all the stigmas. (c) Further than this, sacks were removed in many cases and the stigmas examined with a lens. In all such instances, quite without exception, the stigmas were found to be liberally covered with pollen. . . . (d) In a number of cases the sacks were removed when the blossoms were opened and the stigmas receptive, and pollination was carefully accomplished by hand. In these cases the results were not different. (e) The variety Robinson, in several different experiments in Vermont and in Maryland, has always set more or less fruit. This has seemed to prove its self fertility in those cases and at the same time to show that a sufficient pollination is usually secured under the experimental conditions in question.

"(2) As to the introduction of unnatural conditions. (a) The fact just brought out under (e) . . . seems to show that the conditions are not sufficiently unnatural

> to account for the results secured in our experiments. (b) The principal answer to this objection, however, lies in the fact that blossoms cross-pollinated by hand and inclosed in paper sacks, other conditions being reasonably favorable, almost always make a satisfactory setting of fruit."

Opinions confirmatory of the above are quoted from private correspondence with experts (E. S. R., 6, pp. 46, 47). Studies of pollination affinities have led to the conclusion that all the commonly cultivated Japanese and native varieties belonging to several different species seem to be quite reliably interfertile.

The theory advanced by Heideman[1] that the pollination affinities of plums are to be judged from structural variations of the blossoms was investigated but failed of verification.

Investigations were made on the relation of insects to pollination of orchard plums. Large clusters of plum blossoms of several varieties were covered with coarse mosquito netting, thus excluding the ordinary insect visitors, but permitting free pollination by the wind. Not a fruit was set under the netting, although a crop was obtained from the rest of the tree. An enumeration of 28 species of insects captured on plum blossoms is made. Of these, 18 were Hymenoptera and 10 Diptera. Most of these species take little active part in pollination. The common honeybee is believed to be chiefly instrumental in the distribution of pollen.

Blossoming season of plums (pp. 248-257).—From a study of the duration of the blossoming period of plums in 1898, the following conclusions are drawn:

> "Under circumstances of good weather the blossoms of a given variety are open and the stigmas receptive in sufficient number to insure the setting of a full crop of plums for from 1 to 3 days.
>
> "When the weather is bad, a given variety may remain in blossom for an indefinitely long time, though usually there will not be a sufficient number of pistils in condition to set a crop through more than 5 to 7 days.
>
> "When no pollen is available, or when by any means fecundation is prevented, stigmas will remain receptive 4 to 6 days, even in sunny weather."

But regarding these statements it is remarked that the real pollination is often effected within 3 to 4 hours of a single day in bright, sunny weather, and that though a tree may remain in bloom for 2 or even 3 weeks during cold, rainy weather, it is almost certain not to set any fruit in such a case.

From a comparison of the blossoming seasons of several varieties of plums the conclusion is drawn that probably the variations from year to year in the order of blossoming are of small practical consequence in any given locality.

A further comparison of varieties in widely different localities was made to determine whether the blossoming periods of both follow the same order. In 22 out of 25 varieties selected at random the deviations were "not more than 2 days in either direction—a difference which might easily be caused by local influences of soil or transient influences of climate." The blossoming chart published last year has been reconstructed and improved. It is believed that such a chart is most trustworthy for the locality where the notes are taken, but that, granting room for some exceptions, it may be used in other localities without fear of serious mistakes. In order to assist in its interpretation for other localities and at the same time to give a fuller idea of the progress of the annual flowering season, 2 isophenal charts are arranged to present a view of the blossoming seasons of 2 standard varieties for 1898.

---

[1] C. W. H. Heideman, The Sexual Affinities of *Prunus americana*, Minn. Hort. Soc. Rpt. 23 (1895), p. 187.

The grape, J. C. WHITTEN (*Missouri Sta. Bul. 46, pp. 31-76*).—Studies were made on about 150 varieties with reference to their comparative value for commercial purposes and home use, adaptability of the different types to Missouri, self-fertility, blossoming period, and average size of bunch and berry. Data are tabulated showing the origin of each variety if known, its vigor, health, productiveness, weight of average fruit cluster, weight of average berry, color of fruit, flavor, date of first flowering, full bloom, last flower, ripening, and period of fruiting, with notes on self-fertility. The varieties are also arranged in the order of their ripening in 1898, according to average weight of berry and average weight of bunch, the weights being given for each variety.

> "The following varieties ripened in 1898 ahead of Moore Early: Early Ohio, Champion, Green Mountain, Moyer, Hartford, Jewel, Ives, Janesville, New Haven, Aminia, and Brighton.
>
> "Among the best very early varieties for commercial planting, judging from our own experience and the experience of practical growers, are: Green Mountain, Campbell Early, Jewel, New Haven, Aminia, Brighton, Moore Early, and Norfolk.
>
> "The grapes having the largest berry are: Columbian Imperial, McPike, Eaton, Salem, and Moore Early.
>
> "The Ozark is the most vigorous and productive variety we have tested.
>
> "Among the most promising comparatively new or little-known varieties are America, Aminia, Brilliant, Campbell Early, Green Mountain, Hicks, McPike, New Haven, Norfolk, Ozark, Rochester, and Rommel."

The sacking of most varieties of grapes was found profitable. Green Mountain gave better results under the treatment than any other variety tested. About 40 per cent of the varieties in the station vineyard were found to be self-sterile. Experiments indicated that the source of the pollen had no effect on the character of the fruit, but were inconclusive.

Notes are given on a considerable number of varieties and on the species in cultivation. Æstivalis and Lincecumii are considered best adapted to Missouri. Labrusca produces the largest and finest fruit, but sometimes suffers from the heat of summer.

Cold storage for fruit, E. E. FAVILLE and W. L. HALL (*Kansas Sta. Bul. 84, pp. 31, pls. 2, dgms. 3*).—This bulletin treats of cold storage for fruit on the farm and in cities. Cold storage on the farm may be with or without ice. In one case of home storage without ice, a storehouse was made by lining the bottom and sides of an old hotbed with straw and covering with the same material and oiled muslin. This method is not considered safe in Kansas in a cold winter. Another case is that of a cave in a hillside sloping to the north. Details of construction are given. In order to secure the best system of ventilation and the most even and desirable temperature, the use of an underground pipe for ventilation is recommended, leading from an opening in the floor of the cave to a similar opening on the surface of the ground several rods away. Plans and specifications are given for a cold storage house in which refrigeration is provided for by packing ice in the second story.

The advantages of cold storage at home and in cities are enumerated.

A table partly compiled and partly based on experiments at the station shows the best temperature for preserving summer and winter apples, pears, peaches, grapes, plums, berries and cherries, bananas, lemons, oranges, figs, raisins, watermelons, muskmelons, tomatoes, cucumbers, celery, cranberries, onions, potatoes, asparagus, and cabbage, and indicates the packages in which they should be stored and the time they may be expected to keep.

A series of experiments in the preservation of fruits in cold storage were carried out in cooperation with two cold storage companies in different cities. Trial shipments were made of peaches, grapes, plums, tomatoes, cucumbers, pears, and apples. Egg cases gave superior results as shipping packages for peaches. Grapes packed in sawdust kept better than those stored by any other method. Cut cork is suggested as an even better packing material for grapes. It is believed that the best results in storing grapes can be obtained in a room cooled by dry, cold air currents. Red varieties of grapes kept longest, followed in order by white and black sorts. The early varieties kept best, but no extremely late varieties were tried. For best results in cold storage, a grape should mature slowly in a climate of moderately cool, regular temperature. Tomatoes should be picked when just beginning to ripen. Cucumbers were not a success.

Experiments with pears were on a very small scale. Winter Nelis grown in Kansas did not keep so long as the same variety from California. Varieties with open cores kept best. A quoted opinion advises wrapping each individual peach, pear, and plum. Tests with apples indicated that considerable difference exists in varieties as to the length of time they will keep and the temperature at which they will keep best. Apple scald is briefly described. Notes are given on the production of fruit intended especially for cold storage. The practical points in the handling of fruit for cold storage are gone into throughout the bulletin in great detail.

Cold storage of fruit (*Jour. Bd. Agr.* [*London*], *6* (*1899*), *No. 1, pp. 85–87*).—This is an abstract of a report of experiments in England on cold storage of fruit.

"[Each of 3 chambers] was fitted with tiers of galvanized wire shelves around the sides, and the fruit was placed on these under three different conditions: (1) Exposed on the shelves, (2) enveloped in grease-proof paper, and (3) surrounded or covered by cotton wool. It was found that strawberries could be kept for at least 3 weeks in a temperature of 30°, but it was necessary to surround the fruit with cotton wool, or, in the case of fruit in sieves, to place a pad of that material over the top. When this precaution was not taken, the fruit, though sound, became dull and lost the fresh, inviting appearance which is so important when it is offered for sale. Black currants kept well for 10 days, after which they began to shrivel, but plumped and freshened on exposure to the air so as to be marketable. This was especially the case with black currants that had been stored in market sieves covered with a wad of cotton wool. After a fortnight's storage, the temperature was raised from 30 to 32° F., and this seemed to give the best results. The experiments with red currants were an unqualified success, the fruit remaining perfectly sound for 6 weeks, and maintaining its freshness when exposed to a normal temperature for 16 hours. Cherries covered with wool kept for a month at a temperature of 30°, and at 36° were not only sound, sweet, and juicy, but fresh and clear. After the fourth week the fruit began to wrinkle. . . . Green Gages were kept in excellent condition for 10 weeks and Victoria plums kept for 9 weeks, but the cooking varieties of plums, with that exception, did not lend themselves satisfactorily to cold storage. In the case of apples, specimens of most of the leading dessert sorts were stored on September 17 and October 8, and, with one or two exceptions, they kept until the end of January, a temperature of 36° being found most suitable."

Pears kept at the same temperature, or a trifle under, for 3 or 4 months; individual apples and pears of a number of varieties, most of which did not ordinarily keep later than Christmas, kept in storage until the end of March. Tomatoes were kept for 6 weeks, but the fruit was injured by a discoloration at the point of attachment of the stem.

Belgian horticulture (*Florists' Exchange, 11 (1899), No. 10, pp. 1003, 1004*).—Extract of a paper on this subject read by S. S. Bain before the Canadian Horticultural Association.

Construction and management of hotbeds, F. A. HUNTLEY (*Idaho Sta. Bul. 17, pp. 17–28, figs. 4*).—Popular notes on the construction and management of hotbeds, especially for the home garden. It is recommended that a hotbed for the use of a family of ordinary size contain at least 45 sq. ft. of ground surface. Corner blocks are preferred to posts, and a width of 5 ft. for the hotbed is considered more convenient than 6 ft.

Culture of asparagus and the use of commercial fertilizers, E. C. PRADEL (*Jour. Agr. Prat., 1899, II, No. 35, pp. 299–302*).—Analyses are given of the asparagus soils of the Meurthe-et-Moselle district and of asparagus (fertilizer constituents of edible asparagus and of complete stems). With this data as a basis the author endeavors to show that the addition of some form of commercial fertilizer to such soils supplementary to barnyard manure is a necessity. A formula for this purpose is given, with suggestions as to the time and manner of application.

Asparagus—raising, growing, and forcing, G. HATFIELD (*Garden, 56 (1899), No. 1449, pp. 156–158, fig. 1*).—Paper read before the Royal Horticultural Society at its meeting April 18 and based largely on the results of the author's own experience.

Variation in the graft and the transmission of acquired characters, L. DANIEL (*La variation dans la greffe et l'hérédite des caractères acquis. Paris: Masson, 1899, pp. 220, pls. 10*).—See p. 343.

Peach culture, J. H. HALL (*Trans. Massachusetts Hort. Soc., 1899, pt. 1, pp. 32–38*).—Paper, with discussion, read by the author before the society at its January meeting. It deals largely with New England conditions.

Monograph of the Wayland group of plums, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 280–287, figs. 6, pls. 5*).—The group is stated to be one of the most distinct of the indigenous American plums. The several varieties are more uniform than in most groups. They are especially adapted to the Central and Southern States and probably would be found hardy much farther north. Varieties of this group are characterized by clear white buds and generally by great firmness of flesh. They are especially desirable for shipping long distances, preserving, and spicing.

Plums under glass (*Jour. Hort., 51 (1899), Nos. 2657, pp. 199, 200; 2659, p. 238*).—Popular directions for the growing and management of plums under glass.

Hybrid plums (*California Fruit Grower, 24 (1899), No. 591, p. 5*).—Discussion of this subject based largely on the work of F. A. Waugh.

The forcing of pineapples (*Wiener Illus. Gart. Ztg., 8 (1899), No. 9, pp. 296–299*).—Directions, based on experience, for the successful forcing of pineapples.

Cocoa planting in Samoa (*Planting Opinion, 4 (1899), No. 33, pp. 662, 663*).—The details of cocoa growing and the development of this industry since its introduction in Samoa in 1892 are briefly discussed.

Cacao, G. S. GENMAN and J. B. HARRISON (*Rpt. Agr. Work Bot. Gard. [British Guiana], 1893–1895, pp. 105–121*).

The mango (*Bul. Roy. Bot. Gard. Trinidad, 3 (1899), No. 20, pp. 190–219, figs. 12*).—Illustrated descriptions of 12 varieties of mangoes (*Mangifera indica*), with an account of the growth of mangoes in the Royal Botanic Gardens of Trinidad and a discussion of shipping requirements

The strawberry manual, LAXTON BROS. (*Bedford, England: Laxton Bros., 1899, pp. 139*).—This book comprises information dealing with the origin and history, hybridization, crossing and seedling raising, and cultivation in private gardens and for market. Chapters are also given on forcing, manures, insect and fungus enemies, and suitable varieties for different purposes and various soils.

Report on strawberries for the season of 1899 from the Strawberry Valley Fruit Farm, Maine, E. W. WOOSTER (*Amer. Gard., 20 (1899), No. 249, p. 670*).—This is a brief report on the results obtained in a test of nearly 100 varieties of strawberries. "The most profitable varieties were Parker Early, . . . 15,000 quarts per acre; . . . Glen Mary, Clyde, Haverland, Ridgeway, and Lovett on beds fruiting the first season, and the Bubach and Beverly on beds fruiting the second season." The Clyde was injuriously affected by the wet weather. Glen Mary held its size the best of all the varieties tested. The Hunn was the latest to blossom.

Late strawberries, J. S. W. (*Garden, 56 (1899), No. 1451, p. 198*).—Notes on desirable late varieties, with cultural directions and special consideration of alpine strawberries.

Experiences in rational coffee culture, F. W. DAFERT (*Erfahrungen über rationellen Kaffeebau. Berlin: Paul Parey, 1899, pp. 60, pls. 2, figs. 24*).—Part I of this work deals with the limits of productivity of a coffee plantation, Part II with the factors which influence its productivity, and Part III with the means by which its productiveness may be increased. The work is based on the results of the author's experimental work on coffee culture in Brazil and on the work of Lester Arnold, Rigaud, van Gorkom, Morren, and other investigators in India, Madagascar, Java, and other coffee-producing countries. The chapter dealing with the fertilization of coffee trees is especially instructive.

The hollyhock, R. P. BROTHERSTON (*Jour. Hort, 51 (1899), No. 2658, pp. 205, 206*).—Directions are given for the culture of hollyhocks with regard to the avoidance of the hollyhock disease. The author advises that seed be sown the end of August or first of September and the plants potted about the last of January. They should then be kept in a dry, cold pit for the remainder of the winter and planted out in the spring. Commercial fertilizers have been used with success by the author as a substitute for barnyard manure in the culture of hollyhocks.

Notes on lilies, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 296–302*).—An enumeration of the known species of the genus Lilium, following the order of Baker's Analytical Key as given in Nicholson's Dictionary of Gardening. Eight species new to Baker's list are added, including 1 species that Baker classed as a variety. Brief horticultural notes are given on nearly all species.

Miltonia bleui, H. DAUTHENAY (*Rev. Hort., 71 (1899), No. 17, pp. 400–402, figs. 2*).—A description of this comparatively new orchid obtained by M. Bleu by crossing ***Miltonia vexillaria*** on ***M. rœzlii***.

The new giant violets, J. C. HOUSE (*Garden, 56 (1899), No. 1454, pp. 260, 261, col. pl. 1*).—Six varieties of these violets are described and notes given on their culture in the open and under glass.

Lawn management and seed mixtures, F. P. SPERRY (*Proc. Columbus Hort. Soc., 13 (1898), pp. 28-31*).—Notes on the preparation and care of lawns.

A new drought-resistant sod—Carex alba, P. DE LA BATHIE (*Rev. Hort., 71 (1899), No. 17, p. 403*).—The author has employed this sedge in his garden as a border for flower beds and for lawn purposes with excellent results for 5 years. It has been especially valuable during dry seasons. Cultural directions are given. The plant is thought very desirable for light soils.

Caraganas, W. J. BEAN (*Garden, 56 (1899), No. 1450, pp. 177, 178, fig. 1*).—Detailed descriptions of 12 varieties and species of this hardy shrub, with a discussion of their ornamental features, and recommendations as to the most desirable varieties to grow.

Hedges, their planting and care, P. JURASS (*Deut. Landw. Presse, 24 (1899), No. 70, p. 797*).—Hawthorn hedges are especially considered and suggestions given regarding a large number of other shrubs suitable for hedge growths.

SEEDS—WEEDS.

Impurities of Vermont clover seed, L. R. JONES and W. A. ORTON (*Vermont Sta. Rpt. 1898, pp. 229-234, fig. 1*).—In the spring of 1897, 34 samples of clover seed were obtained from farmers in various portions of the State. These were carefully examined for impurities, which are divided into inert matter and viable seeds, including all foreign seeds that were apparently sound. Twelve samples of alsike and 20 of red clover were examined, the results being shown in tabular form. The percentage of viable weed seeds in red clover varied from 0.3 to 3.2, with an average of 1 per cent. In the alsike the weed seed varied from 0.4 to 5.2 per cent, with an average of 2.5 per cent. In a number of the samples several weed seeds considered most pernicious were found to be quite abundant. Most noteworthy of these were the sheep sorrel, English plantain, bracted plantain, wild carrot, and dodder. Sorrel was found present in 60 per cent of the red clover samples examined, and the English plantain occurred in 70 per cent of them. It seems from a statement made in the report that the larger seed dealers have facilities for cleaning the seed, and the purity of the sample depends largely upon the demand for high or low priced seed.

Influence of size of seed on germination, A. J. J. VANDEVELDE (*Bot. Jaarb. Dodonæa, 10 (1898), pp. 109-131, pls. 6, figs. 2*).—The author reports upon germination studies of 1,800 each of large, average, and small seeds of peas, oats, rye, wheat, and barley. Each lot of seed was divided into lots of 100 and germinated under identical conditions.

Among the results given it is stated that the time required for the germination of large seeds is greater than for small ones, but the difference is slight, being unappreciable in the case of peas and rye, and even less with wheat and barley.

The total germinations were greater for the small seed in every case except with barley. For peas, rye, and wheat the difference is considerable, and for oats it is slight. In the case of barley the large seed possessed the greatest germinative energy.

The author believes that in agricultural practice, depth of seeding, variation in composition of the soil, insect injuries, etc., exert a much greater influence than size of seed. These conclusions apply only to the germination of the seed, without any reference to vigor or fertility of the plant.

On the artificial use of enzyms in germination, F. A. WAUGH (*Vermont Sta. Rpt. 1898, pp. 290–295*).—In continuation of investigations previously reported (E. S. R., 9, p. 844), the author has studied the effect of a number of diastases on germination of old seed. In previously reported experiments a number of different kinds of seeds were used, while in those presented in this report the experiments were confined to tomato seeds. The experiments are said to confirm the tentative generalizations of the previous year, and it is claimed that the various enzyms used act upon the seeds by the conversion of a proportionately large quantity of the starch contained, and it can hardly be questioned that this conversion is to the advantage of the seeds in germination. The tomato seeds which react especially well toward various enzym preparations contain an unusual amount of fat. What the connection between these two facts may be is not yet clear.

Weeds of Oklahoma, E. E. BOGUE (*Oklahoma Sta. Bul. 41, pp. 12, figs. 14*).—The present bulletin, which is designed in some respects to replace Bulletin 17 of the station (E. S. R., 7, p. 872), describes as far as possible those weeds that are most abundant throughout the Territory and which interfere with agriculture in all its branches. Some of the worst weeds of the Territory are omitted, as they are only so far known in restricted localities. Suggestions are given, under the discussion of each species, for their destruction.

Among the weeds listed are the following: Perennial ragweed, Buffalo bur, crab grass, bull nettle, Torrey night-shade (*Solanum torreyi*), horse nettle, prairie acacia, pigweed, bindweed, fleabane, horseweed, sunflower, croton, snow-on-the-mountain, tumbleweed, passion vine, and purslane.

Notes upon Vermont weeds, L. R. JONES and W. A. ORTON (*Vermont Sta. Rpt. 1898, pp. 219–228, figs. 7*).—In response to a circular of inquiry sent out by the botanist of the station, a number of replies relative to the more troublesome weeds of the State were received. These were grouped into several categories based upon the frequency with which they were reported. Those most frequently reported are: White daisy, kale (*Brassica* sp.), orange hawkweed, wild carrot, witch grass, golden-rod, yellow daisy, plantains, ragweed, sorrel, docks, and hardhack. Other lists are given in which 10 less serious offenders are mentioned, and a list of some 60 others occasionally mentioned completes the report.

Report of the seed-control station at Gothenburg (Sweden) for 1897–98, J. E. ALÉN (*Gothenburg, 1898, pp. 15*).

Effect of electricity on seed germination, G. TOLOMEI (*Rend. Acad. Lincei, Rome, 7. ser., 5 (1898), No. 1, pp. 177–183*).

Some germination studies on cereals, L. H. PAMMEL (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 194–203*).—Notes are given on the effect of numerous factors on the germination of cereals. The germination of wheat as affected by latitude is commented upon and numerous studies given on the germination of corn.

Notes on the germination of seed within the fruit, J. C. COSTERUS (*Bot. Jaahrb., Dodonæa, 10 (1899), pp. 135–141, fig. 1*).—Attention is called to the germination of seed within various citrus and other fruits.

Concerning the quality and germinative ability of conifer seed, A. BURGERSTEIN (*Wiener Illus. Gart. Ztg., 24 (1899), No. 6, pp. 193–196*).

On the germination of Neotia nidus avis, M. BERNARD (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 20, pp. 1253–1255*).—The author states that in the germination of the seed of this orchid, mycorrhizæ are absolutely indispensable. The symbiosis which is established is very complete, and it is probable that the seeds of most orchids are in this way able to germinate and grow in rather sterile soils.

Notes on the management of birch seed, W. SOMERVILLE (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, p. 319*).—The seed are sown broadcast as soon as ripe in an open, moist but not wet seed bed, lightly covered with sand and rolled. The bed is kept moist by a covering of branches and watered if necessary. This covering must be removed when the seedlings begin to appear. A light cover of spruce leaves is needed as a winter protection. In this way the author says he never fails to obtain satisfactory results.

The weeds of New South Wales, J. H. MAIDEN (*Agr. Gaz. New South Wales, 10 (1899), No. 6, pp. 489–493, pl. 1*).—This is the beginning of a systematic enumeration of the weeds of the country. The plants are discussed botanically and economically and suggestions given for their eradication.

The use of chemicals for weed destruction, C. DUSSERRE (*Chron. Agr. Canton Vaud, 12 (1899), No. 12, pp. 265–268*).—Reports experiments with copper sulphate, iron sulphate, and sodium nitrate for the destruction of mustard in fields of cereals. Copper sulphate, 5 per cent solutions at the rate of 800 to 1,000 liters per hectare, will destroy the weeds without serious injury to the cereal crop. Iron sulphate is less efficient, requiring at least 30 per cent solutions. It is said that 1,000 liters of a 20 per cent solution of nitrate of soda will destroy the flowers and leaves of charlock but will not destroy seed already formed. It also has a strong fertilizing value. These treatments can only be given to cereals, being injurious to other crops.

DISEASES OF PLANTS.

Report of the botanists, L. R. JONES and W. A. ORTON (*Vermont Sta. Rpt. 1898, pp. 189–236, figs. 14*).—This contains a report on potato and apple diseases and their remedies, asparagus rust, club root of cabbage and turnip, a partial list of parasitic fungi of Vermont, notes on Vermont weeds, impurities of clover seed, and observations upon the causes and conditions of sap flow in the sugar maple.

During the season covered by this report the various forms of potato blights were recognized as seriously injurious to the foliage. Owing to the prevalence of cloudy weather, the plants at the beginning of August were in a state to be severely attacked by the tip burn. The advantage of Bordeaux mixture in preserving the general vigor of the plants and warding off disease was clearly shown. The fungus diseases made their appearance late in the summer, and were checked to some degree by the application of Bordeaux mixture. Experimental work with fungicides was carried on in two fields, which reemphasizes the fact that applications of Bordeaux mixture to potato foliage brings a large financial return.

Potato-scab experiments were conducted in which the relative merits of corrosive sublimate and formalin were compared, and in many ways the latter proved the more desirable as a preventive of the potato scab. In addition to having no retarding effect, formalin apparently slightly stimulated the growth of the potato plants.

Notes are given upon apple scab and apple scald. Spraying experiments were conducted for the prevention of apple scab in 1897, in which different applications of Bordeaux mixture and Paris green were compared. The results of the treatment are tabulated, from which it appears that those trees sprayed 3 times yielded about 3 times as much fruit as the checks. On those sprayed 5 times, the estimated value of the fruit was 7 times as great as of those receiving no treatment.

The attention of the station was again directed to the scald of apples, which is usually troublesome on the Rhode Island Greenings. A preliminary report of investigation of this disease has already been issued (E. S. R., 9, p. 847). From investigations carried on the last year, it appears probable that the primary cause of the scald must be sought in the climatic and orchard conditions, the condition of the storehouse being secondary.

The occurrence of the asparagus rust (*Puccinia asparagii*) in a number of gardens in the vicinity of the station in 1897 is reported. The disease is briefly described and remedial measures largely compiled from New Jersey Stations Report for 1896 (E. S. R., 9, p. 657) are given. Notes are also given on the club root of cabbage, specimens of which were received in August, 1897.

A partial list of the parasitic fungi of Vermont is given, together with the host plants of each.

Formalin for grain and potatoes, J. C. ARTHUR (*Indiana Sta. Bul. 77, pp. 38-44*).—The author briefly describes a number of smuts of cereals and also potato scab. It is suggested that the use of formalin for smut in wheat and oats, and for scab in potatoes, has been found by many trials to be one of the cheapest, simplest, and most efficient remedies yet suggested. A number of trials have been conducted with this fungicide, and data relative to its effect on wheat is given, in which it appears that so far as the seed grain is concerned a treatment of 2 hours in a solution of the strength of 1 lb. of formalin to 50 gal. of water is slightly, if at all, injurious to the growth of the plants.

In connection with the use of this substance for prevention of potato scab attention is called to the previous publications relative to the use of this fungicide (E. S. R., 9, p. 456; 10, p. 263), and the recommendations there given are repeated.

Further studies of cucumber, melon, and tomato diseases, A. D. SELBY (*Ohio Sta. Bul. 105, pp. 217-236, figs. 2*).—The prevalence of diseases of the cucurbits and tomatoes was discussed in Bulletin 87 of this station (E. S. R., 10, p. 361), and in 1898 further investigations were conducted for their prevention.

The principal disease this season, as formerly, was the downy mildew (*Plasmopara cubensis*), but owing to the earlier harvesting of the crop, the actual loss was less than the previous year.

The anthracnose of cucurbits has increased in abundance and destructiveness. A wilt of cucumbers and muskmelons due to a species of Fusarium has prevailed besides the usual bacterial wilt. *Phyllosticta cucurbitacearum* and *Cercospora cucurbitæ* are reported as spotting cucumber leaves, and *C. citrullina* as growing on watermelon foliage.

The practicability of saving the late crop of cucumbers from downy mildew by the use of Bordeaux mixture was fully demonstrated. Spraying for this purpose need not be begun earlier than July 25 or August 1. Bordeaux mixture is also recommended for the prevention of anthracnose, downy mildew, and leaf blight of muskmelons, although some failures are recorded.

The recommendations of previous bulletins relative to the treatment of tomato plants with Bordeaux mixture are again repeated.

Further studies upon spraying peach trees and upon diseases of the peach, A. D. SELBY (*Ohio Sta. Bul. 104, pp. 201–216, pls. 3*).—In continuation of experiments published in Bulletin 92 of this station (E. S. R., 10, p. 557) the author has given further studies upon the efficiency of spraying peach trees for the prevention of various diseases.

The peach-leaf curl is said to have been very destructive during 1898, and a further demonstration of the efficiency of spraying with Bordeaux mixture before the blossoms open was made. For this purpose applications should be made as early as April 12, and it is said the first spraying may be made successfully either in the fall or in March. Whale-oil soap is said to have considerable efficiency when applied as the buds are swelling, but is more expensive and not as efficient as Bordeaux mixture. Peach yellows was exceptionally virulent during the past season and the disease seems to be spreading throughout the orchards of the State.

Black rot in 1898, A. PRUNET (*Bul.* [*Min. Agr. France*], *18* (*1899*), *No. 2, pp. 265–286*).—The author states that black rot was less prevalent throughout France in 1898 than usual and attributes this to the unusual atmospheric conditions. In some regions it is thought that probably a parasite of the black-rot fungus also aided in checking the disease. The parasite, *Sporotrichum parasiticum*, is said to attack the sclerotia of the black rot, destroying them and rendering the spores incapable of germination.

Comparative studies were made of a number of fungicides, each being compared with some well-known fungicide and particularly with Bordeaux mixture. According to the nature of their active principles the different fungicides are grouped into 4 classes, those containing copper, copper and mercury fungicides, mercury alone, and those having nitrate of silver for their base. The mercuric and nitrate of silver fungicides proved rather injurious, and on the whole none of those tested showed any advantage over Bordeaux mixture.

The time of application of fungicides was again considered, and the investigations confirmed the results reported in 1897 (E. S. R., 9, p. 761). Experiments are briefly reviewed in which 4, 5, and 7 applications of fungicides were given grapevines. The different number of applications was somewhat dependent upon whether the attack of the previous year had been a severe one or not.

The forms of preservation and reproduction of black rot, J. PERRAUD (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 20, pp. 1249–1251*).—The fungus causing grape black rot is known to be reproduced in a number of ways, namely, by means of pycnidia, spermagonia, perithecia, conidiophores, sclerotia, and mycelial spores analogous to chlamydospores. These, however, are not all forms which carry the fungus over from one year to another.

The author's investigations show that the particular forms concerned in the transition of the fungus from one year to another are the stylospores arising from the autumnal pycnidia, sclerotia, and perithecia. The winter spores of the pycnidia are borne principally upon the leaves, branches, and diseased wood. The perithecia and sclerotia exist mostly upon the fruit. ' The general practice, which has been recommended, of burying the diseased grapes can not, in the author's opinion, be considered except as one of several means for the destruction of the parasites. This method, he says, only destroys a greater or less number of germs, conditional upon whether the buried grapes shall not be uncovered by subsequent cultivation. From this it follows that the destruction of diseased leaves and vines and winter treatment of vines are quite necessary.

Aseptic treatment of vines, L. P. BARRETTO (*Rev. Vit., 10 (1898), p. 106; abs. in Ann. Agron., 25 (1899), No. 3, p. 141; Gard. Chron., 3. ser., 25 (1899), No. 611, p. 218*).—The author applies aseptic treatment to his vineyard. All old wood is decorticated, the whole stock disinfected, and the wires of the trellis sterilized by heat; all old dried leaves are burned, the posts are washed with copper solution, and the whole vineyard receives an application of copper salts as a preliminary operation. The author believes that perfect asepsis can be assured only on stony ground where there is but little moist, unwholesome exhalation and where disinfection can be easily effected. The above precautionary treatment yielded good results and the vines were preserved from rot. In another experiment, dusting with ammonium sulphate proved equally efficacious.

The mosaic disease of Holland tobacco, C. J. KÖNING (*Ztschr. Pflanzenkrank., 9 (1899), No. 2, pp. 65–80, pl. 1, figs. 2*).—A report is given of an extensive series of experiments made to ascertain the cause of the mosaic disease of tobacco. Diseased and sound leaves and plants were studied in many ways, but no specific organism could be found which was capable of producing the disease. Inoculation experiments with a number of suspected organisms were carried out but with negative results. The author was able to produce the disease upon sound plants only where the plant juices from diseased leaves were injected or otherwise introduced into sound leaves. Attempts were made to separate the active agent by means of glycerin and alcohol without success, as such extracts would not produce the disease, the "unknown virus," as it is called, probably being destroyed in this way.

Experiments are reported in which the effect of different fertilizers on the production of the disease is shown, the experiments in this case having been made upon plats of 0.5 hectare each. In these experiments where turf and horse manure were applied, the growth of the plants was good and only 3 per cent diseased, although all the suckers were affected. Turf and 500 kg. Peruvian guano produced good growth of plants with sound leaves, but 30 per cent of the suckers were spotted. Sheep manure produced good strong leaves, 2 per cent of which were diseased, and 15 per cent of the suckers. Turf and lime gave a good crop, but 7 per cent of the leaves and 40 per cent of the suckers were affected. The fertilizers in which kainit and Thomas slag were used produced good plants free from disease. The same may be said of pig manure and muck, with and without potash, and of horse manure, cow manure, and muck.

A living fluid contagium as the cause of the mosaic disease of tobacco leaves, M. W. BEIJERINCK (*Verhand. Konink. Akad. Wetensch. (Amsterdam), 2. sec., 6 (1898), No. 5, pp. 22, pls. 2; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, pp. 319, 320*).—The author, who has been investigating for some time the mosaic disease of tobacco leaves, reaches the conclusion that the disease is not due to bacteria, but to what he terms "a living fluid contagium." When passed through a porcelain filter, the juice of a diseased plant, although devoid of all bacteria, is found to retain its infective properties. The virus attacks only those tissues and organs which are in the most active condition of growth and of cell division. It is said to gain entrance either through the leaves or the roots and appears to be chiefly conveyed through phloem. The virus may be dried, may pass the winter in the soil, and an alcoholic extract may be dried at 40° C. without losing its infective power; but it is quickly destroyed by boiling. In the milder forms of the disease, the virus chiefly attacks the chlorophyll granules, but in the more severe cases the whole of the protoplasm is affected. In the mild type of the disease, the leaves in the earlier stages seem spotted with dark-green patches, which later become brown or orange-brown. In severe attacks, especially as a result of artificial infection, the leaves become malformed and monstrous. In some of the experiments the absence of chlorophyll was noted, and this was found to be due to the association of *Bacillus agglomerans* with the virus.

The author believes that a number of diseases of hitherto unexplained origin are due to this cause. Among them he mentions peach yellows and peach rosette.

Culture experiments with heterœcious rust fungi, H. Klebahn (*Ztschr. Pflanzenkrank., 9 (1899), Nos. 2, pp. 88–99; 3, pp. 137–160, figs. 4*).—Studies are given of the species of Melampsora, which infest various willows and Populus. A list is given of the heterœcious species, together with their æcidial, uredo, and teleutospore hosts; and notes are given of rusts occurring on Carex and Ribes; on Phalaris and Arum; on the specialization of *Puccinia smilacearum digraphidis;* on *P. orchidearum phalaridis;* on *P. moliniæ;* on *P. cari-bistortæ; P. polygoni*, and on *Phragmidium subcorticum.*

Diseased iris bulbs, G. Massee (*Gard. Chron., 3. ser., 25 (1899), No. 652, p. 412, fig. 1*).—The author reports having received from two widely separated localities iris bulbs which were attacked by a fungus. The parasite forms black patches on the surface of the bulb. These at first are small in size and few in number, but increase until finally the bulb presents a charred appearance. The fungus at first is quite superficial, but later the mycelium penetrates the tissues of the bulb, causing its decay.

If the attack is only superficial, soaking the bulbs for 1 hour in a solution of 1 part of formalin to 400 parts of water will destroy the fungus without injuring the bulbs. Where badly attacked, all bulbs should be burned.

The fungus causing this disease is said to be *Mystrosporum aductum*, n. sp. A technical description is given of the fungus, which is nearly related to a similar parasite of cultivated onions. The latter fungus (*M. alliorum*) differs in having smaller and minutely warted spores.

Botrytis cinerea as a hothouse pest, J. Beauverie (*Compt. Rend. Acad. Sci. Paris, 128 (1899), Nos. 13, pp. 846–849; 20, pp. 1251–1253*).—Under the name "Toile" the author describes a disease which has long been known to horticulturists as causing considerable destruction to seeds, seedlings, and cuttings in hothouses. The attacks are made by the mycelium of a sterile fungus which is scattered through the soil penetrating to some depth. The identity of the fungus has been a source of some discussion, and the author reports a series of experiments with *Botrytis cinerea* cultivated on carrots in a saturated atmosphere at a temperature of about 33° C. After cultivating this fungus for some time under the conditions in which the previously mentioned disease is known to occur, the author claims to have induced a disease corresponding exactly with that produced in the ordinary way.

The conidial form of the saprophyte became transformed into a sterile parasite and retained this form with considerable tenacity. The conditions favorable for the development of the sterile form are a high temperature, 30° C. or more, a humidity approaching saturation, a soil of mediocre fertility, and a confined atmosphere. These conditions are those most frequently met in propagating hothouses.

As means for preventing the attacks of this fungus the author cites experiments conducted in greenhouses at Luxemburg during the past 6 years, in which the soil was sterilized by heating with good results. Applications of a solution of copper sulphate and ammonia, it is thought, would also destroy the fungus in the soil.

Parasitic fungi, G. Lagerheim (*Bihang Svenska Vetensk. Akad. Handl., 24 (1898), No. 4, pp. 22, pls. 3; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, No. 4, p. 420*).—The occurrence of 2 new species of parasitic fungi is reported, namely, *Empusa phalangicida* on a Phalangid, as yet the only species discovered parasitic on other animals than insects; and *Iola lasioboli*, parasitic on *Lasiobolus equinus*, this being the first known example of a basidiomycete parasitic on a discomycete. The author also reports the occurrence of *Physoderma leproides* parasitic on alfalfa in Ecuador.

A partial list of the parasitic fungi of Vermont, W. A. Orton (*Contrib. Bot. Vermont, No 2, pp. 21*).—Reprinted from Vermont Station Report for 1898 (see p. 355).

Fungi of Colorado, Wyoming, and Nebraska, H. Hume (*Proc Davenport Acad. Sci., 7 (1899), pp. 246–257, pl. 1*).—Notes are given on collections made in these States during 1895–97, and *Puccinia crandallii* on the leaves and sheaths of *Festuca kingii*, and *Microstroma americanorum* on leaves of *Cnicus americanus* are described as new by Pammel and Hume.

Notes on plant enemies, K. Sajó (*Illus. Landw. Ztg., 19 (1899), No. 37, pp. 383–385*).—The author popularly describes a number of fungus diseases of cultivated plants and gives notes on injuries due to insects, worms, etc. Some relations between soils and diseases are pointed out.

The destruction of the smuts of cereal grains and the prevention of potato scab, H. L. Bolley (*North Dakota Sta. Bul. 37, pp. 363–379, figs. 3*).—This bulletin is intended to give a short statement of the diseases in question, outline the investigations of the station previously published, give statements of some of the results obtained in an attempt at prevention of disease, discuss methods of investigation, and suggest means for prevention. No new experimental data are introduced, most of the information being drawn from Bulletins 1, 19, and 27 of the station (E. S. R., 2, p. 740; 7, p. 39; 9, p. 143).

The rusts of our grain fields, O. Lugger (*Farm Student's Rev., 4 (1899), Nos. 9, pp. 138–140, figs. 3; 10, pp. 154, 155, figs. 6*).—Popular descriptions of the life history of cereal rusts.

Investigations on cereal rusts, Pommer (*Braunschw. Landw. Ztg., 67 (1899), No. 26, p. 121*).—Notes the prospective study of the subject of cereal rusts.

Rusts and similar diseases of cereals (*Braunschw. Landw. Ztg., 67 (1899), No. 26, pp. 121, 122*).—Brief notes on the causes of a number of diseases of cereals and the amount of injury done to the crops.

The rusts and smuts of cereals, G. Lafosse (*Rev. Sci.* [*Paris*], *4. ser., 11 (1899), No. 16, pp. 493–498*).—A résumé of the present state of information of the rusts and smuts of cereals.

The smuts of cereals and their prevention, Tancré (*Landw. Wchnbl. Schleswig-Holstein, 49 (1899), No. 29, pp. 540–544*).—Notes are given on *Ustilago carbo*, *U. destruens*, *U. maydis*, *Tilletia caries*, *T. lævis*, and *Urocystis occulta*, and recommends soaking seed grain in copper sulphate solutions as a preventive measure for most of the fungi.

Wheat smut, its cause and means for prevention (*Bol. Soc. Agr. Mexicana, 23 (1899), No. 32, pp. 636–638*).—Describes *Tilletia caries* and recommends treating seed with copper sulphate solutions prior to sowing.

Influence of soaking cereals in copper sulphate solutions on germination, K. Kittlausz (*Fühling's Landw. Ztg., 48 (1899), Nos. 15, pp. 572–586; 16, pp. 605–616*).—The effect on the germination of soaking rye, oats, barley, and wheat in different strengths of solution and for different lengths of time is shown.

Fungus diseases of grapes, A. A. YACHEVSKY (*St. Petersburg: Min. Agr. and Imp. Domains, Dept. Agr., 1899, pp. 83, pls. 5, figs. 18; rev. in Selsk. Khoz. i Lyesov., 194 (1899), July, p. 180*).—Notes are given on a number of the more destructive parasitic diseases of the grape. The life histories of the fungi are described and suggestions given for combating their attacks.

Report on the inspection of the Trans-Caspian Province and Turkestan vineyards in 1898 (*Selsk. Khoz. i Lyesov., 194 (1899), July, pp. 55–58*).—Notes are given on a number of well-known fungi that were observed on the grapevines, and mention is made of several other species which are thought to be new to science. No descriptions are given of the latter.

Brunissure and its causes, V. DUCOMET (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 33, pp. 198–204*).—It is claimed that as a rule brunissure is not of parasitic origin but is due to unfavorable soil and weather conditions. It may sometimes be caused by fungi, but rarely.

Report of investigations on black rot in 1898, A. PRUNET (*Prog. Agr. et Vit. (Éd. L'Est), 30 (1899), No. 30, pp. 108–119, figs. 3*).—In continuation of investigations begun in 1897 (E. S. R., 9, p. 959) the author has studied the most advantageous times for the application of fungicides, and the previous observations are confirmed.

On the use of copper sulphate for combating grape Peronospora, G. CUBONI (*Extr. from Sup. Bol. Soc. Agr., 1899, Apr. 15*).—An address before the Italian Agricultural Society.

A new remedy for combating grape mildew, J. DUFOUR (*Chron. Agr. Cant. Vaud, 12 (1899), No. 13, pp. 304–306*).—A mixture of black soap 1 kg., potassium sulphid 500 gm., and water 100 liters is recommended.

A core rot and blackening of horse-radish, P. SORAUER (*Ztschr. Pflanzenkrank., 9 (1899), No. 3, pp. 132–137, pl. 1*).—A description is given of a disease of horse-radish in which the central cylinder of the root is blackened and a sort of gummosis produced.

The mosaic disease of tobacco, R. FRANCÉ (*Kisérletügyi Kozlemények, 2 (1899), No. 4, pp. 198–204, pls. 2*).—Notes are given on the causes of the mosaic disease of tobacco and the anatomical changes produced by it. Among the causes discussed are insects, fungi, and bacteria, the author believing the disease to be due to the latter cause.

Leaf spot of the olive, V. PEGLION (*Separate from Bol. Soc. Agr., 1899, pp. 7*).—Notes are given of the leaf spot of olives, which is said to be due to *Cycloconium oleaginum*.

Coffee disease in Nicaragua, G. MASSEE (*Bul. Roy. Bot. Gard. Trinidad, 3 (1899), No. 20, p. 182*).—The author identifies as *Stilbum flavidum* the fungus which seriously attacks coffee leaves in Nicaragua, and recommends spraying with Bordeaux mixture and burning diseased foliage as preventive agencies to be adopted.

The cacao pod disease (*Bul. Roy. Bot. Gard. Trinidad, 3 (1899), No. 20, pp. 183–185, fig. 1*).—This disease, which was previously noted (E. S. R., 11, p. 166), is said to be due to attacks of *Phytophthora omnivora*. Associated with it is another, *Nectria bainii*, described as a new species by Massee. The relationship between the two fungi is as yet unknown. The disease is said to cause a depreciation of fully 25 per cent in the fermented and dried beans.

Some climatic and fungus diseases of the chestnut, G. H. POWELL (*Amer. Gard., 20 (1899), No. 242, p. 579, figs. 2*).—Notes are given of a body blight of chestnut trunks, a disease of leaves due to some undetermined fungus, sun scald, etc.

ENTOMOLOGY.

Some insects injurious to garden and orchard crops, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Bul. 19, n. ser., pp. 99, figs. 20*).—*The squash ladybird* (*Epilachna borealis*); *its literature and biology*.—The article contains an account of the appearance and distribution of this herbivorous ladybird. Its food plants are pumpkin, cantaloupe, watermelon, cucumber, prickly cucumber (*Echinocystis lobata*), and the one-seeded bur cucumber (*Sicyos angulatus*). The larva has the habit of marking out circular patches on the leaves, within which it feeds. The eggs hatch in 7 days, the larvæ mature in 16 days, and the pupal period extends over 6 days, giving a total of 29 days from egg to beetle. The evidence goes to show that the species is single brooded. Among its natural enemies are mentioned *Podisus spinosus* and *Euphorocera claripennis*. The beetle can be controlled by application of arsenites or by hand picking of the adults and egg masses.

The history of the common squash bug (*Anasa tristis*).—The author has discovered a fifth immature stage in this species, making five distinct stages beside the egg and the adult. Technical descriptions are given of the egg and the five immature stages, as well as the adult. The life cycle from the egg to the adult requires 4 weeks, or in some cases from 32 to 34 days. The insect is considered as single brooded. Among its enemies are numbered toads, lizards (*Sceloporus undulatus*). Two egg parasites are mentioned, *Hadronotus anasæ* and *Ooencyrtus anasæ*. This species has pushed north as far as Orono, Me. Young plants may be protected with covers or by means of repellents, such as land plaster or gypsum saturated with kerosene or turpentine. The vines should be gathered and burned as soon as the crop is harvested.

The horned squash bug (*Anasa armigera*).—A detailed description of this species is given, so as to distinguish it from the last-named species. It has five immature stages. The minimum period of the entire life cycle is 32 days. The egg masses are smaller than those of *A. tristis*, numbering not more than 20. There is but a single generation annually. This insect probably has the same natural enemies as has *A. tristis*. A few late squashes may be set out as a trap crop, and these may then be sprayed for the destruction of the squash bugs which will have gathered upon them.

Some observations in the life history of the squash-vine borer (*Melittia satyriniformis*).—A technical description of the egg is given for the first time. The author describes also the larva and its different stages, as well as cocoon, chrysalis, and moth. The species is partially double brooded in the District of Columbia, normally two brooded in the Gulf States, and single brooded in the North. The remedies which are found to have most value are harrowing of infested fields late in the fall and plowing deeply in spring, or the reversal of this process, to prevent the moths from issuing. Dead vines and old plants should be destroyed as soon as the crop is harvested.

Notes on the pickle worm (*Margaronia nitidalis*).—This insect was observed to eat holes in muskmelons and cantaloupes and related plants. A larva transformed to a chrysalis on October 5 issued as an adult on the 25th of the same month, thus requiring 20 days for the chrysalis condition. The larvæ seem to feed first upon the leaves, and later to bore into the leafstalks.

The melon caterpillar (*Margaronia hyalinata*).—This insect was taken in the District of Columbia for the first time in the fall of last year. It is reported from all the Gulf States and from the District of Columbia to Texas, as well as in Columbus, Ohio, Buffalo, N. Y., and Hamilton, Canada. While the larvæ are feeding upon the foliage or upon the outside of the stem, they may be readily destroyed by the use of Paris green.

The northern leaf-footed plant bug (*Leptoglossus oppositus*).—This insect resembles in its habits the squash bug. It has been reported as injurious from Tennallytown, D. C., and from Keedysville, Md.

The banded leaf-footed plant bug (*Leptoglossus phyllopus*).—This insect is reported as injuring oranges, as well as the strawberry, peach, plum, currant, eggplant, and cotton bolls. Its normal food plant is the yellow thistle (*Carduus spinosissimus*). Its distribution includes the entire Gulf region, as well as Arizona, Missouri, and the Indian Territory. Both of these plant bugs may be hand picked or captured in inverted umbrellas or in bags saturated with kerosene. The yellow thistle may be planted about the garden as a trap crop.

Notes on the striped cucumber beetle (*Diabrotica vittata*).—A technical description of the egg is given for the first time. As deterrents are mentioned sulphur, plaster, and ashes dusted upon the leaves. Paris green is also effective when the insects are on the surface of the leaf. Kerosene emulsion and pyrethrum have also been used with good success. The wild cucumber (*Echinocystis lobata*) could be planted as a trap crop.

A new webworm enemy of the cabbage and other cruciferous plants (*Hellula undalis*).—The species is recorded as injuring cabbage, turnips, beets, etc. The moth is reported as laying its eggs in the heart of the cabbage and other vegetables, and the larvæ are said to twist the leaves so as to inclose themselves. The insect is a European importation. A technical description is given of the moth, larva, and pupa. It is now distributed in the Lower Austral region and will probably extend into the Upper Austral. A tachina fly (*Exorista piste*) has been reared from the caterpillar of this insect as well as the Ichneumonid fly (*Limneria tibiator*). Paris green applied as a spray in the proportion of 1 lb. to 150 gal. of water should be effective in the destruction of this webworm.

Notes on the garden flea hopper (*Halticus uhleri*).—The species is reported as injurious to smilax, late potatoes, tomatoes, beans, peas, and cowpeas, and especially to beans. A large number of native weeds and plants are also frequented by this insect and serve as its food plants. The author gives a description of the insect in several stages, and calls attention to deficiencies in our knowledge of its life history. Kerosene emulsion sprayed directly upon the insects is effective in their destruction.

The imbricated snout beetle (*Epicærus imbricatus*).—This beetle is recorded as injuring strawberry plants, eating the leaves and afterwards the whole stem. A careful description of the insect in its various stages is added. An individual beetle under observation lived, as the author states, "an active life of 57 days in addition to the time before and during hibernation. In this time she deposited eggs almost daily. It will be seen by the above figures that a total of 540 eggs were laid in this time, and it is probable that the entire quota might reach as high as 600." Arsenicals applied either dry or as a spray at a rate of 1 lb. to 100 gal. of water are effective remedies against this beetle.

The brown fruit chafer (*Euphoria inda*).—The insect is described in all of its stages from egg to adult and a record is given of its egg-laying habits. Regarding the larval condition, the author reports experiments which show conclusively that the larva is not injurious, its food being confined to decaying vegetation and manure. Egg-laying begins about the first of May. The eggs hatch in about 11 days and the life cycle from the deposition of the egg to maturity of the beetle is about 12 weeks. The author believes that the reports of injuries by the adult beetle are considerably exaggerated. The beetle is recorded as injurious to peaches, apples, tomatoes, cotton bolls, and various fruits. Among its natural enemies is the *Typhia ornata*. The beetles may be readily captured by jarring into bags or nets.

Brief notes on the May beetle (*Lachnosterna arcuata*).—Technical descriptions are given of the egg, larva, pupa, and adult. Rearing experiments gave a total life period of 2 years and 51 days from the egg-laying until the issuance of the adult beetle. The beetles are recorded as particularly injurious to sugar maple, having gouged out portions of the leaves and even cutting off the leaves from the trees. As parasites of the white grub are mentioned *Ophion bifoveolatum*, *Pelecinus polyturator*, *Cryptomeigenia theutis*, *Microphthalma disjuncta*. *Drasterius elegans* and *Tetramorium cæspitum* are reported as preying on the white grubs. Bisulphid of carbon and bran-arsenic mash are considered the most effective remedies.

The spinach flea-beetle (*Disonycha xanthomelæna*).—This insect is recorded as living upon the common chickweed (*Stellaria media*). Careful descriptions are given of the egg and the larva. Its only natural enemy so far known is *Hypostena barbata*. The arsenites are the best remedies against this insect.

The tobacco flea-beetle (*Epitrix parvula*).—The author gives an account of recent injuries by this insect. The full life cycle is reported as requiring 28 days. The food plants of this insect belong to the Solanum family.

The eggplant flea-beetle (*Epitrix fuscula*).—A description of the egg is given for the first time. The insect is reported as attacking the leaves of the eggplant. It is said to infest also the strawberry and potato. Its distribution is from New Jersey to Georgia and across the continent.

The cucumber flea-beetle (*Epitrix cucumeris*).—This beetle is recorded as destructive to tomatoes. Its food plants all belong to the order Solanaceæ. As remedies pyrethrum and Paris green are mentioned as well as the growing of trap crops of jimson weed.

The cherry-leaf beetle (*Galerucella cavicollis*).—This beetle is recorded as eating holes in the leaves of cherry trees and as damaging the foliage of peach trees. A description is given of the adult beetle and of the larva and egg. An arsenical spray will be found to be an efficient remedy.

The plum-leaf beetle (*Nodonota tristis*).—This beetle was noticed feeding upon plum trees, peach, apple, cherry, and choke-cherry. Eggs were deposited side by side in a fold of the leaf in irregular rows.

The rose-leaf beetle (*Nodonota puncticollis*).—This beetle is recorded as injurious to roses and ornamental willows. Eggs were deposited in the same manner as in *N. tristis.* A beetle was found upon which was a larval mite *Eupalpus echinatus.* As these beetles do not fly readily, they may be captured by jarring them into inverted umbrellas, or other similar appliances, saturated with kerosene.

The fruit-tree bark beetle (*Scolytus rugulosus*).—This beetle is recorded as attacking mountain ash and Juneberry. Kerosene rubbed upon the trunk and large branches of trees infested with this beetle proved an efficient remedy in destroying the beetles and did not injure the trees.

The banded hickory borer (*Chion cinctus*).—This insect was found at work in the branches of plum trees at Colonial Beach, Va.

The grape-cane borer (*Amphicerus bicaudatus*).—This beetle is recorded as injuring ash-wood lumber and is also recorded as having attacked living green ash (*Fraxinus viridis*).

The eye-spotted apple-twig borer (*Oberea ocellata*).—This species is reported from Boerne, Tex., as being found in large numbers in the tips of branches of peach and plum trees. The beetle is said to attack the pear tree also and poison sumac.

Notes on insect pests from the entomological section, Indian Museum, E. BARLOW (*Indian Mus. Notes, 4 (1899), No. 3, pp. 118–142*).—The notes include a number of studies and experiments with tea pests, insects destructive to cereals, forest insects, fruit-tree insects, as well as remarks on the value of certain insecticides. The use of arsenic is recorded as being very effective in the destruction of locusts. It was applied as follows:

> "Take 1 lb. arsenic, 1 lb. caustic soda. Take 4 gal. of water, bring to boiling point, add the caustic soda; when dissolved, add the arsenic, stir well and boil for a few minutes, care being taken not to inhale the fumes. Keep this mixture under lock and key. Take as required half a gallon of this mixture and add 4 gal. of hot or cold water and 10 lbs. of brown sugar. Dip bagass, grass, or mealie stalks in this liquor and place along roads, in canefields, or anywhere about grass or low-growing crops, or splash with a whitewash brush onto anything which the locusts may be observed to have a taste for. Locusts will come from a hundred yards or more, attracted by the smell of the sugar. They eat and die, and are eaten by other locusts."

Experiments were tried in storing cereals in pits to prevent the attacks of weevils. Only partial success is recorded, many of the pits having proved too moist for the grain. In some pits charcoal was placed in the bottom, and in others quicklime, care being taken to prevent the contact of the grain with the lime. The weevils were thereby prevented from doing injury to the grain.

The tarnished plant bug, J. M. STEDMAN (*Missouri Sta. Bul. 47, pp. 77–87, figs. 3*).—This insect is said to be practically free from the attacks of all predaceous and parasitic insects. The pest attacks nearly all garden and field crops, as well as a large variety of uncultivated plants. Its depredations are perhaps most seriously felt by the nurserymen and fruit growers, since it attacks the young developing fruit buds of nearly all kinds. When the young buds are punctured and the sap sucked out by these insects, the buds turn black and die, or fall off. The result is a serious check on the growth of the plant.

The peach, pear, and apple are reported as suffering most severely, but the plum, quince, and cherry are also seriously injured. Small fruits suffer badly, the grape, raspberry, currant, blackberry, gooseberry, and strawberry receiving most injury. The author believes that the chief cause of the buttoning of strawberries is the attack of this bug. Experiments with insecticides showed that those portions of the strawberry field which were best protected from the attacks of this insect exhibited the least buttoning.

The author describes the 4 immature and adult stages of the insect. On account of the great variety of food plants, it is especially difficult to control by insecticides. The burning of rubbish along fences and fields late in the fall is suggested as a palliative remedy. Good success is reported from the use of a large butterfly net in sweeping small fruit trees and bushes in the early morning before the bugs have become active. On larger trees kerosene emulsion was used with good results. If the force pump with kerosene attachment is used, it should be set so as to discharge a spray of 8 per cent kerosene. The emulsion should be applied early in the morning while the bugs are stupid. In the case of strawberries the kerosene emulsion can not be used, for the reason that the strawberries would thus be tainted. Pyrethrum is the best remedy in this case. It may be used dry mixed with four times its weight of common wheat flour, and applied in the early morning while the dew is on, or as a spray in the proportion of 1 lb. of pyrethrum for every 15 gal. of water. A remedy known as rose-leaf insecticide, a patent preparation of tobacco, was tried with good success.

The grape-berry moth (Polychrosis (Eudemis) botrana), G. DEL GUERCIO (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1899, No. 1, pp. 117–193, figs. 28*).—This article gives a rather exhaustive account of the grape-berry moth, including a discussion of the egg, larva, chrysalis, moth, and the habits and metamorphosis of the species. Besides the grape, the insect is found upon *Lyriodendron tulipifera, Rosmarinus officinalis*, and *Daphne gnidium*. The author discusses the nature and extent of damages done by this insect, as well as climatic and other conditions which are favorable or unfavorable to its development. The parasitic and predaceous insects which are the enemies of the grapeberry moth are discussed and figured. Two fungus parasites are found upon the insect in question, *Botrytis bassiana* and *Isaria farinosa.*

Numerous experiments were conducted in the destruction of the insect in all its stages, and formulas are given for making various emulsions of alcohol, soap, benzin, and pyrethrum. There are three broods of larvæ from the last of April until the end of October. One brood is found upon the flower buds and flowers, one in the small and medium-size grapes, and the third in the mature or nearly mature grapes. The first brood pupate in the margin of the leaves, the second among the desiccated grapes, and the the third under the bark of the stems. These last pupæ pass the winter as such. The insect does not hibernate in the egg or larval condition. The author recommends especially the spraying of the infested flowers by the use of an alcoholic emulsion of soap with benzin and pyrethrum. It is also recommended that the larvæ or chrysalids should be destroyed in the grapes, and that when the infestation is unusually bad, the grapes should be gathered earlier than usual. The hibernating chrysalids may also be easily destroyed. The choice of methods of destruction by mechanical means or manual labor, or by application of insecticides, will depend upon the price of insecticides and manual labor in the particular locality.

Emergency report on tent caterpillars, M. V. SLINGERLAND (*New York Cornell Sta. Bul. 170, pp. 553-564, figs. 4*).—This bulletin contains a brief account of the appearance and habits of the apple tent caterpillar and forest tent caterpillar. The different stages of the insect are figured. The remedies recommended against the apple tent caterpillar are the destruction of the tents upon wild-cherry trees, the collection of the egg masses by school children, and spraying with Bordeaux mixture to which Paris green has been added in the proportion of 1 lb. to 150 gal. of Bordeaux mixture.

The remedies which are suggested to be used against the forest tent caterpillars are the destruction of the egg masses and jarring the caterpillars from the trees after the trees have been banded with tarred paper or otherwise, so that the caterpillars can not climb the trees again.

Legislation against crop pests—dangerous pests prescribed by the board with remedial suggestions, W. M. SCOTT (*Georgia State Bd. Ent. Bul. 1, pp. 32, figs. 7*).—This bulletin contains a copy of amendments to the State law regulating the department of horticulture, State entomologist, and fruit tree and nursery inspection. It also gives a list of the rules adopted by the board of entomology for the guidance of the State entomologist in the enforcement of the act of the general assembly of Georgia.

The list of dangerously injurious pests as adopted by the board is as follows: San José scale, new peach scale (*Diaspis amygdali*), cabbage webworm (*Hellula undalis*), black knot, peach yellows, peach and plum rosette, and mistletoe.

Concerning the San José scale, the author gives an account of its appearance and the method of its attacks. Its food plants are listed and it is reported from 30 counties of the State. The ordinary fumigation with hydrocyanic-acid gas, mechanical mixtures of kerosene and water, and of whale-oil soap are described. The author relates that the San José scale suffered severely and a large percentage was destroyed by low temperature during February. The temperature was from —4 to —8° F., and it was noted that the San José scale suffered much more severely than the Forbes scale.

The new peach scale is figured and described and the usual remedies recommended. There are said to be from 3 to 4 broods from the eggs in Georgia. At the time of the appearance of any brood, the author recommends the application of a 10 per cent kerosene wash or whale-oil soap at the rate of 1 lb. to 4 gal. of water. This scale is reported to have been almost annihilated by the February freeze.

The cabbage webworm (*Hellula undalis*) is reported as being one of the most destructive enemies to cultivated cruciferæ, some gardeners having found it almost impossible to raise turnips, cabbages, radishes, or other cruciferous vegetables with any profit on account of the destructiveness of this insect. The insect is described in all of its stages, and an account is given of its life history and habits. The moth deposits the eggs singly. Each moth lays from 20 to 30 eggs. The eggs hatch within 2 to 3 days, and the young larvæ spin a slight web and roll the leaves partially together as a means of protection. As the larvæ become older, they spin a bag in which they are rather effectively concealed. In the laboratory the larvæ require from 20 to 25 days to develop. The cocoons are formed on the leaf of the plant or beneath the sand. The pupal stage lasts from 10 to 12 days. The moths fly in the evening after sunset and deposit their eggs on the under surface of the leaves. The complete life cycle of the insect is less than 6 weeks, and the author believes that there are 3 broods annually in the State. While the author has not experimented extensively with remedies, he believes that Paris green sprayed upon the plants in a judicious manner will be effective in checking the attacks of this insect. The use of lantern traps is also recommended, and the burning of all trash, as weeds and cabbage stalks, during the winter.

The author gives notes of a biological and economic nature on black knot, peach yellows, and peach and plum rosette, with suggestions of the usual remedies.

For checking the attacks of mistletoe, it is recommended that small twigs which are attacked by the plant should be removed and burned and that the mistletoe should be dug out of larger branches which it infests during the winter.

Apiculture by simple methods, R. Hommell (*L'Apiculture par les méthodes simples. Pp. 338, pls. 6, figs. 102; abs. in Jour. Agr. Prat., 1899, II, No. 36, p. 357*).—This work contains chapters on the biology of bees, honey, honey plants, the growth of colonies, swarming, management of bees, their diseases and statistics. The main purpose of the book, as the author states, is to outline methods of bee culture which are so simple as to appeal to every one.

Foul brood (*Rev. Internat. Apicult., 21 (1899), No. 8, pp. 153–163*).—A discussion by a number of authors of various remedies and methods to be adopted in combating this disease.

Experiments in bee keeping, C. R. Peck (*Vermont Sta. Rpt. 1898, pp. 307–309*).—An experiment was tried in moving queens during the honey flow. The swarms thus treated were so disturbed that they made less honey than undisturbed swarms. Extracted honey was fed back to a number of swarms with results which indicate that the procedure is of questionable value.

An undescribed parasitic disease of the silkworm, E. Verson (*Un'Affezione parassitaria del Filugello non descritta ancora, XIII, Padova, 1899, pp. 11, pl. 1; separate from R Stazione Bacologica Sperimentale*).—The author describes an apparently new bacterial disease of the silkworm. The disease may not prove fatal to the caterpillar, but the chrysalids and adults from diseased caterpillars may be easily recognized by the modification of their color, the adult showing a lead color.

Beneficial insects, E. D. Sanderson (*Amer. Farmer Mag., 6 (1899), No. 2, pp. 120–124, figs. 7*).—Popular notes on predaceous and parasitic insects.

Insects—Part II, D. Sharp (*London and New York: Macmillan Company, 1899, pp. XII+626, ills.*).—This part of the author's work on insects treats of the remainder of the Hymenoptera, Coleoptera, Lepidoptera, Diptera, Thysanoptera, and Hemiptera. The anatomy, development, and metamorphosis of the insects are thoroughly discussed in connection with each group.

Injuries done by insects in the country, E. D. Sanderson (*Amer. Farm. Mag., 6 (1899), No. 1, pp. 8–11, figs. 9*).—Popular notes on estimations of losses from the depredations of insects.

Report on the entomological work, L. Zehntner (*Verslag. Proefsta. Suikkerriet. West-Java, 1898, pp. 80–92*).—This article contains an account of the outbreaks of a number of injurious insects and of the work of the entomological department in general.

Entomology, L. Bruner (*Nebraska Sta. Rpt. 1898, pp. XXXVII–XLII*).—The report contains brief notes on the native grasshoppers of the State, with references to experiments with the South American grasshopper disease, notes on the chinch bug, the fall webworm, the spring cankerworm, onion thrips, melon louse, and the San José scale. The latter is said not to have been found in the State thus far.

Report of the entomological section, C. P. Gillette (*Colorado Sta. Rpt. 1898, pp. 161–165*).—Three remedies were tried for the codling moth—the daily gathering of fallen apples, catching the larvæ under bandages, and two sprayings with Paris green. The latter method was far the most effective. Notes are given on the study of the native grasshoppers, scab mite of sheep, insecticide tests, and experiments in the apiary.

Insect pests of 1898, M. V. Slingerland (*Proc. West. New York Hort. Soc., 1899, pp. 71–77*).—Notes on pear Psylla, tent caterpillars, cankerworms, and the grapevine flea-beetle.

Diseases and injuries of fruit trees, O. Kirchner and H. Boltshauser (*Atlas d. Krankheiten u. Beschädigungen unserer landwirtschaftlichen Kulturpflanzen. Series V: Obstbäume. Stuttgart: E. Ulmer, 1899*).—This part of the atlas contains 30 plates illustrating insect and fungus diseases of fruit trees. Brief biological notes are given together with suggestions of proper remedies.

Three insect enemies of shade trees, L. O. Howard (*U. S. Dept. Agr., Farmers' Bul. 99, pp. 30, figs. 11*).—This is a reprint with some annotations of an article by the same author in the Yearbook of this Department for 1895 (E. S. R., 8, p. 804).

Insects and other arthropods injurious to plants, A. De Scabra (*Arch. Rural, Portugal, 4 (1899), No. 8, pp. 120–123*).—Brief notes on *Melolontha vulgaris*, *Agrotis segetum*, *Aphis phaseoli*, and *A. fabæ*.

Some prune pests, A. B. CORDLEY (*Oregon Bd. Hort. Rpt. 1898, pp. 417-432*).—An account of the peach-tree borer, San José scale, and brown rot.

The codling moth, J. R. CASEY (*Oregon Bd. Hort. Rpt. 1898, pp. 413-416*).—A report on some experiments in banding trees in order to prevent injuries by this insect.

On the destruction of hazel trees in the Crimea by Lecanium corni, S. MOKRZETSKI (*Selsk. Klroz. i Lyesov., 192 (1899), Feb., pp. 413-420*).

The destruction of acorns and pine seeds by Gastropacha quercus and methods of preventing its injuries, ALTUM (*Ztschr. Forst u. Jagdw., 31 (1899), No. 1, pp. 35-44*).—Recommends the destruction of the caterpillars, harrowing of places badly infested, rolling the ground, and the use of Raupenleim.

Everyday butterflies—a group of biographies, S. H. SCUDDER (*Boston: Houghton, Mifflin & Co., 1899, pp. 391, pls. 9, figs. 47*).—This volume treats of the common butterflies of the eastern United States and Canada. The number of species about which observations are made is 62. The greater number of the species are figured and all are described in a general way, and notes are given concerning the life history and habits, food plants, and breeding places of all of the species.

The gray field slug (Limax agrestis), SCHMOLDT (*Fühling's Landw. Ztg., 48 (1899), No. 13, pp. 487-490*).—The paper discusses the habits and biological relationships of this slug, and contains accounts of the appearance of immense numbers of the slug at certain seasons. The natural enemies which are mentioned are the moles, shrews, crows, starlings, and toads.

The remedies which are suggested for fighting the slug on a large scale are all of the nature of an irritant upon the skin. The slug requires moist conditions and when any substance comes in contact with the skin which has a strong attraction for water, the body of the slug loses moisture rapidly and is much weakened or killed. The author recommends the sprinkling of salt upon the slugs. It is also stated that the scattering of grains in the field where the slugs are abundant is an effective remedy, the grains adhering to the skin of the slugs, causing excessive irritation of the skin with consequent formation of large quantities of mucus.

The hamster in Belgium, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 6, pp. 173-192, figs. 3*).—The common hamster (*Cricetus frumentarius*) is described, and an account is given of its habits and injuries to crops. Its natural enemies are *Martes foina*, *M. putorius*, and *Mustela vulgaris*. Poisoning by various methods and fumigation are the remedies recommended for use against it.

A revision of the genus Hydrœcia, J. B. SMITH (*Trans. Amer. Ent. Soc., 26 (1899), No. 1, pp. 1-48, pls. 2*).—The author describes 36 species of this genus in a monographic arrangement with bibliographical references to the original descriptions.

Spraying for profit, H. E. WEED (*Griffin, Ga.: Horticultural Publishing Co., 1899, pp. 72, figs. 37*).—A handbook of practical information regarding the insects and fungus diseases which are most common and most destructive, the various insecticides which have been found most effective in controlling these pests, and the spraying pumps and machinery which are most convenient and suitable for this work.

Spraying—when, how, and why, A. W. BRYANT (*Trans. Illinois State Hort. Soc., 1898, pp. 253-261*).—The writer classifies insects according to their feeding habits, and gives directions for preparing Paris-green solutions, Bordeaux mixture, and kerosene emulsion.

Insecticides and fungicides, E. E. FAVILLE (*Trans. Kansas State Hort. Soc., 23 (1898), pp. 90-94*).—The paper contains popular notes on spraying of fruit trees and garden vegetables.

Tests with phosphocarbid of calcium in 1898, E. CHUARD (*Chron. Agr. Canton Vaud, 12 (1899), No. 11, pp. 243-247*).—This substance holds phylloxera in check, but can not be relied upon for complete extermination of these insects like bisulphid of carbon.

The perfecting of the method of treatment against Cochylis (*Prog. Agr. et Vit., 20 (1899), No. 27, pp. 3, 4*).—Recommends the following insecticide: Water, 100 liters; turpentine, 2 kilos; soft soap, 3 kilos.

Experiments in cyaniding oranges, A. H. BENSON and H. TRYON (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 450–456*).—The treatments recorded in this paper were made against *Aspidiotus ficus, Chionaspis citri,* and *Mytilaspis gloveri.* The results of the experiments were as follows: Hydrocyanic-acid gas, even in a very dilute state, destroyed all the scale insects in both mature and larval conditions when they were confined in it for 1 hour The greater number of the eggs were also destroyed.

Dry rubbing of fruit to remove the scale insects injures the skin so that the gas acts upon the substance of the orange and discolors it. Drops of water on the fruit absorb the gas and may cause discoloration. It is not necessary to use 5 fluid oz. of sulphuric acid and 10 fluid oz. of water to generate the gas from 1 oz. of 98 per cent cyanid of potassium.

Annual report of the special committee for plant protection for 1898, FRANK and SORAUER (*Arb. Deut. Landw. Gesell., No. 38, pp. 197*).—This report contains brief notes and suggestions of remedies for a great variety of injurious insects, birds, mice, nematode worms, and rabbits. The injurious animals are arranged in lists under the name of the plants which they damage.

FOODS—ANIMAL PRODUCTION.

Description of a new respiration calorimeter, and experiments on the conservation of energy in the human body, W. O. ATWATER and E. B. ROSA (*U. S. Dept. Agr., Office of Experiment Stations Bul. 63, pp. 94, pls. 8, figs. 12*).—In a previous publication (E. S. R., 9, p. 863), that portion of the respiration calorimeter which had to do with the income and outgo of matter was described. The present bulletin describes the special devices which have to do with the income and outgo of energy, and reports 2 experiments in which the balance of matter and energy was determined, as well as a number of check experiments in which the accuracy of the apparatus was tested by means of heat generated by an electric current and by alcohol burned inside the respiration chamber.

The respiration chamber has 2 metal walls, one of zinc and the other of copper. These are protected by 3 walls of wood with air spaces between. The metal walls are maintained at the same temperature; hence no heat can pass in or out of the respiration chamber. The heat given off from the body of the subject in the respiration chamber and that due to external muscular work performed by the man inside the chamber is carried off by a current of cold water which passes through a series of pipes inside the chamber.

"By regulating the temperature of this water current as it enters and also its rate of flow, it is possible to carry away the heat just as fast as it is generated and thus maintain a constant temperature inside the chamber. The amount of the outgoing water and its increase in temperature are measured, thus determining the amount of heat carried away.

"In order that the heat taken up by the absorbers and carried out by the water current shall represent exactly the amount given off from the man's body or otherwise produced in the chamber, it is necessary to provide that there shall be no passage of heat through the walls, or rather, that the small quantities that may pass in and out shall exactly counterbalance each other, and that the ventilating current of air shall leave the chamber at the same temperature as it enters, so that it shall carry out neither more nor less heat than it brings in. The excess of water vapor in the air leaving the chamber over that in the air entering represents water given off from the body of the subject, and the heat required to vaporize it must be added to the heat carried off by the current of water to obtain a measure of the total heat given off by the subject. . . .

"In some of the experiments the man had as little muscular exercise as practicable. In these so-called rest experiments no attempt was made to measure the muscular work. In others, so-called work experiments, the amount of work done was measured by a specially devised ergometer, consisting of a stationary bicycle, which was belted to a small dynamo. The electric current generated passed through an incandescent lamp inside the chamber, where its energy was transformed into heat. The strength of current and voltage was determined by instruments outside the calorimeter. The heat equivalent of the muscular work done was thus added to and measured with the heat given off from the body. The duration of the work and the amount of the electric current generated gave data for the computation of the amount of work performed."

The special devices for regulating the temperature of the walls of the calorimeter, for regulating the temperature of incoming and outgoing currents of air, and for measuring the volume and temperature of the current of water which passes through the absorbers in the respiration chamber are described in detail, as are also the methods of conducting experiments with men.

The test experiments are discussed at length.

"In the electrical tests the measurements of heat generated and found were practically identical, the differences between the theoretical and actual results averaging about 0.1 per cent—that is, about 1 part in 1,000. In the alcohol tests the average amounts found by actual experiment were: For carbon, 99.9 per cent; hydrogen, 100.6 per cent; and heat, 99.9 per cent, respectively, of the theoretical amounts.

"The determinations of carbon dioxid and water made by burning large quantities of alcohol in the respiration chamber agree reasonably well with each other and with the theoretical amounts. The variations, indeed, are not greater than are found in ordinary laboratory experience when alcohol is burned in the combustion furnace by the usual methods of organic analysis.

"The agreement between the results given by the respiration calorimeter and the bomb calorimeter for the heat of combustion of alcohol . . . is also very satisfactory when the great difference in the circumstances of the experiments is taken into consideration."

In one of the experiments with men the subject performed as little work as possible; in the other a considerable amount of work was performed. Each experiment lasted 4 days. The average daily income and outgo of nitrogen and carbon and the calculated gain or loss of protein and fat are shown in the following table:

Average daily income and outgo of nitrogen and carbon in rest and work experiments, with the estimated gain or loss of protein and of fat.

Experiment.	Nitrogen.				Carbon.					Calculated gain or loss.	
	In food.	In feces.	In urine.	Gain (+) or loss (—).	In food.	In feces.	In urine.	In respiratory products.	Gain (+) or loss (—).	Of protein.	Of fat.

Rest (No. 9)	119.4	115.0	2,275	2,354	2,310	+1.5
Work (No. 6)	119.4	103.1	3,830	3,864	3,726	—2.7

The experiments and the sources of error involved in them are discussed at length, as well as the bearing of this work upon the problem of the conservation of energy in the animal body.

"We would perhaps be unwarranted in assuming that the experiments thus far made completely demonstrate the application of the law of the conservation of energy in the human organism. They do, however, seem to us to be reasonably near to such demonstration, especially when we take into account the possible sources of error—chemical, physical, and physiological—which have been discussed above.

"It is certainly safe to assume that the principle followed in the experiments is correct, and that the apparatus and methods are accurate to the degree required for the experimental study of a large variety of the fundamental problems of biological chemistry and physics. Among these are the metabolism of energy and the production of heat by the body in the performance of its ordinary functions, as circulation, respiration, and digestion; the relations of muscular and mental work to the metabolism of matter and energy; the demands of the body for nutriment under different conditions of work and rest; the duties performed by the different nutrients of food in supplying the needs of the body; and finally, the nutritive values of food materials and the amount and proportions best adapted to the needs of people of different classes, with different occupations, and in different conditions of life. That such inquiries may be valuable for the study of food and nutrition in disease is equally apparent. Of course they are fundamentally necessary for a more thorough understanding of the economy of feeding domestic animals."

The physiological effect of creatin and creatinin and their value as nutrients, J. W. MALLET (*U. S. Dept. Agr., Office of Experiment Stations Bul. 66, pp. 24*).—A number of experiments in which the author was the subject are reported on the physiological effect of creatin and creatinin, the principal nitrogenous materials in meat extracts. In addition, methods of estimating creatin and creatinin were studied. The principal conclusions follow:

"By far the larger part of the flesh bases ingested, if not absolutely the whole, does not undergo metabolism with the production of urea or anything else, but on the contrary is eliminated by way of the kidneys. In the case of creatinin it is excreted unchanged, while creatin is changed wholly or very largely into creatinin. . . .

"The fact of the quantitative recovery of creatin and creatinin from the urine evidently accords fully with the generally accepted belief that these substances can not serve to build up proteids, and therefore are not to be classed among tissue-forming food materials.

"On the whole, this investigation is unfavorable to the idea of the creatin of living muscle being the main antecedent of urea in nitrogenous metabolism. . . .

"However this may be, and admitting that it is still an unsolved problem what nitrogenous substance or substances may properly be regarded as intermediate between muscle proteids and urea, it may fairly be regarded as established for nutrition investigations that the so-called flesh bases, creatin and creatinin, occurring in food may be entirely disregarded as sources of energy, being excreted practically without having undergone change. . . .

"In the discussion of the results of analyses of meat and forms of food prepared from it, such as soups and the like, it is evidently wrong and misleading to confound together, under the head of protein or proteid materials, the proteids proper, capable of building up the nitrogenous tissues of the living body and of furnishing muscular energy and heat by oxidation, and these so-called flesh bases, which, taken in along with food, are not available for either of these important purposes. This error is the more serious that creatin and creatinin, containing so large a percentage of nitrogen as they do, appear to represent and are counted as representing much more than their own weight of nutrient material, whereas they should be excluded altogether in food analyses from the nutrient material really present."

Food consumption under conditions of abnormal work, A. P. BRYANT (*Dietet. and Hyg. Gaz., 15 (1899), No. 7, pp. 393–397*).—From records of the kinds and amounts of food consumed by a professional bicycle rider during a six-day race, the author computes the amount of nutrients in the daily diet and its fuel value. These were protein 262 gm., fat 192 gm., carbohydrates 791 gm., and fuel value 6,100 calories. The amount of muscular work performed was also calculated.

"In the dietary here described, if the weights of food consumed are correctly reported and the food materials were of average composition, the protein used was over 2½ times the amount found in the average food consumption of a considerable number of families of working people, and the energy nearly twice as great. That in this case the diet was not greatly at variance with the needs of the body is indicated by the fact that there was but little change in the body weight during the six days."

The nutritive value of margarin compared with butter, E. BERTARELLI (*Riv. Ig. e San. Pubb., 9 (1898), Nos. 14, pp. 538–545; 15, pp. 570–579*).—Three experiments with healthy men are reported in which the value of margarin and butter was tested when consumed as part of a simple mixed diet. In one experiment the value of a mixture of olive oil and colza oil, which is commonly used in Italy in the neighborhood of Turin, was also tested. The author himself was the subject of one of the tests. He was 24 years old. The subjects of the other tests were 2 laboratory servants; one 27 years old, the other 32 years old. The coefficients of digestibility and the balance of income and outgo of nitrogen in the different experiments were as follows:

Digestion experiments with margarin, butter, and oil.

	Time.	Coefficients of digestibility.			Nitrogen.			
		Protein.	Fat.	Carbohydrates.	In food.	In urine.	In feces.	Gain.
	Days.	*Per cent.*	*Per cent.*	*Per cent.*	*Gms.*	*Gms.*	*Gms.*	*Gms.*
Laboratory servant, P. G.: 500 gm. white bread, 270 gm. veal, 70 gm. butter, 250–300 cc. wine	5	81.75	92.67	97.25	15.7	9.6	2.6	3.5
Laboratory servant, P. G.: 500 gm. white bread, 250 gm. veal, 70 gm. margarin, 250–300 cc. wine	5	79.50	93.90	97.07	15.7	10.3	3.2	2.2
Author: 450 gm. white bread, 250 gm. meat 70 gm. butter.	6	81.85	94.25	97.35	13.5	10.1	2.5	.9
Author: 450 gm. white bread, 250 gm. meat, 70 gm. margarin	6	77.80	93.73	96.70	13.5	9.6	3.1	.8
Laboratory servant, F. D.: 824 gm. white bread, 250 gm. meat, 61.6 gm. butter	5	85.32	95.80	97.38	16.5	13.2	2.9	.4
Laboratory servant, F. D.: 859 gm. white bread, 250 gm. meat, 61.6 gm. margarin	5	82.92	95.33	97.24	16.9	12.5	3.4	1.0
Laboratory servant, F. D.: 910 gm. white bread, 250 gm. meat, 61.6 gm. olive and colza oils	5	83.27	95.82	97.56	17.5	13.4	3.5	.6

The principal conclusions follow: When properly prepared margarin differs but little from natural butter in chemical and physical properties. On an average 93.5 to 96 per cent of fat was assimilated when margarin was consumed and 94 to 96 per cent when butter formed part of the diet. The moderate use of margarin did not cause any disturbance of the digestive tract.

Uses of the cassava crop, H. E. STOCKBRIDGE (*Florida Sta. Bul. 49, pp. 20–45, pls. 8*).—The author discusses the value of cassava as a feeding stuff and reports experiments with pigs and cattle. The fact is recognized that cassava is a food especially rich in carbohydrates and that it should be supplemented with nitrogenous material. The composition of a number of Florida feeding stuffs suitable for this purpose is quoted, among them being beggar-weed hay, crab grass hay, crowfoot hay, Spanish moss, pindars, sand-spur hay, velvet beans, and wire-grass hay. Suitable combinations of cassava with other feeding stuffs for horses, steers, cows, and pigs are suggested. The uses of cassava as a food for man are discussed and a number of receipts for preparing it are given. Its value for the manufacture of starch and glucose is pointed out. "As a raw material for the manufacture of starch, 6 tons of cassava produces 2,400 lbs. of commercial starch, as against 1,200 lbs. obtainable from 40 bu. of corn." According to analyses based on samples grown on several different plats, cassava contains 5.17 per cent water and 94.83 dry matter. The dry matter has the following percentage composition (food and fertilizer constituents): Protein, 2.54; fat, 0.55; resins, alkaloids, etc. (ether extract), 0.34; amids and sugars (alcohol extract), 16.96; crude fiber, 5.06; starch, 72.33; ash, 2.21; potash, 0.90, and phosphoric acid, 0.24. The fertilizing value of a number of by-products from cassava starch industry was found to be as follows:

Fertilizing value of by-products in the manufacture of starch from cassava.

	Water.	Volatile matter.	Nitrogen	Phosphoric acid	Potash.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Wash water	99.64	0.30	....	0.03	0.05
Fine cassava pulp	93 23	6 66	0.32	.38	.16
Coarse cassava pulp	89.14	10.73	.45	.06	.06
Cassava-bark residue	79 60	18.19	.75	.12	1.43

Experiments with pigs (pp. 23–28).—A test to compare cassava with corn, chufas, pindars, and goobers was made with 12 grade Duroc-Jersey pigs divided into 4 lots of 3 each. It began January 14, 1896, and covered 75 days. The average gain per pig was as follows: On cassava, 53 lbs.; corn, 59 lbs.; chufas, 21 lbs.; pindars, 16 lbs.; and goobers, 19 lbs. The cost of food per pound of gain was 1.04 cts. on cassava (at $6 per ton) and 3.06 cts. on corn. With pigs at 3 cts. per pound, there was a profit of 1.07 cts. per pound of gain on the cassava, and a loss of 0.35 ct. on the corn. Considering these data and the cheapness of growing cassava, the author concludes that "cassava properly used and fed must certainly be a very much more profitable crop than any other crop which can be converted into hogs and hog products."

Experiments in fattening beef on cassava (pp. 28–31).—A test of the value of cassava for fattening cattle was made with 2 animals, although the results for only 1 are reported. This was a "common Florida cow of the larger class." She was very thin at the beginning of the test and had received no food for some months except what she picked up in the woods. The test began February 19, 1899, and continued 75 days. The cow was fed all the cassava she would consume, which averaged 15 lbs. per day, and 2 lbs. of cotton-seed meal. To meet Florida conditions, she was kept in a hummock pasture, this being supplemented by an occasional feeding of pea vines, velvet beans, or crab-grass hay. At the beginning of the test the cow weighed 450 lbs. The live weight at the close of the test was 726 and the dressed weight 502 lbs. The cost of the food was estimated at $2.62, and the profit at $8.42. "Cassava proves itself a most superior beef-fattening food. The cost of live-weight beef produced by feeding cassava is 1.1 cts. per pound, and in 75 days a profit of 59.10 per cent was made by fattening beef upon cassava."

Alfalfa—feeding notes, H. M. Cottrell (*Kansas Sta. Bul. 85, pp. 14–16*).—In a test previously reported (E. S. R., 11, p. 182), pigs fed dry

Kafir corn and alfalfa hay were compared with lots fed whole Kafir corn, dry Kafir-corn meal, and wet Kafir-corn meal, respectively. In the present article the author discusses the profits from feeding the alfalfa hay.

"Valuing the alfalfa hay at $3 per ton, the average price on Kansas farms, and fat hogs at 3 cts. per pound live weight, the Kafir corn fed alone brought 22.4 cts. per bushel, while the Kafir corn fed with alfalfa hay brought 31.4 cts. per bushel after deducting the cost of the hay fed with it. . . . In a former experiment (E. S. R., 11, p. 182), pigs were pastured through the summer on alfalfa with a light feeding of corn. After deducting the probable gain from the corn, the gain per acre from the alfalfa pasture was 776 lbs. of pork. These facts indicate that to produce pork most cheaply the Kansas farmer must have alfalfa pasture in summer and alfalfa hay in winter."

Pasturing sheep on alfalfa, W. W. COOKE (*Colorado Sta. Bul. 52, pp. 1–23*).—A test of the value of alfalfa pasturage for sheep is reported, and the experience of a number of sheep raisers in the Arkansas Valley is quoted. In the test at the station 11 cross-bred Shropshire-Merino sheep were bred to a Shropshire ram in the fall of 1897. They were fed throughout the winter on alfalfa hay, with a little silage during a part of the time. Immediately after the lambs (11 in number) were dropped grain was added to the ration, and both ewes and lambs were turned out on an alfalfa pasture April 20. The test closed September 6. One of the ewes and one of the lambs died from bloat. Late in April the 10 remaining ewes were sheared, yielding 54 lbs. of wool. The ewes weighed on an average 90 lbs. each at the beginning of the test and 103 at the close. The lambs weighed 94 lbs. The ewes were sold for $3.50 per head and the lambs were valued at $4 per head. It is calculated that the net returns from the test were $23.20. "It should be remembered that these are the financial results, notwithstanding the 9 per cent loss from bloat on both ewes and lambs."

From the experience of sheep raisers in the Arkansas Valley the following general deductions are drawn regarding the value of alfalfa pasturage:

"The average of the statements from the various individuals seems to be about 10 ewes and their lambs to 1 acre of good alfalfa pasture, running on the land from the middle of April until the first of October. This would require very good alfalfa, and it is probable that 8 ewes to the acre would be nearer average conditions. The ewes would feed on the stubble fields practically without cost during October and November, leaving 4½ months that they would have to be hay fed.

"A full-grown ewe will eat 5 lbs. of hay per day, or 2⅘ tons of hay to run the 8 ewes through the winter. If we estimate an acre to produce 4 tons of alfalfa, then it would require ⅘ of an acre to supply hay for the winter and 1 acre to pasture them during the summer. . . . For the last 4 years lambs have averaged being worth 4 cts. a pound, live weight, on the farm the first of October. It is fair to presume that a person who was planning for pasturing alfalfa would have the lambs dropped in March; and they ought, then, to weigh 70 lbs. the first of October and be worth $2.80 each. The ewes would need to be fed grain for 60 days, 1 lb. per day, costing in all 40 cts. for each ewe. The ewes should shear 7 lbs. of wool each, worth at least 10 cts. per pound. . . .

> "[On the basis of these suppositions] $24.80 represents the return from the land that will produce 7 tons of alfalfa, or about $3.50 per ton for cutting and feeding about half the alfalfa and letting the sheep harvest the other half. Out of this return would need to be deducted the interest on the investment and any losses by bloat that may occur.
>
> "Whether or not any greater return for the alfalfa can be obtained in any other way, each farmer will need to answer for himself. It is believed that the items of income as given above are conservative estimates, and that profits much larger than this would often be obtained."

The dangers from pasturing sheep on alfalfa are mentioned, and the precautions to be observed are enumerated.

Raising early lambs, W. W. COOKE (*Colorado Sta. Bul. 52, pp. 24–32*).—To determine whether early lambs may be profitably raised in Colorado, tests extending over 3 years (1895–1898) were made. Each year 25 Shropshire-Merino and 25 Horned Dorset-Merino ewes were used. Fifteen of the Shropshire ewes were bred to Shropshire bucks and 10 to Dorset bucks; 15 of the Dorset ewes were bred to Dorset bucks and the remainder to Shropshire bucks. In the 3 years 61 Shropshire lambs, averaging 54 lbs. live weight and 26 lbs. dressed when 84 days old, were sold at an average price of $3.64 per head. In the same time a total of 74 Horned Dorset lambs, averaging 55 lbs. live weight and 25 lbs. dressed when 86 days old, were sold for an average of $3.57 per head.

> "The financial results are in favor of the Horned Dorsets. The first year they grew the faster, but in both the other years the Shropshires made the most weight and sold for the most per head. But the Dorsets produced so many more lambs as to more than overbalance their slower growth. On the whole the Dorsets brought in $40 more than the Shropshires, or about $\frac{1}{6}$ of the total income. This difference is due entirely to the larger number of lambs reared by the Dorsets. Their record is practically 100 per cent, since 74 lambs were sold from 25 ewes in 3 years."

In the above experiments it was calculated that the average yearly income from lambs for the 50 ewes was $162.93. To this should be added 70 cts. per head for wool. This makes the total yearly income from 1 ewe $3.96. At the close of the experiments the ewes were sold for a little more than they cost. In the author's opinion these returns compare very favorably with those which can be obtained from sheep pastured on the range. The data on which these calculations are based are discussed in detail. The experience of a number of individuals on raising early lambs in the Arkansas Valley is quoted.

The chemical composition of American food materials, W. O. ATWATER and A. P. BRYANT (*U. S. Dept. Agr., Office of Experiment Stations Bul. 28 (rev. ed.), pp. 87, figs. 4*).—In addition to historical statements regarding early American food analyses and a discussion of the principal constituents of food and methods of cutting carcasses of cattle, calves, sheep, and pigs, the bulletin contains the maximum, minimum, and average composition of the more important American food materials. These include meats of different kinds and cuts, fish, shellfish, eggs and dairy products, flour and cereal products, bread, vegetables, fresh and canned fruits, nuts, cakes, pastry, etc. The bulletin is a compilation based on over 4,000 individual analyses gathered from widely scattered sources.

Margarin products from the standpoint of hygiene and nutrition, A. Jolles (*Oesterr. Chem. Ztg., 2 (1899), Nos. 3, pp. 70–72; 4, pp. 105, 106; 6, pp. 157, 158; 8, pp. 213–216*).—This is an address reviewing the status of the subject. With reference to the digestibility and relative nutritive value of margarin, the author concludes that the matter is by no means settled. He reports a long experiment made by himself with a dog, which showed pure margarin to be equal in digestibility and nutritive value to pure natural butter. Stress is laid upon the fact that in such experiments pure material must be employed and the periods of observation at least 8 days.

Extensive investigations are cited as showing that the germ content of margarin is less than that of pure butter.

Paraffin as an adulterant of oleomargarine, J. F. Geisler (*Jour. Amer. Chem. Soc., 21 (1899), No. 7, pp. 605–608, pls. 2*).—The author mentions finding paraffin in 5 different samples collected in New York and Brooklyn, the amount of paraffin ranging from 5 to 11.76 per cent. The paraffin was extracted and exhibited as proof of the adulteration.

"It is pertinent to say that the object of the use of paraffin in oleomargarine is not to cheapen the article, but to make a more homogeneous fat mixture by preventing the separation of the fats and oils, and also affect the general consistency and appearance of the mass and its behavior under the trier in sampling. One of these samples was with difficulty distinguished from butter by physical tests."

The author discusses the effect of consuming paraffin, concluding that "at the present time there are no data to warrant anyone in saying that the use of paraffin, as above, is harmless in its effects upon the system."

Wheat for alimentary pastes in France, J. C. Covert (*U. S. Consular Rpts., 1899, No. 226, pp. 468–470*).—According to the author there is always a demand in France for wheats rich in gluten. These are used for the manufacture of alimentary pastes such as macaroni, spaghetti, etc., and for mixing with other wheat for use in bread making. The desirability of giving attention to growing such wheats in the United States is insisted upon.

Standard cookery book, N. Dubois and E. Bernard (*La cuisine classique. Paris: E. Dentu, 1897, ed. 17, vol. 1, pp. LXIV + 431, pls. 33; vol. 2, pp. 525, pls. 68*).—This is a very extended treatise on the subject of cookery, including methods of preparing and serving different foods.

The value of alcohol as a food, R. O. Neumann (*Arch. Hyg., 36 (1899), No. 1, pp. 1–44*).—A number of experiments are reported in which the author was the subject. The balance of income and outgo of nitrogen was determined. The author concludes that alcohol is a food; that is, it can replace fat and protect protein. The fact that alcohol has toxic properties is also insisted upon. The article contains an extended bibliography.

The digestibility of margarin, R. Kayser (*Ztschr. Öffentl. Chem., 5 (1899), pp. 101–103; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, p. 725*).—Summary of various investigations.

Handbook of dietetic treatment and dietetics, E. von Leyden (*Handbuch der Ernährungstherapie und Diätetik. Leipsic: G. Thieme, 1897–98, vol. 1, pp. X + 622; vol. 2, pp. VI + 825*).—These volumes contain chapters on nutrition in health and disease by a considerable number of specialists.

Practical dietetics with special reference to diet in disease, W. G. Thompson (*New York: D. Appleton & Co., 1896, pp. XXII + 802*).—In addition to a large amount of material on the diet suited to persons suffering with different diseases, the volume contains much matter on the composition, character, and uses of different foods and beverages; cooking and preservation of food, digestibility, average rations, and prison and other special dietaries.

Report of the examination of foods and feeding stuffs, Pfeiffer (*Ber. Thätigkeit Landw. Vers. Sta. Univ. Jena, 1898, pp. 5–8*).—The examination of butter and of a number of feeding stuffs, in accordance with the regulations controlling their sale, is briefly reported.

Concentrated feeding stuffs, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Rpt. 1898, pp. 172–176*).—Analyses are reported of cotton-seed meal, gluten meals and feeds, Cleveland flax meal and linseed meal, corn bran, wheat bran and middlings, ground corn and oats, and a number of mixed feeds. The need of a law regulating the inspection and sale of feeding stuffs in Vermont is pointed out.

Division of animal physiology, KÜNNEMANN (*Ber. Thätigkeit Landw. Vers. Sta. Univ. Jena, 1898, pp. 23, 24*).—A number of foods and feeding stuffs were examined with a view to the detection of harmful constituents.

The food value of fresh and ensiled maize, H. WIBBENS (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 11* (*1899*), *No. 131, p. 100*).—Analyses are reported of fresh and ensiled maize.

The nutritive value of maize and maize forage, R. DUMONT (*Prog. Agr. et Vit.* (*Éd. L'Est*), *20* (*1899*), *No. 21, pp. 637–640*).—A general article.

The value of maize by-products as a feeding stuff, C. MONNOT (*Jour. Agricole* [*Paris*], *10* (*1899*), *No. 113, pp. 151–155*).—The value as a feeding stuff of the residue from maize used for the manufacture of glucose, beer, or starch is insisted upon and a number of feeding experiments with cattle briefly reported.

A digestion experiment with alfalfa hay (*Kansas Sta. Press Bul. 41, folio*).—As determined by a digestion experiment with a steer, hay made from alfalfa cut when in full bloom had the following coefficients of digestibility: Total digestible nutrients, 55.29; protein, 10.43 (albuminoids, 7.86; amids, 2.57); fat, 0.69; crude fiber, 15.99; and carbohydrates, 28.18 per cent.

The nutritive value of the Calabriaan citrus fruit pomace, F. GABBRIELLI (*Staz. Sper. Agr. Ital., 32* (*1899*), *No. 2, pp. 204–208*).—An analysis of pomace of citrus fruits is reported and its feeding value discussed.

Investigations on the metabolism of horses at work and resting, N. ZUNTZ and O. HAGEMANN (*Untersuchungen über den Stoffwechsel des Pferdes bei Ruhe und Arbeit. Berlin: Paul Parey, 1899, pp. X + 440, pls. 7, fig. 1*) —This is the publication in book form of an article previously noted (E. S. R., 11, p. 72).

Contribution to the subject of metabolism with insufficient diet, F. N. SCHULTZ (*Arch. Physiol.* [*Pflüger*], *76* (*1899*), *No. 7–8, pp. 379–410, fig. 1*).—A considerable number of experiments with rabbits and dogs are reported. These are discussed in detail. The possibility of removing fat from the animal body by partial fasting is also discussed at length, as well as the possibility of estimating the amount of fat in the body by determining the amount in a control animal. Analysis showed that flesh which was apparently free from fat still contained appreciable amounts which consisted quite largely of cholesterin.

Horses, cattle, and sheep of Hungary (*Képek Magyararszága'llattenyésztéséből. Budapest, pp. 16 + pls. 100*).—This work, which is published by authority of the Minister of Agriculture, consists of 100 plates of the animals exhibited at the Hungarian Millennial Celebration in 1896 and descriptive text in Hungarian, German, French, and English.

Cattle-feeding experiments, A. P. AITKEN (*Ann. Rpt. Distrib. Grants Agr., Education, and Research* [*Great Britain*], *1897–98, pp. 142–150*).—Abstracted from another publication (E. S. R., 10, p. 981).

The modern sheep (*Kansas State Bd. Agr. Quart. Rpt. 1899, Mar. 31, pp. 1–156, pl. 1, figs. 33*).—This volume contains many articles by different authors on breeds of sheep, breeding, fattening, and general care of sheep, and the value of different feeding stuffs, and on sheep diseases. A number of experiments made by the different experiment stations with sheep are quoted in considerable detail.

Raising sheep for mutton, C. F. CURTISS (*U. S. Dept. Agr., Farmers' Bul. 96, pp. 48, figs. 18*).—The author discusses the profitable production of sheep for wool and mutton, quoting extensively from the work of the stations, especially that of the Iowa Station.

Hog raising in the South, S. M. TRACY (*U. S. Dept. Agr., Farmers' Bul. 100, pp. 40*).—A popular bulletin describing the breeds and breeding of pigs, their diseases, and insect enemies, with special reference to conditions in the South. The author concludes that the obstacles to successful pig raising in the South can be overcome and that this industry may be made very profitable.

DAIRY FARMING—DAIRYING.

Feeding tests and their methods, J. L. HILLS (*Vermont Sta. Rpt. 1898, pp. 310–346, 370–400*).—Experiments on the proper length of feeding periods, the relative feeding value of different rations, and the experimental error in feeding tests were made in continuation of the previous year's work (E. S. R., 9, p. 877). Thirty-two cows were used in the tests, which lasted in all 25 weeks. In addition to hay and silage the following mixed feeds were employed: (1) Cotton-seed meal 3, linseed meal 3, corn meal 4, and wheat bran 6 parts; (2) Atlas gluten meal 8, corn meal 4, wheat bran 6 parts; (3) cotton-seed meal 2½, linseed meal 2½, corn meal 5, wheat bran 6 parts; (4) Atlas gluten meal 10, corn meal 3, wheat bran 5 parts; and (5) corn meal 4, wheat bran 8 parts.

Full data for the experiments, including weights of cows, barn temperatures, analyses and digestible ingredients of the fodders and feeds, records of the individual cows and the like, are tabulated. The details of the investigation and the results obtained are summarized by the author as follows:

"*The proper length of feeding periods.*—Four different grain rations were fed with hay and silage as roughages. The rations were so planned that a 'medium' and 'wide' ration were used with one lot of 8 cows, and two 'medium' rations with a second lot of 8 cows. Nutritive ratios averaged 1:6.1 to 1:9.8 and 1:6.4 to 1:6.9. The tests were thus of rations with nutritive ratios widely apart and with nutritive ratios closely alike. In these tests, periods 3 weeks long were as accurate measures of the character and extent of variations as were those lasting 4, 5, or 6 weeks, when the rations fed were widely apart in their nutritive ratios; but the effect upon both quantity and quality of varying rations which are closely alike in their nutritive ratios was somewhat magnified when they were fed for but 3 or 4 weeks. Judgment, experience, and individual circumstances need to be called into play in the choice of period length. The present and the former investigation have not settled the question absolutely, but may prove of use in the formation of judgment. The writer's present opinion is that with a sufficient number of cows at hand and 25 weeks before the opening of the pasture season, the 5-week period (12 days preliminary, 23 days experimental) is to be preferred over those of longer or shorter duration. It enables three comparisons to each cow, and apparently the results need no discount because of possible temporary effects. If suitable animals are few, or time is short, the 4-week period (10 days preliminary, 18 days experimental) will give results sufficiently accurate for all practical purposes, but which may need some discounting as regards quality changes.

"*The relative feeding value of rations of nearly equal balance.*—Different rations of nearly equal balance were fed in two experiments to 11 cows. Nutritive ratios ran from 1: 6.6 to 1: 6.3 and from 1: 6.1 to 1: 6.3.

"A unit of dry matter in the Atlas ration made 6 per cent more product than did a unit of dry matter in the cotton-seed-linseed ration, a reverse of last year's result. The trend in individual cases, however, was generally uniform. A unit of dry matter in the corn-silage ration made 10 per cent more product than did one in the corn-sunflower-head ration. The quality of the milk remained unaltered throughout. The results showed slight differences in one case, and considerable differences in the other case of feeding rations of equal balance. The present status of the matter seems indeterminate and further experiment is needed.

"*The relative feeding values of medium and of wide rations.*—Hay, silage, mixed feed Nos. 1 and 5 were fed to 11 cows. Nutritive ratios averaged 1:6.1 and 1: 10.0. From 6 to 11 per cent increase in production followed the substitution of the cotton-seed-linseed ration in place of the corn-and-bran ration. The quality of the milk remained unchanged.

"*The relative feeding values of medium and of wide rations, the latter fed in scant amount.*—Hay, silage, mixed feeds No. 1 and 5 were fed to 4 cows. Eight pounds of No. 1 and only 3 lbs. of No. 5 were fed. Nutritive ratios averaged 1 : 5.9 and 1 : 11.8. Production paralleled feeding. Lessening or increasing the dry matter eaten one-fourth respectively lowered or bettered production one-fourth. The milk was slightly poorer on the 'wide-scant' ration, but since the solids-not-fat as well as the fat were lowered no 'disproportionate' change was noted.

"*Experimental error.*—Uniform rations were fed 4 cows for from 9 to 20 weeks, and quite uniform production resulted. A pound of dry matter made essentially the same amounts of milk, solids, and fat at one time as at another. It is probably unsafe, however, to lay stress on apparent differences in feeding values that do not exceed 5 per cent.

"*Practical conclusions.*—Assuming that two-thirds of the manurial ingredients reach the soil, and allowing 20 cts. per hundred for skim milk, the total and the daily net gains of one ration over another in butter, skim milk, and manure, expressed in dollars and cents, are as follows:

Relative superiority of different rations.

Ration.	Days of feeding one cow.	Net gain.	Daily net gain, one cow.
			Cts.
Cotton-seed-linseed ration *vs.* ration of equal parts corn and bran	402	$12.46	3.10
Atlas ration *vs.* cotton seed-linseed ration	474	14 22	3.00
Cotton-seed-linseed ration *vs.* ration of 2 parts corn 1 part bran	115	2.58	2.24
Cotton-seed-linseed ration *vs.* ration of 2 parts corn 1 part bran (the latter fed in scant quantities)	92	4.13	4.49

"The Atlas ration proved superior and furnished the cheapest protein, the cotton-seed-linseed ration ranking second. The gain in the last experiment was entirely in skim milk and manure. The scantily fed cows lost flesh.

"The addition of sunflower heads to corn silage injured it and lowered production."

Record of the station herd for 1896–97, J. L. Hills (*Vermont Sta. Rpt. 1898, pp. 355–365*).—The record of 29 cows from November 1, 1896, to October 31, 1897, is given and compared with previous records of the station herd. The record of 20 of the cows belonging to the herd for 3 years and of 27 for 2 years is summarized in the following table:

Average record of 20 cows for 3 years and 27 cows for 2 years.

	Yield of milk.	Fat content of milk.	Yield of butter.	Cost of food.	Cost of purchased grain.	Cost of food per lb. butter.	Proceeds of butter sales.
Average of 20 cows:	*Pounds.*	*Per cent.*	*Pounds.*			*Cents.*	
1894-95	5,864	4.94	338	$53.16	$19.92	17.6	$79.30
1895–96	5,927	5.01	347	43.54	14.75	13.5	79.77
1896–97	6,475	4.87	368	49.77	19.26	14.0	89.24
Average of 27 cows:							
1895–96	5,657	5.12	338	42.56	14.45	13.3	77.76
1896–97	6,012	5.04	354	48.66	18.98	13.8	85.80

"The herd, as a whole, made the most milk and butter per cow during 1896–97. The butter was made more cheaply during 1895-96. . . . The excess of proceeds per cow over total cost of food for the 3 years, respectively, is $26.34, $32.51, and $34.59. The more favorable result of the last year is entirely due to better selling prices. . . .

"As in past years the Ayrshires rank high in yield and in economy of production of milk, and relatively low in economy of production of butter."

Studies in milk secretion, H. H. WING and L. ANDERSON (*New York Cornell Sta. Bul. 169, pp. 519–552, pls. 4, dgms. 3*).—The records of the university herd from 1891 to 1898 are presented in tables and discussed. The herd consists of about 20 grade Jersey and Holstein cows, and has been developed from the ordinary stock of the neighborhood by a course of breeding and selection begun in 1875. The results of the studies are given in the authors' general summary and conclusions:

"A good grade herd can be bred up from a herd of ordinary cows by the use of first-class thoroughbred sires and a careful selection of the best heifers.

"By breeding in this way the university herd has increased in milk production from an average of 3,000 lbs. per cow in 1874 to an average of 7,575 lbs. in 1898.

"It pays to select heifers from the best cows as well as to use only well-bred bulls. Milk such heifers at least one year and then retain only those which give promise of being profitable producers.

"The greatest production for one lactation period was by Ruby in 64 weeks, 16,089.5 lbs. of milk and 531.32 lbs. of fat, equivalent to 625 lbs. of butter containing 85 per cent fat.

"The average production for 7 years was 7,330 lbs. of milk, 275 lbs. of fat, and 3.76 per cent fat. The average for each year varied from 6,875 lbs. of milk in 1892–93 and 266 lbs. of fat in 1895–96 to 7,575 lbs. of milk in 1897–98 and 292 lbs. of fat in 1893–94.

"The average gain in production of milk as the cows increased in age was 5 per cent from two to three year olds, 18 per cent from three to four year olds, and 15.3 per cent from four-year-olds to full aged cows.

"The average gain in production of butter fat was 5.5 per cent from two to three year olds, 17 per cent from three to four year olds, and 13.6 from four-year-olds to full aged cows.

"Beginning with the third week after calving and dividing the remainder of the lactation into periods of 4 weeks, and then considering the average daily yield of milk of all the cows for the first period as 100, there was a gradual decrease in milk flow to 55 during the eleventh period. Calculating the average percentage of fat in like manner, there was a decrease to 96 in the second period and then a gradual increase to 106 during the eleventh period.

"Speaking in other terms, there was an average decrease in yield of milk as lactation advanced of about 5 per cent from each period of 4 weeks to the next. In percentage of fat there was an average increase of about 0.5 per cent from month to month.

"As a rule, a cow will produce more butter during the first few weeks of a lactation period than at any equal subsequent time during the same lactation.

"The general effect of the change from barn to pasture was an increase in both milk flow and percentage of fat for the first 2 weeks, and for the next 3 weeks a slight decrease in milk and percentage of fat below the daily average for the last 3 weeks in the barn.

"During the year 1892 20 cows produced milk for 62½ cts. per hundredweight, and fat for about 16 cts. per pound for the food consumed.

"In general, the cows consuming the most food produced both milk and fat at the lowest rate."

The effect of fatigue upon the quantity and quality of milk, J. L. HILLS (*Vermont Sta. Rpt. 1898, pp. 367, 368*).—Ten cows were driven 10 miles and shipped 50 miles by rail. During the 24 hours in transit they were not milked. Tables show the yield and composition of the milk for each milking for the first, second, fifth, and sixth days after arrival, and the average for 2 days 3 weeks after arrival. Considerable individual variation was observed.

> "The quantity of milk was lowered as an immediate result, but normal flow seems to have been nearly restored by the end of the second day. The fat percentage dropped during the first day and was decidedly increased the second day, remaining a little high during the next few days, as compared with the flow of 3 weeks later. Solids-not-fat averaged about the same, except for the second milking."

The results are compared with those of a similar test with 25 cows previously reported (E. S. R., 8, p. 86).

> "The main results are identical in each case, save that the temporary lowering of quality observed in the present test did not occur in the former trial while enrichment did ensue. 'It seems safe to conclude as a result of the two tests that fatigue tends to lessen the milk flow temporarily, to affect variously its quality for the first one or two milkings, and to raise the quality for a while after the second milking."

The effect of food upon the quality of butter, J. L. Hills (*Vermont Sta. Rpt. 1898, pp. 347–350*).—The effect of various feeding stuffs upon the quality of butter and upon churnability as previously determined (E. S. R., 9, p. 884) was practically confirmed in a study made in connection with the experiments noted above. The rations used contained hay and silage with the following concentrated feeds: (1) Atlas gluten meal, corn meal, and wheat bran; (2) corn and bran; (3) cotton seed, linseed meal, corn, and bran; (4) bran and cotton-seed oil, and (5) bran.

Tables give the scoring and chemical analyses of the butter and the data for churning. Butter made from cows on ration 4 ranked lowest. The use of Atlas gluten meal appeared to decrease the exhaustiveness of the churning.

Preservation of milk samples, J. L. Hills (*Vermont Sta. Rpt. 1898, pp. 350–355*).—The author presents the results of an investigation made by D. Stuart, of the agricultural department of the university, on the comparative merits of various preservatives for milk samples. The experiments included tests of 57 chemicals, 29 of which it is stated had not hitherto been used for this purpose. The results obtained by other investigators on the use of 93 chemicals as antiseptics are also noted.

Of the 122 different chemicals mentioned the following only are considered useful for this purpose: Mercuric chlorid, a mixture of 10 parts mercuric chlorid and 50 parts borax, potassium chromate, potassium bichromate, sodium sulphite, sodium bisulphite, copper-ammonium sulphate, sodium salicylate, and formaldehyde.

The use of potassium chromate and bichromate is noted as causing the samples to churn easily and producing tenacious cream and black curd in warm weather and with the steam tester; sodium salicylate as not dissolving readily and being costly, bulky, and inconvenient to handle; and copper-ammonium sulphate as lessening the miscibility of the sample and giving it an unpleasant odor.

> "Mercuric chlorid is relatively costly, and virulently poisonous, a serious objection. The mixture of mercuric chlorid and borax seems efficient, and while less poisonous than the pure salt is still open to objection on this score. Sodium sulphite and bisulphite must be used in considerable quantity, and they do not prevent

a putrid smell. Formaldehyde (formalin) seems to have but a single fault, that it tends to harden the casein, thus making it somewhat more difficult to 'cut' the curd by the sulphuric acid. Greater thoroughness in mixing obviates this. . . . In the course of our experiments 0.13, 0.25, 0.50, 0.75, 1.25, 2.50, 3.75, 5.00, 8.75, and 12.50 per cents of formalin were added respectively to 10 jars of milk. These samples were tested periodically for a month, without diminution of the fat reading, which coincided (corrected for dilution when the preservative was used in large quantities) with the analysis of the fresh and untreated milk. The fat columns were clear in every case, regardless of the relatively large amounts of preservative used. . . . Used in amounts of 1 per cent or more it tends to increase the total solids from 0.20 to 0.50 per cent. This may be due to the polymerization of the aldehyde, to the conversion of the milk sugar into galactose, to both, or indeed to some other cause not understood. This effect is not observed when it is used in small quantities."

Brief notes are given on the composition of 9 commercial preparations for preserving milk tested at the station.

Bacteriology of milk, L. L. LEWIS (*Oklahoma Sta. Bul. 40, pp. 16, figs. 8*).—In connection with a popular discussion of the subject the author gives the results of a number of experiments in the preservation of milk by pasteurization and by the use of formalin. Determinations were made of the number of bacteria in the first, middle, and last milk drawn; in milk after standing 1, 2, 3, and 4 hours at 33° C., and in milk pasteurized for 15 minutes at 60° and for 15 minutes at 70° C. The time required for milk not pasteurized, and milk pasteurized for 15 minutes at 60° and for 15 minutes at 70° C. to develop sufficient acid to neutralize 1.5 cc. of deci-normal soda solution was 25, 30, and 46 hours, respectively. Pasteurization increased the keeping qualities of milk to which formalin had been added in the proportion of 1 to 30,000, but did not with formalin added in the proportion of 1 to 10,000. The morphology and growth upon various media of 4 bacilli isolated from pasteurized milk are reported in detail.

Killing the tubercle bacillus in milk, C. E. MARSHALL (*Michigan Sta. Bul. 173, pp. 311–321, fig. 1*).—The work of a number of investigators along this line is reviewed and experiments conducted at the station are reported.

In one series of 5 experiments sterilized milk was infected with tuberculous material from different cows and then pasteurized by heating to 68° C., holding at that temperature for 20 minutes, and cooling rapidly. In each experiment one guinea pig for control was inoculated intra-abdominally with 1 cc. of the infected milk before pasteurization, and a number of guinea pigs were similarly inoculated with 5 cc. of the pasteurized milk. All of the control animals died from tuberculosis within a few weeks, while none of the 13 animals inoculated with the pasteurized milk became tuberculous.

As a temperature of 68° C. for 20 minutes does not produce a cooked flavor in the milk and is shown by the experiments to kill the tubercle bacillus, the author argues that a lower temperature for pasteurization should not be adopted.

In 3 experiments milk was heated in a receptacle placed within a water bath in imitation of crude methods of pasteurization. The temperature of the water and milk during the process of heating is given. The results are considered as showing that any method of pasteurization controlled entirely by the temperature of the water is unreliable.

Several experiments were made in pasteurizing milk artificially infected with tuberculous material, at a temperature which would give the milk a cooked flavor. This was done by heating the water surrounding small bottles of the milk to the boiling temperature, removing the heat, and allowing the milk and water to stand for 5 or 30 minutes. Four guinea pigs inoculated with the unpasteurized milk developed general tuberculosis within a few weeks. The 12 inoculated with 5 times the quantity of pasteurized milk remained free from any trace of the disease.

An apparatus, devised at the station for family pasteurization of milk where the slightly cooked flavor and odor are not objectionable, is described and illustrated, and directions are given for using.

"This pasteurizing apparatus was suggested by Novy's laboratory pail sterilizer, and consists of a covered pail with a perforated bottom placed upon a water bath provided with a shoulder to receive it. There is a hole in the cover so as to provide for a continuous stream of steam. Inside the pail is a rack which holds the bottles in position. The water bath is shallow and flanges out from the shoulder. By this means a large heating surface is presented and the water is soon raised to the boiling point upon the application of heat."

The excretion of micro-organisms through the lacteal glands, K. BASCH and F. WELEMINSKY (*Arch. Hyg., 35 (1899), No. 3-4, pp. 205-226*).—The authors inoculated guinea pigs in various ways with cultures of anthrax, typhus, diphtheria, cholera, and *Bacillus bovis morbificans* to determine whether the germs of these diseases could be transmitted through the milk. There was no transmission of the anthrax, typhus, diphtheria, or cholera germs, the milk in each case being sterile.

The authors conclude that in general disease germs are not transmitted to the milk except such as produce hemorrhages or an abnormal condition of the glands. It is believed, however, that the question must be settled separately for each disease and for different kinds of animals.

Tubercle bacilli in butter, O. KORN (*Arch. Hyg., 36 (1899), No. 1, pp. 57-65*).—Twenty samples of butter, most of them produced by peasants near Freiburg, all unsalted, and some from sweet and some from ripened cream, were examined for tubercle bacilli. Three of the samples produced death from peritonitis in all of the guinea pigs in which they were inoculated. Of the remaining 17, 4 were found to contain virulent tubercle bacilli.

The author strongly recommends compulsory testing of all dairy herds, and the exercise of great care in the selection of laborers entirely free from tuberculosis for the care of the animals and the handling of the milk.

The relation of acid fermentation to butter flavor and aroma, C. H. ECKLES (*Iowa Sta. Bul. 40, pp. 53-64*).—This is a semipopular article on the above subject, including some original work and citing examples from experience. The author's conclusions are summed up as follows:

"Butter flavor is produced mostly by the bacterial fermentations which have taken place in the milk and cream. The kind of flavor produced depends upon the class of bacteria causing the fermentation. Cream ripened with common bacteria found in hay dust (*Bacillus subtilis*) gives a very undesirable flavor to butter.

"The general superiority of butter flavor in the summer season is mainly due to the difference in the fermentations that are in the milk.

"This difference is due to the greater number of bacteria of the acid class found in the milk during the summer season.

"The ripening of a good quality of natural cream is mostly a development of acid bacteria. When good-flavored cream is ready for churning, the number of bacteria per cubic centimeter varies from 280,000,000 to 3,000,000,000. Of this number the acid-producing bacteria constitute from 91 to 98 per cent. As the process of ripening advances, the relative percentage of acid bacteria greatly increases. As this proceeds, some species disappear; others are prevented from increasing in numbers.

"A good natural skim-milk starter is practically a pure culture of acid-producing bacteria.

"The flavor-producing power of four species of acid-producing bacteria was tried by using them to ripen pasteurized cream. Any one of these gave the butter the typical flavor and aroma produced in natural ripening.

"The most common milk-souring organism (*Bacterium lactarii*), all things considered, gives the most satisfactory results of any of the species tried as a culture for ripening cream.

"Practical experience and experimental evidence both indicate that the most important factors in cream ripening are the development of the typical acid fermentations and the elimination or suppression of other and injurious types of fermentations."

On the bacteriology of cheese, C. GORINI (*Bol. Not. Agr., 19 (1897), pp. 388-397; abs. in Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 1, pp. 44-46*).—The author studied the effect of the conditions of growth in cheese on the physiological activity of seven different forms of bacteria, i. e., *B. lactis niger*, *B. lactis thermophilus*, and five different forms belonging to the group *subtilis*. He found that bacilli which were biologically very similar behaved differently in regard to milk fermentation, according to the temperature and the presence or absence of air. Bacilli which soured milk at a high temperature peptonized it at a lower temperature. The higher temperature favors the increase of bacilli, which attack the milk sugar and produce lactic acid, and this in turn checks the action of the bacteria, so that the casein remains intact. A proof of this is that when the milk is neutralized peptone formation takes place. The exclusion of air checks the peptonizing of the casein especially. When the vacuum was not complete, the milk was curdled, but no peptonizing action took place, although it progressed rapidly as soon as fresh air was admitted. It is claimed that the investigations show that bacteria may attack the milk sugar or the casein, depending upon the conditions under which they are placed.

Cream raising by dilution, J. L. HILLS (*Vermont Sta. Rpt. 1898, pp. 365, 366*).—One hundred and twenty trials were made with two sizes of the "Wheeler Gravity Cream Separator," using herd and stripper milk from Jersey and Ayrshire cows.

"These same milks were closely skimmed by the centrifugal separator, which, moreover, was able to extract some cream from the diluted skim milks. The 'gravity separator' left in the skim milk 13 per cent of the fat of the mixed milk, 40 per cent of the fat of the Ayrshire milk, and 17 per cent of the fat of the stripper milk. The centrifugal separator left between 1 and 2 per cent of the fat of these milks behind in the skim milk. The results speak for themselves and call for no further comment."

Notes are given on the Wheeler can and on similar tests made at the New York Cornell Station (E. S. R., 10, p. 591).

Concerning patents on gravity or dilution separators, H. H. WING (*New York Cornell Sta. Bul. 171, pp. 18, figs. 8*).—Conclusions from tests of several cans for cream raising by dilution are quoted from Bulletin 151 of the station (E. S. R., 10, p. 591), and descriptions, mainly in the form of extracts from the specifications and claims under which patents were granted, are given of the Aquatic, Thayer, Phillip, Rector, Wheeler, Hunt, Rosback, and Doty gravity cream separators or creaming cans. The author holds that the patents granted on these cans, in which the dilution of milk with water is recommended to facilitate the separation of the cream, cover unimportant details of construction and that "anyone desiring to use this process of doubtful utility is perfectly free to do so without let or hindrance from the holder of any patent right whatever."

Miscellaneous dairy notes, J. L. HILLS (*Vermont Sta. Rpt. 1898, pp. 368–370*).—Analyses are given of samples from 3 lots of Vermont creamery butter shipped to the English market.

Two patent churns were tested, in one of which the churning was accomplished by a narrow disk of wood whirling through the cream, and in the other by pumping air through the cream. Neither was considered as desirable as the ordinary concussion churn.

Analyses are given of the milk drawn from one cow on the seventh, fourth, third, second, and last day before calving, and the average analyses of the milk for the 6 weeks following. A lactometer reading of 51.5 on the seventh day previous to calving is thought to be the highest on record.

Thirty-four comparisons were made of the Babcock test and the Bartlett modification of the Babcock test (E. S. R., 9, p. 184). The results averaged 0.05 per cent less by the modified method. "The modification appears to have merit, but, as intimated by its originator, ought to be used only by those well skilled in the usual method of testing."

Cow ties and stalls (*Hoard's Dairyman, 30 (1899), No. 33, pp. 654, 655*).—Several are described and illustrated.

An experimental creamery building at Hoorn, K. H. M. VAN DER ZANDE (*Landbouw. Tijdschr., 1898, pp. 1–10*) —A plan for an elaborate experimental creamery building with a bacteriological laboratory.

Dangers in milk and means of combating them, R. GATTA (*Jour. Hyg., 24 (1899), No. 1185, p. 185*).

Dairy sanitation, C. M. DAY (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 8, pp. 473–477*).—Advises approved sanitary methods so as to prevent the entrance of pathogenic bacteria into milk.

The milk supply of cities, H. W. CONN (*Pop. Sci. Mo., 55 (1899), No. 5, pp. 627–640*).—Recommends organized milk companies which can handle and pasteurize milk on a large scale.

Experiments with pasteurizing apparatus, F. FRIIS (*43. Ber. Kgl. Vet. Landbohojskoles Lab. Landokon Forsog. Copenhagen, 1899, pp. 152, ills.*).—An account of a number of tests with different kinds of pasteurizing apparatus.

Butter and margarin—composition, properties, manufacture, adulteration, preservation, marketing, and legislation (*Le beurre et la margarine (composition, propriétés, fabrication, alterations, conservations, commerce, legislation). Paris: Gauthier-Villars, 1899, pp. 163*).

How to make farm dairy cheese, T. L. HAECKER (*Hoard's Dairyman, 30 (1899), No. 35, p. 692*).– Detailed directions are given.

Officials, associations, and educational institutions connected with the dairy interests of the United States for the year 1899 (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 26, pp. 8*).—A list of each.

VETERINARY SCIENCE AND PRACTICE.

Contribution to the study of immunity; properties of mixtures of toxins with their antitoxins; constitution of toxins, J. DANYSZ (*Ann. Inst. Pasteur, 13 (1899), No. 7, pp. 581–595*).—The results of the experiments recorded in this paper may be summarized as follows: The particular manner of the action of toxins as well as properties of the mixtures of a toxin and its antitoxin is not due to differentiation of the toxin into different substances more or less toxic, but simply to the presence of phosphates in these mixtures in greater or less proportions, depending upon the greater or less attenuation of the toxins. A single active substance can produce different results in different animals under different conditions, according to the variable proportions of the phosphates and other salts contained in the mixtures. This accounts for the difference in susceptibility in different animals to the action of the same toxin.

Combating disease-producing germs, C. E. MARSHALL (*Michigan Sta. Bul. 172, pp. 293–310*).—The author gives a general discussion of the relationship of infectious diseases to unsanitary conditions and accumulations of filth.

Among chemical substances which are good disinfectants, the author mentions the following: Corrosive sublimate, carbolic acid, formalin, sulphur fumes, whitewash, chlorid of lime, salicylic acid, and boracic acid. Directions are given for preparing proper solutions, liquid or gaseous, of these various substances for use in disinfection.

A number of methods for disinfecting houses, stables, utensils, and clothes are given.

For disinfecting creameries, no substance is entirely reliable unless the woodwork has been previously cleaned from all oily filth. The creamery may then be disinfected by means of formalin gas. Barns and stables are usually too open to allow the use of any fumigating disinfectant, and the author recommends spraying the woodwork with a solution of corrosive sublimate. When yards and pastures become infected with a contagious disease, the main reliance must be placed upon the action of direct sunlight. Animal excreta may be disinfected by the use of chlorid of lime, slack lime, or carbolic acid.

Texas fever, L. L. LEWIS (*Oklahoma Sta. Bul. 39, pp. 28, figs. 5*).—The author gives a general account of the protozoan germ which causes the disease and of the appearance and habits of the cattle tick which carries the germ.

A number of cattle-dipping experiments were tried in the summer of 1898. Two hundred and forty cattle were dipped under the supervision of the experiment station. The vats and chutes are described and figured in detail. The vat used had a capacity of about 1,500 cattle a day and cost $210. The object of these experiments was to secure an oil which would effectively destroy the ticks and not irritate the skin of the cattle. The cattle were dipped in oil from 40 to 42 in. deep. The ticks were all killed. When the cattle were allowed to go into the vat upon an incline, the legs were exposed longer to the action of the oil and the ticks were more effectively destroyed than when the cattle were plunged suddenly into the vat. By the former arrangement it is not considered necessary to fill the vats with a solid mass of oil. The first cattle dipped were dropped through from a trap door 2 ft. above the surface of the oil They were allowed to drip 10 minutes after leaving the vat. Within 2 hours after the dipping a number of animals showed signs of irritation about the eyes, but this irritation was not serious if the cattle were kept quiet and prevented from becoming dusty. Oil was found to be more severe on the Jerseys and light-colored animals than on dark ones.

A test was made to determine the effect on the skin and eyes, and changes in temperature from oil which came from the National Oil Company of Cleveland, Ohio. The oil had a specific gravity of 0.854 and contained no sulphur. Sulphur was added to the extent of 0.75 per cent. Only very slight elevations of temperature took place, and the temperature soon fell to the normal. The irritating effects upon the skin and eyes were much less noticeable than in the case of dynamo oil. The animals which were used in this experiment were not infested with ticks, but experiments conducted in the laboratory led the author to believe that this oil is as effective as the dynamo oil in the destruction of ticks.

A detailed tabular record is given of the results of experiments in producing immunity by means of inoculation of the defibrinated blood of animals which had partially or entirely recovered from the disease.

The number of animals experimented with was small, but the results were favorable.

Foot rot (*Rpt. Agr. Expts. Cornwall, 1898, pp. 50-51*).—Two objects were had in mind in making experiments with regard to this disease: To devise a practical remedy, and to determine whether or not the disease is indigenous to native soils. For curing the disease the following remedy was applied: Two pounds of arsenic and 2 lbs. of common soda were boiled in 1 gal. of water for half an hour. Five gallons of water were added to this solution and the whole was then placed in a long trough so that the depth of the solution was about the same as the depth of the hoof. Loose portions of the hoof were scraped off and the sheep were then made to walk through this trough. The treatment was repeated once a fortnight until a cure was affected. Two or three such treatments were usually sufficient for a permanent cure.

In order to determine whether or not this disease is indigenous to the soil, a tract of land which had the reputation of being favorable to the foot rot was selected. Sheep free from foot rot were then placed upon this tract and kept there for about 2 months. No cases of the disease developed.

The gapeworm and the white intestinal worms of poultry, F. V. THEOBALD (*Jour. Bd. Agr. [London], 6 (1899), No. 2, pp. 157-165, fig. 1*).—In this paper the author discusses the amount of loss caused by the gapeworm. This worm has been found in the sparrow, starling, rook, hooded crow, linnet, martin, swift, magpie, green woodpecker, and earthworm, in addition to domestic poultry. The earthworm has been believed by some authors to be a necessary intermediate host for the gapeworm, but, as has already been shown and as the author again demonstrated by experiments, the eggs of the gapeworm when fed to healthy poultry develop readily into adult gapeworms. The earthworm is therefore to be considered as one means of carrying the worms, rather than a regular intermediate host. The symptoms of the disease and post-mortem appearances are described in some detail.

On the subject of treatment, the author recommends immediate isolation of all birds which are infected with gapeworms in order to prevent further spread of the disease by coughing up adult worms. For the treatment of fowls suffering from the disease the use of a fumigating box is advised. This box should be large enough to hold several birds at once. Through a small opening finely-divided chalk mixed with finely-ground camphor should be blown. The dust mixture should be in proportion of 1 oz. of chalk to half an ounce of camphor. The dust is then inhaled by the fowls, the camphor causes the gapeworms to loosen their hold, and the dust induces violent coughing of the fowls, which is usually sufficient to eject the worms.

Report on the progress of dermatology in the field of pathology in 1898, E. KROMAYER (*Centbl. Allg. Path. u. Path. Anat., 10 (1899), No. 16-17, pp. 617-638*).—A discussion of the literature of the subject with a bibliography of 360 titles.

On preventive inoculation, W. M. HAFFKINE (*Proc. Roy. Soc. [London], 65 (1899), No. 418, pp. 252–271*).—A discussion of various general problems connected with the interpretation of the meaning of artificial immunity.

The possibility of the development of the typhus bacilli upon cooked potatoes in the presence of coli bacillus and ordinary soil bacteria, E. PFUHL (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 2–3, pp. 49–51*).—The author undertook these investigations during a typhus epidemic in order to determine whether typhus could be transmitted in cooked potatoes. Several experiments made with this purpose in view gave results which indicate that typhus bacilli live and multiply plentifully in the presence of coli bacillus and other bacteria such as are found in the ordinary soil of the garden.

Animal diseases, A. T. PETERS (*Nebraska Sta. Rpt. 1898, pp. XVII–XXV*).—The report gives a brief account of the author's work on the following diseases: Blackleg, calf cholera, cornstalk disease, ergotism, glanders, hog cholera, keratitis, rabies, Texas fever, and tuberculosis. Over 33,000 doses of blackleg vaccine were distributed in the State, the greater part of them being furnished by the Pasteur Vaccine Co., and Bureau of Animal Industry. Ergotism is said to have been unusually prevalent in the State during the past year.

Symptomatic anthrax of cattle transmitted to man, G. FALCONE (*Giorn. R. Soc. Accad. Naz. Vet. Ital., 48 (1899), No. 36, pp. 844–848*).—Man may become infected by eating the meat of animals suffering from this disease.

The morphology of actinomyces, H. BRUNS (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 1, pp. 11–17*).—From a case of actinomycosis in man the author obtained the pathogenic germ and made numerous cultures upon different media. From these pure cultures inoculations were then carried out on rabbits, mice, and guinea pigs. In no case was the author able to produce actinomycosis in the experiment animals and concludes, therefore, that the actinomyces in question is a species distinct from the actinomyces of cattle.

Anthrax, A. BERGSTRAND (*Landtmannen, 10 (1899), Nos. 32, pp. 522, 523; 33, pp. 538–540*).—A discussion of the nature of the disease with various practical suggestions as to methods for preventing infection of herds and for stamping out the disease

The agglutination of anthrax bacillus by normal human blood, LAMBOTTE and MARÉCHAL (*Ann. Inst. Pasteur, 13 (1899), No. 8, pp. 637–641*).—The author carried on investigations by means of which he found that the serum of normal human blood has the power of agglutinating the anthrax bacillus. The agglutinating power is manifested even in a very dilute solution of the serum; for example, 1:350. The blood of 41 persons was used in these experiments.

Some reflections upon the anthrax epidemics of West Gothland, W. FLACK (*Landtmannen, 10 (1899), No. 31, pp. 493–495*).—A brief article describing the extent of the ravages from this disease and recommendations of means for preventing its spread.

Report on the work of the agricultural bacteriological laboratory of the Department of Agriculture for 1898 (*Selsk. Khoz i. Lyesor., 194 (1899), July, pp. 23–54*).—This report covers investigations on the following topics: The biology and relationship of a rat-destroying bacillus; the pathological anatomy of mouse and rat diseases; the influence upon the virulence of mouse destroying bacteria of various saprophytes grown on the same culture medium; determination of the absolute virulence of various mouse-destroying bacteria; a comparative study of methods of sterilizing milk; field experiments in the destruction of susliks; the action of various mouse-destroying bacteria upon domestic animals; and the distribution of cultures to correspondents of the laboratory.

Experimental tuberculosis in the ass and the effect of tuberculin, S. STOCKMAN (*Jour. Comp Path and Ther., 12 (1899), No. 2, pp. 125–137, fig. 1*).—The article contains an account of cases of tuberculosis in an ass, mule, and horse. The author concludes with regard to the tuberculin test that the small quantity of tuberculin

which is ordinarily employed for the detection of tuberculosis is not sufficient in itself to account for the fever reaction. It is suggested that the hypodermic injection of the tuberculin causes a hemorrhagic condition in that particular spot and that as a result of this hyperemic condition some of the tubercle bacilli are killed and the substance which causes fever is set free from these dead bacilli. The author has injected from 10 to 30 cc. of tuberculin into a healthy dog without producing any fever reaction.

Congenital tuberculosis in the calf, J. McFADYEAN (*Jour. Comp. Path. and Ther., 12 (1899), No. 2, pp. 156–162*).—Three cases are recorded and outlined in some detail. The author discusses also the distribution of the tuberculous lesions in these calves.

On the transmission of the tubercle bacillus through the placenta, ANCHE and CHAMBRELENT (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 11 (1899), No. 4, pp. 521–545, pl. 1*).—The number of authentic cases of transmission of the tubercle bacillus by means of the placenta is very small. It has never been observed to take place before the fifth month of pregnancy. The tuberculous lesions are in such cases generalized and found in nearly all organs.

Some of the economic aspects of the prevention of tuberculosis in cattle, S. DELÉPINE (*Veterinarian, 72 (1899), No. 859, pp. 453–466*).—Discusses the necessity of fighting the disease and the cost of so doing, and adds statistics from experiments.

On the agglutination of the tubercle bacillus, MONGOUR and BUARD (*Compt. Rend. Soc. Biol., Paris, 11. ser., 1 (1899), No. 23, pp. 564, 565*).—The authors have observed that the agglutinating reaction takes place more rapidly and more clearly in a more resisting subject, and agglutination, therefore, appears to them to be a reaction of defense.

Action of microbes on the development of tubercle bacillus, F. RAMOND and P. RAVANT (*Arch. Med. Exper. et Anat. Path., Paris, 1. ser., 11 (1899), No. 4, pp. 494–497*).—The presence of other bacteria has in general the effect of stimulating the development of the tubercle bacillus.

Colic of horses, GRAF (*Ztschr. Veterinärk., 11 (1899), No. 7, pp. 342–356*).—Considers the following affections: Obstruction of the gullet and stomach, colic of the small and large intestines, cramp colic, and wind colic.

Vaccinations against contagious pneumonia of horses, C. TROESTER (*Ztschr. Veterinärk., 11 (1899), No. 7, pp. 356–364*).—Contains a discussion of the symptoms of the disease and reports on experiments for producing immunity by vaccination.

Ascending paralysis of the spinal cord in the horse, J. McCALVÉ (*Rec. Med. Vet. Paris, 8. ser., 6 (1899), No. 13, pp. 401–410, figs. 3*).—The series of symptoms takes the following order: Motor paralysis of the posterior legs, loss of sensibility in these parts; motor paralysis of the muscles of the trunk, loss of sensibility of this region; anæsthesia of the trunk, motor paralysis of the muscles of the front legs, and loss of sensibility of these parts. The author gives an account of the microscopic appearance of the spinal cord, with illustrations.

The treatment of acute laminitis with antifebrin, ST. FRIIS (*Maanedsskr. Dyrlæger, 11 (1899), No. 3, pp. 97–112*).—Gives details of numerous experiments in treating horses for this disease.

AGRICULTURAL ENGINEERING.

Irrigation engineering, L. G. CARPENTER (*Colorado Sta. Rpt. 1898, pp. 176–198*).—A brief summary is given of the work of this department of the station in the following lines: Water supply, duty of water, seepage measurements, losses from ditches and canals, and origin of seepage water.

In the study of water supply the record of the flow of the Poudre River has been continued (making a continuous record for 15 years) and rain guages have been put into the hands of observers stationed at different points in the watershed of this stream. The results of the observations on the flow of this stream have been published in local papers so that users of the water would be informed in advance of the rise or fall of the water in the stream. A table is given which shows the dates of high water during the last 15 years and the average flow for the week during which this maximum was reached. A table also shows the average flow from April 26 to November 1 during the same years. The latter shows fluctuations of from 451 cubic ft. in 1898 to 1,761 cubic ft. in 1884.

Observations on the level of water in a series of wells extending from the stream to the foothills beyond all irrigation ditches are reported.

A brief outline is given of a series of observations on duty of water which the station has undertaken at different points, and the plan and results of observations on seepage at a number of different places in the State are reported. The latter observations include measurements of seepage on the Poudre, Arkansas, Big Thompson, Little Thompson, and Rio Grande rivers and on the St. Vrain Creek. Observations on losses from ditches and canals mostly in the Arkansas Valley in continuation of those already given (E. S. R., 10, p. 795) are reported.

Irrigation in the Yakima Valley, J. SHOMAKER (*Irrig. Age, 13 (1899), No. 12, pp. 410-413*).

Irrigation, S. M. WOODBRIDGE (*South. California Acad. Sci., Agr. Exper. Sec. Bul. 7, pp. 9, figs. 5.*)—A description of methods of surface irrigation, subirrigation, and interirrigation as practiced in California.

Report of the Thebus irrigation commission, 1899 (*Cape Town: W. A. Richards & Sons, 1899, pp. 68, pls. 5, charts 9*).—This report deals with the feasibility of storing the water of Thebus River for irrigation purposes.

The water wheel, the evolution of the American type of water wheels (*Irrig. Age, 13 (1899), No. 12, pp. 416-420*).—Review of an article by W. W. Tyler in *Jour. Western Soc. Engineers, Apr., 1898.*

Artesian water in New South Wales, J. W. BOULTBEE (*Jour. and Proc. Roy. Soc. New South Wales, 32 (1898), pp. 88-103*).—Data on the number and flow of artesian wells.

The Kankakee marsh lands (*Drainage Jour., 21 (1899), No. 8, p. 201*).—A brief note on the proposed plan for draining some 500,000 acres of these lands.

Good roads for farmers, M. O. ELDRIDGE (*U. S. Dept. Agr., Farmers' Bul. 95, pp. 47, figs. 49*).—An attempt is made in this bulletin "to present in the plainest possible language the fundamental principles of road building and maintenance and to furnish instruction and advice to those whose facilities are limited and who are often supplied with but the natural materials." The topics discussed are principles which should govern location and treatment of roads—grades, drainage, water breaks, side ditches, subdrainage; different kinds of roads—earth roads, sand roads, roads of sawdust, tan bark, etc., corduroy roads, hard roads, gravel roads, shell roads, and stone roads; trees alongside of roads; and cost of roads.

Must the farmer pay for good roads? O. DORNER (*U. S. Dept. Agr., Office of Road Inquiry Circ. 31, pp. 40, figs. 43.*—This pamphlet, published by the League of American Wheelmen, and adopted as a circular of the Office of Road Inquiry of this Department, is intended to give a better understanding of the system of State aid to road building which has been in force in New Jersey for a number of years and has also been adopted in Connecticut, Pennsylvania, and New York, and is under consideration in Minnesota.

State aid to road building in Minnesota, A. B. CHOATE (*U. S. Dept. Agr., Office of Road Inquiry Circ. 32, pp. 12, figs. 5*).—By mistake this was originally issued as Circular 31 of the Office of Road Inquiry (E. S. R., 10, p. 896).

Road improvement in governors' messages, R. STONE (*U. S. Dept. Agr., Office of Road Inquiry Circ. 33, pp. 14*).—Extracts bearing on road improvement from messages of governors to the legislatures of Alabama, California, Connecticut, Delaware, Indiana, Kansas, Maryland, Missouri, New Hampshire, New York, North Carolina, Ohio, Oregon, Rhode Island, Vermont, and West Virginia.

STATISTICS—MISCELLANEOUS.

Eleventh Annual Report of Colorado Station, 1898 (*Colorado Sta. Rpt. 1898, pp. 99-235*).—This contains a financial statement for the fiscal year ending June 30, 1898; a report by the director on the station staff and the work of the station and substations during the year, including a subject list of station publications; and reports by the botanist and horticulturist, agriculturist, entomologist, chemist, meteorologist, and irrigation engineer, and the superintendents of the Rainbelt Substation at Cheyenne Wells and the Arkansas Valley Substation at Rockyford, parts of which are noted elsewhere.

Eleventh Annual Report of Georgia Station, 1898 (*Georgia Sta. Rpt. 1898, pp. 10*).—Organization list of the station; brief report on station equipment, work, and publications, and financial statement for the fiscal year ending June 30, 1898.

Eleventh Annual Report of Illinois Station, 1898 (*Illinois Sta. Rpt. 1898, pp. 16*).—The publications and principal lines of station work during the year, subject list of bulletins published since the organization of the station, financial statement for the fiscal year ending June 30, 1898, and the organization list of the station are given.

Eleventh Annual Report of Indiana Station, 1898 (*Indiana Sta. Rpt. 1898, pp. 22*).—This report covers the work of the station for the 6 months ending June 30, 1898, and includes the organization list of the station; brief reports by the director, agriculturist, horticulturist, chemist, botanist, and veterinarian, and a financial statement for the fiscal year ending June 30, 1898.

Tenth Annual Report of Kentucky Station, 1897 (*Kentucky Sta. Rpt. 1897, pp. XI + 131*).—This contains the organization list of the station; a financial report for the fiscal year ending June 30, 1897; reports by the director, chemist, entomologist and botanist, horticulturist, and meteorologist on the work during the year, and reprints of Bulletins 66-71 of the station on the following subjects: Tobacco (E. S. R., 8, pp. 976, 997), the San José scale in Kentucky (E. S. R., 9, p. 261), analyses of commercial fertilizers (E. S. R., 9, p. 338), wheat (E. S. R., 9, p. 639), the woolly mullein (*Verbascum phlomoides*) in Kentucky (E. S. R., 10, p. 359), the gape disease of poultry (E. S. R., 10, p. 393), and analyses of commercial fertilizers (E. S. R., 10, p. 337).

Annual Report of Minnesota Station, 1898 (*Minnesota Sta. Rpt. 1898, pp. XIX + 566*).—This includes the organization list of the station; list of bulletins published during the year; financial statement for the fiscal year ending June 30, 1898; report by the director outlining the results obtained in the different departments during the year; a meteorological record noted elsewhere, and reprints of Bulletins 53-59 of the station on the following subjects: Effects of the rotation of crops upon the humus content and the fertility of soils, production of humus from manures (E. S. R., 9, pp. 632, 611), human food investigations, the rational feeding of men (E. S. R., 9, p. 777), the Orthoptera of Minnesota (E. S. R., 10, p. 466), sugar beets (E. S. R., 10, p. 543), fattening lambs in winter (E. S. R., 10, p. 575), fattening steers in winter (E. S. R., 10, p. 671), and fattening lambs and wethers in winter (E. S. R., 11, p. 179).

Twelfth Annual Report of Nebraska Station, 1898 (*Nebraska Sta. Rpt. 1898, pp. 56*).—This includes a brief report on the staff, equipment, lines of experimentation, and publications of the station for the year; departmental reports, parts of which are noted elsewhere, setting forth the work of the various departments and giving results in some cases, and a financial report for the fiscal year ending June 30, 1898.

Eleventh Annual Report of Vermont Station, 1898 (*Vermont Sta. Rpt. 1898, pp. 125–404*).—This includes the organization list of the station; table of contents of the bulletins published during the year and of the report; financial statement for the fiscal year ending June 30, 1898; report by the director, briefly summarizing the results obtained in each department during the year; list of available publications, and abstracts of Bulletins 60–65 of the station on the following subjects: Insects of the year (E. S. R., 10, p. 459), hardy apples for cold climates (E. S. R., 10, p. 437), home-grown grapes in Vermont (E. S. R., 10, p. 440), and analyses of commercial fertilizers (E. S. R., 10, p. 623). The work of the departments of chemistry, botany, horticulture, apiculture, and dairy husbandry, as set forth in the different departmental reports, is noted elsewhere.

Proceedings of the twelfth annual convention of the Association of American Agricultural Colleges and Experiment Stations, A. C. TRUE, W. H. BEAL, and H. H. GOODELL (*U. S. Dept. Agr., Office of Experiment Stations Bul. 65, pp. 138*).—This gives the officers and committees of the Association, list of delegates and visitors in attendance, and the proceedings of the convention held at Washington, D. C., November 15–17, 1898, an account of which has already appeared (E. S. R., 10, p. 704).

Statistics of the land-grant colleges and agricultural experiment stations in the United States for the year ending June 30, 1898 (*U. S. Dept. Agr., Office of Experiment Stations Bul. 64, pp. 39*).—A summary of this has already appeared (E. S. R., 10, p. 1001).

Experiment Station Work—X (*U. S. Dept. Agr., Farmers' Bul. 97, pp. 32, figs. 5*).—This number contains articles on the following subjects: Manure from cows, plants for alkali soils, influence of alkali on plants, feeding value of the corn plant, sows and pigs at farrowing time, the soy bean as a feeding stuff, alfalfa hay for hogs, animal matter for poultry, water and animal diseases, construction and cooling of cheese-curing rooms, and irrigation investigations.

Suggestions to Southern farmers (*U. S. Dept. Agr., Farmers' Bul. 98, pp. 48*).—Summaries are given of 11 papers read at the Interstate Farmers' Convention held at Vicksburg, Miss., February 8–10, 1899, as follows: Mississippi soils and their capabilities, W. L. Hutchinson; The dairy cow as a restorer of fertility, T. L. Haecker; Cotton seed and its products, B. W. Kilgore; The relation of live-stock farming to home-making, V. C Meredith; Southern agriculture, Mississippi and Louisiana, W. C. Stubbs; Expansion in the farmer and the farmer in expansion, W. M. Beardshear; Horticulture, G. H. Van Houten; Agricultural education, W M. Liggett; Stock and how to feed them, W C. Welborn; The peculiar advantages of the South for growing forage crops and feeding stock, W. R. Dodson and The Weather Bureau and the farmer, W. L. Moore.

Report on the condition of winter grain on April 1, 1899, and the losses of farm animals during the year ending March 31, 1899, with statistics of foreign crops, J. HYDE (*U. S. Dept. Agr., Division of Statistics Rpt. [illegible] n. ser., pp. 38*).—During the year ending March 31, 1899, the total loss of farm [illegible]s in the United States from exposure and disease "was over 7,500,000 head, of which swine constituted 11.9 per cent, sheep 29.2 per cent, cattle 24.7 per cent, and horses 1.2 per cent. . . . On the basis of the average values, as ascertained on January 1 last, the estimated loss from exposure aggregated about $26,000,000, and that from disease about $49,000,000, or a total of $75,000,000, five-sixths of which may be said to be theoretically preventable."

Crop circulars for May, June, July, and August, 1899, J. HYDE (*U. S. Dept. Agr., Division of Statistics Crop Circs. May, June, July, and Aug., pp. 20*).—These contain the usual data relative to conditions of farm and orchard crops during these months, with summarized temperature and rainfall records for the same periods, and a discussion of the foreign crop situation.

NOTES.

Idaho Station.—The board of regents is at present constituted as follows: President, G. A. Roberthan, of Pocatello; vice-president, F. N. Gilbert, of Moscow: secretary, F. E. Cornwall, of Moscow; A. H. Alford, of Lewiston; J. B. Goode, of Cœur d'Alene; C. E. Harris, of Montpelier; J. E. Hickman, of Preston; and Mrs. Geo. Williams, of Hailey. Samuel Avery, Ph. D., formerly of the University of Nebraska, has succeeded C. W. McCurdy as chemist. A new farmhouse, a silo with a capacity of 75 tons of corn, and additions to the farm barns have been built. Considerable new fencing has also been built. The farm experiments with potatoes and fodder plants are now being conducted, and feeding experiments will soon be begun.

Maine Station.—The station has just completed, at a cost of about $3,500, an addition to the office and laboratory building, 22 by 28 ft. The basement will be used as a calorimeter room, the main floor as a food laboratory, and the second floor as the director's office and library.

Massachusetts Hatch Station.—H. T. Fernald, formerly professor of zoology in the Pennsylvania State College and State economic zoologist, has been appointed associate entomologist of this station.

New Mexico Station.—J. D. Tinsley has been given leave of absence for two months for the purpose of study in the Division of Soils in this Department. He has recently been assigned to work in soil physics and meteorology, instead of biology, as formerly. C. A. Keffer, agriculturist and horticulturist, has been elected horticulturist of the Tennessee college and station.

Ohio Station.—The board of control has been reorganized by the election of J. T. Robinson as president. J. W. T. Duvel, assistant botanist, resigned October 28 to accept a fellowship in chemical biology at the University of Michigan.

Oklahoma College and Station.—There has been a marked increase in attendance in the college, 259 students being enrolled. The total enrollment for last year was 219. The purchase of 3 Herefords and 3 Shorthorns has been made by the college. A ten weeks' course in agriculture, horticulture, and mechanics will be given during the winter term. The new building for the joint use of the departments of chemistry in the college and station is completed. The building is of brick, the college portion being 40 by 60 ft. and two stories, and the station portion a one-story and basement wing 30 by 50 ft.

Meeting of the American Pomological Society.—The twenty-sixth biennial session of the American Pomological Society, held at Philadelphia September 7 and 8, 1899, was distinguished by a large and enthusiastic attendance of representative horticulturists from all parts of the country. The number of accredited delegates present was about 150. A considerable number of experiment station horticulturists were present and read papers or took part in the discussions.

The meeting was presided over by C. L. Watrous, who, in his presidential address, called attention to the present needs of American pomology, urging, among other things, the necessity of carrying on fruit breeding as systematically as stock breeding, of being guided by isothermal rather than territorial lines in fruit planting, and of establishing a national herbarium of pomology as a check upon fraud.

Thomas Meehan spoke of Philadelphia's contribution to the history of pomology. The list of contributions includes the Seckel and Kieffer pears, and the Bartram, Alexander, and Maxatawney grapes, the last of which was the first good white grape of American origin.

J. H. Hale spoke upon the subject of Culture, stating that in a dry season the orchard should be cultivated twice a week until the fruit has developed.

L. O. Howard spoke of the present status of Smyrna fig culture in California, with special reference to the Blastophaga. The recent successful importation of the Blastophaga by this Department, in the speaker's opinion, renders Smyrna fig culture practicable in California.

Nomenclature and systematic pomology was the subject of a paper by F. A. Waugh, enumerating the rules formulated by the Cornell Lazy Club, already referred to in these pages (E. S. R., 10, p. 712), and discussed their application. The secretary read a paper by T. V. Munson on Revision and control of horticultural nomenclature, which advocated the enactment of legislation prohibiting the renaming of varieties or the publication of false descriptions of fruits. It was recommended that the supervision of pomological nomenclature be placed in charge of the Division of Pomology of this Department. The reading of these two papers gave rise to a discussion as to the methods of carrying out the suggestions, resulting in its reference to a committee.

W. R. Lazenby presented a paper on The origin and development of buds in certain fruit plants, in which the different kinds of fruit buds were distinguished and classified. J. C. Whitten spoke of the Relation of color to the growth of flower buds of the peach, referring to his experiments in the artificial whitening of trees to retard growth (E. S. R., 9, p. 835).

The first evening there were two stereopticon lectures, one by H. J. Webber on Systematic plant breeding, illustrating its possibilities by work with the orange, and the other by W. T. Swingle on Fruit culture in the Mediterranean countries

G. H. Powell presented a paper on the Importance of the plant individual in horticultural operations, in which a number of examples of individual variation were cited. The preeminent importance of aristocratic blood in fruit propagation was emphasized. For developing an aristocracy among trees pedigrees are essential. Pedigree plants differ from selected plants in that the genealogy of the latter has just begun.

W. M. Munson spoke of The blueberry, its past, present, and future, giving an account of the work with this plant at the Maine Station, and briefly reviewing other cultural experiments in this country.

American horticulture at Paris in 1900 was discussed in a paper by G. B. Brackett, which outlined the purposes and plans of the American exhibit.

J. W. Kerr spoke on The evils attendant on prevailing methods of marketing. The discussion that followed the reading of this paper brought out the point that methods of marketing fruit are changing and that many of the present evils will probably soon be remedied.

W. B. Alwood, in a paper on The technique of apple growing in Virginia, called attention to the peculiar adaptabilities of different soils of the State for apple culture. J. Craig spoke on Some results of the freeze of 1898-99 in Iowa, discussing root killing of fruit trees in the Northwest, and gave an account of experiments in cutting back trees injured by freezing and in banking trees after the freeze. G. L. Taber presented Some fruit notes from Florida, particularly on the damage done by the severe freeze of last winter to the orange orchards. H. E. Van Deman spoke of The relations of commercial fertilizers and soiling crops to fruit culture, and advocated the use of leguminous plants as sources of nitrogen for fruit crops.

In a paper on The breeding of fruits for the prairies C. G. Patten asserted that the problem of adapting fruits to the Northwest is almost exclusively one of breeding.

In addition to these papers the following were read by title and will be published in the proceedings of the society: Improvement of American grapes, S. A. Beach; Fruit evaporation, J. R. Caldwell; American plums for America, E. S. Goff; Horticultural schools of the high-school grade, S. B. Green; Orcharding in Montana, S. M. Emery; Fruit culture in the Hawaiian Islands, C. E. Hoskins; The future of commercial orcharding in the South, F. S. Earle; The Russian remedy for root killing of apple trees, N. E. Hansen, and Quality as a factor in apple culture, C. W. Garfield.

The report of the committee on revision of catalogue was read by the chairman, W. H. Ragan. It was suggested that the plan of catalogue revision be broadened by sending out a special form of inquiry concerning the behavior of fruits and ascertaining their ratings by a large number of practical fruit growers instead of by a comparatively limited number, as at present.

F. M. Hexamer, as chairman of the committee on new native fruit, reported upon the most promising varieties of apples, peaches, grapes, strawberries, and black raspberries.

The report of the committee on the awards of medals was presented by the chairman, F. M. Hexamer. Silver medals were awarded to the New Jersey State Horticultural Society, to Ellwanger & Barry, to the Arkansas Experiment Station, to the Michigan Substation at South Haven, to the Pomona nurseries, to Roland Morrill, and to John Charlton. Three bronze medals were also awarded, and honorable mention given to eleven exhibitors.

The officers elected for the ensuing year were: President, Charles L. Watrous, Des Moines, Iowa; first vice-president, Thomas Meehan, Germantown, Pa.; secretary, W. A. Taylor, Washington, D. C.; treasurer, L. R. Taft, Agricultural College, Mich.

EXPERIMENT STATION RECORD.

VOL. XI. No. 5.

The object and purpose of the experiment stations, and the best means of realizing them, has been a frequent subject of discussion ever since the passage of the Hatch Act. While it is generally recognized that the stations are primarily for investigation and not for elementary instruction, the popularity of compiled bulletins, institute work, reading courses, and other forms of general instruction has more than once threatened to carry a station off its feet and swamp its work of investigation. An instance of a tendency to give considerable prominence to these features is found in a recent statement by a station officer of long standing. In discussing the means of bringing the station work nearer to the farmers and gardeners of the State, he strongly advocates the popular bulletin, and an extensive correspondence with the farmers, encouraging them "to write to the station on every problem that they meet," these letters to be answered "promptly and as fully as possible," and where feasible published in weekly press bulletins.

He believes the building up of a large general correspondence to be the most successful way in which the stations everywhere can get closer to their constituents, and while he admits that this will involve a large amount of labor on the part of station officers, he holds that "that is what we are here for, largely." He is convinced that "more direct good is done to the farmer by those who stand in the gap and translate the results of the scientist into the language of the farm, than is done by those who content themselves with the investigations of the matters under study and confine themselves to tabulated bulletins of a scientific character, which the farmer does not read." As a further means of carrying out this conception of the station, "the organization of reading clubs under the direction of the station officers," farmers' institute work and an extension of this to "work at teachers' institutes in the line of nature studies" and "the issuing of leaflets of an instructive character," are advocated. Evidently the writer realizes that this programme will make serious inroads on the time which the average station worker has at his disposal after attending to his duties as a college professor, for he concludes with an expression of hope that he may "see the time when the station officers will be engaged solely in station work and its extension to the tillers of the soil and the teachers of our schools," and believes that then "the college can get students better fitted for the taking up of scientific work and more enthusiastic in the study of nature and her problems."

It is interesting to note that the writer concludes an enumeration of the lines of work which he has in progress with the hope that in the future his division "may be able to show some results from investigation, as well as to publish information bulletins of a popular character."

The presidential address of Dr. H. P. Armsby before the recent convention of the Association of American Agricultural Colleges and Experiment Stations bears directly upon this subject, and states it from a different point of view. As he looks at it, "the function of the experiment station is not the impossible task of giving him [the farmer] recipes suited to every conceivable emergency. Its business is to enlarge his knowledge of the natural forces which drive his farm, as the steam drives the engine, and to teach him to control them instead of being controlled by them. It is not a device to save the farmer the trouble of thinking. On the contrary, its constant and insistent demand is that he think more. It can help him permanently and effectively only to the extent to which he can by such thinking digest and assimilate its help."

Dr. Armsby conceived the experiment station to be fundamentally and in its broadest sense an educational institution—not designed to do the work of the agricultural college, the farmers' institute, reading and correspondence courses, or the agricultural press, but rather the "fountain from which shall flow the stream of knowledge and inspiration which shall fructify and vivify this vast system." The nature of its educational work was held to be essentially higher than that of the agricultural college—the education which comes from and through research; and he believed that any large amount of elementary undergraduate instruction was incompatible with the most efficient station work. "The experiment station, in method and spirit, is the agricultural university, the school of the specialist, the teacher of the teachers, the head and crown of the whole system. If this be true, how unwise from an educational standpoint to hamper and dwarf it by requiring work of a lower grade. . . . Still less does the work of primary and secondary education belong to it. It is not its function to distribute general agricultural information through its bulletins and reports. It is not called upon to aid directly in the introduction of nature studies into the schools nor in the conduct of correspondence courses, nor to systematically attend farmers' institutes, nor, except incidentally, to act as a bureau of information. . . . It is an unfortunate and mischievous confusion of ideas which looks upon these [various means for bringing the results of science to the people] and even officially designates them in station publications and State laws as experiment-station work. The ideas of the general public regarding the work of the stations are hazy enough at best. Let us not add to their confusion. All these things are things of the utmost, perhaps of paramount, immediate importance, but they are not *station* work. They are all forms of teaching, and teaching is the business of the school, and not of the station. The central idea of the station is research—the discovery and promulgation of new truth."

These statements were made with a full appreciation of the popularity and the utility of extended correspondence with farmers, of popular compiled bulletins, institute work, etc., and with a realization of the urgent need for general instruction in the elementary principles of agriculture. But the very fact that the station is the source from which the supply of new knowledge is derived makes it imperative that it should be allowed to specialize and devote itself mainly to the acquisition of knowledge, which will be expounded and diffused and given practical application by agricultural instructors, institute workers, writers, and other means. "When we dry up the springs among the hills, the mills along the river will sooner or later cease to grind. It is in the educational function of the station that we find the true reason for holding strictly to the historical conception embodied in section 2 of the Hatch Act, and when we defend this conception against those who would make of the station a school or a tract society, we are defending the highest interests of the farmers themselves."

The difficulty which many people seem to have in determining the proper functions of the experiment station grows in large measure out of the complex organization of our stations and their intimate relations with the agricultural colleges. The error is often made of giving undue prominence to the direct and immediate benefit which the station may confer upon the farmer through advice and instruction, without realizing that experimentation must precede this popular education and must be relied upon as the fundamental means of advancing agriculture. The various means employed for diffusing popular agricultural information are assuredly useful and worthy in their place, and no doubt abundant appreciation is shown for the efforts to give immediate aid to the farmer through popular bulletins, extensive correspondence, newspaper articles, etc. The farmers need such instruction and the States would do well to provide it for them through the agricultural colleges or boards of agriculture. In fact, we believe that those agricultural colleges which find it a difficult matter to secure students in their regular courses would do well to exert themselves strenuously in endeavors to reach the farmers through different forms of university extension. We also hold that it is the duty of experiment station officers to present such accounts of their work as are intended for the farmers' use in the most attractive and readable form. Necessarily the records of elaborate investigations will often be tedious reading for all except specialists. The wise station will not overload its bulletins for farmers with such details.

But, on the other hand, we believe more firmly than ever that those station officers who are charmed with the popular applause which follows the publication of compiled information are in great danger of suffering loss of professional standing through diversion from their work as investigators, and of so weakening the stations whom they serve that in a comparatively brief time they will lose the respect and confidence of the farmers. We believe that an impartial appeal to the record would show cases in which the progressive work of station officers had been materially reduced in amount and quality because of their increasing engrossment in various educational enterprises. We are sure, also, that it is those stations which have most closely adhered to the fundamental conception that they are institutions for research, which have attained the greatest measure of success in the eyes of practical men. For, after all, thorough work tells, and the farmers can discern superficiality as well as any other men. To them it is obvious that an experiment station is established to experiment, and as soon as the genuine experimental work produced by any station diminishes materially in amount and quality all the clamor raised by an outpouring of letters, lectures, and press notices will not serve to hide from them the fact that that station has degenerated.

With so large and important a field as our experiment stations have to fill in the performance of their legitimate service, it is hard to see why they should think of abandoning it to do the work which other institutions are especially created to perform. Never has there been so great a demand on the part of practical men for definite solutions for agricultural problems which can only be obtained by thorough original investigations, and whenever success attends such investigations the appreciation of the public is shown in a decided and substantial manner. Investigators have therefore great encouragement to persist in their researches, and can well afford to let those who prefer to diffuse information rather than increase knowledge go their way and to rejoice with them in whatever success may attend their labors.

THIRTEENTH ANNUAL CONVENTION OF THE ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

E. W. ALLEN,
Office of Experiment Stations.

For the second time in the history of the Association the meeting of 1899 was held in the far West, affording an opportunity for the delegates from the East to study the agricultural conditions and problems of the western States, and making it possible for an unusually large number of delegates from institutions west of the Mississippi to attend. The convention met in San Francisco, California, July 5–7, in conjunction with the Association of Official Agricultural Chemists (see p. 204). Delegates and visitors were present from 34 States and Territories, representing about 60 institutions.

Advantage was taken of the reduced railroad fare to California secured by the meeting of the National Educational Association at Los Angeles, and a large number of the delegates from the East met at Chicago and journeyed across the continent together in cars chartered for the party. The magnificent hospitality and the many courtesies extended to the delegates and their friends by individuals and representatives of various organizations, and the opportunity furnished by the week of excursions to view the different agricultural features of the State, made the convention a notable one in the history of the Association.

GENERAL SESSIONS.

The general sessions were held in the assembly hall of the Academy of Science, and the section meetings in the parlors of the Occidental Hotel and in rooms in the Mills Building, near by. H. P. Armsby, director of the Pennsylvania Experiment Station, presided over the general sessions and delivered the presidential address. This was a scholarly presentation of the experiment station ideal. The speaker conceived the experiment station to be primarily and in its broadest sense an educational institution—not an institution to furnish the farmer with recipes for his work, but to enlarge his knowledge of the principles and to strengthen his ability to intelligently apply them in practice. Ideally the station should be the source of knowledge and inspiration for the agricultural college—the capstone of agricultural education. Being an institution for higher education in agriculture, it should be divorced as fully as possible from the routine of elementary instruction, which was regarded as a dissipation of the energy of the station investigator. He made it very plain that the station is for investigation rather than for popular education, and insisted that this should be the central idea, whatever else the stations do. In conformity with this ideal, the qualifications of station workers and of the director were considered. The "director who inspires" was regarded as the ideal rather than the "director who directs."

A telegram of greeting was received from the Secretary of Agriculture.

Resolutions of sympathy were adopted for E. W. Hilgard, director of the California Station, who was prevented by illness from attending the convention which he had urged so cordially to meet in San Francisco.

The report of the executive committee was read by H. H. Goodell. It suggested a plan for making the work of the sections of the Association more effective by limiting the number of topics, discussing methods rather than the results of work, especially such results as have already been published in bulletins or annual reports, and selecting such subjects as will open up a field for investigation. The subject of military detail to land-grant colleges had received the attention of the committee, but without satisfactory outcome. Following the death of Senator Morrill the committee invited M. H. Buckham to prepare resolutions in memory of the late Senator, and G. W. Atherton to prepare an address on his life and services, and recommended the observance by the colleges of April 14, 1899, as Morrill day. The bust of Senator Morrill belonging to the Association had been tendered to the Library Committee of Congress, with the suggestion that it be placed in the Congressional Library. The work of various special committees appointed at the last convention was briefly reviewed; and reference was made to the Free Homestead Bill and its possible effect on the funds of the land-grant colleges.

The report of the treasurer was presented, showing a balance of over $1,000 in the treasury.

The report of the chairman of the section on agriculture and chemistry was read by J. L. Hills. He reviewed the experimental work which had been in progress during the year, and discussed the effect of the inspection work on the research work of the stations. He pointed out the dangers from this police work where suitable provision for its execution is not made, and suggested that by organization, deputization, and employment of special assistants, the interference of this inspection work with the regular research work of the station could be minimized.

The report from the section on mechanic arts was presented by C. S. Murkland, who touched upon the proposed legislation for the establishment of engineering experiment stations, and pointed out that the experimental work in mechanic arts was largely being carried on with the assistance of students rather than by special investigators. He gave some illustrations of the work in progress in this line, and brought out the value of work in mechanic arts for developing force in the student.

The report from the section on horticulture and botany was read by L. H. Pammel. He discussed the required work in botany in the colleges, and advocated greater uniformity in this respect. He gave statistics of the number of students and the special lines of botanical work which they pursue. The importance of giving more attention to instruction in physiological botany was emphasized. The collections of the horticultural and botanical departments were discussed, showing that few institutions have garden herbaria. In conclusion the lines of station work in horticulture and botany were enumerated.

The report for the section on entomology was read by C. W. Woodworth, who discussed the inspection work, especially for the San José scale, and gave a survey of the work of investigation and teaching done by the entomologists.

No report was presented from the section on college work.

Elwood Mead announced the meeting of the National Irrigation Congress at Missoula, Mont., in September, and urged the importance of the stations in the irrigated region participating in this congress.

The report of the bibliographer was presented by A. C. True, who also made a brief report for the committee on indexing agricultural literature.

H. P. Armsby presented a report on the station exhibit at the Paris Exposition, giving an outline of the general plan of the exhibit and the material promised by the stations.

By appointment, M. H. Buckham pronounced a graceful and discriminating eulogy on the late Senator Justin S. Morrill, and introduced memorial resolutions. In discussing the Morrill Act the speaker showed that the intention of its author was to provide an education that should be first liberal and then practical, as adapted to the needs of the industrial classes. His central idea was to liberalize the industries and lift them to the plane hitherto occupied alone by the professions, an idea which the speaker held to be unique, and the crystallization of which he declared to be one of the great epoch-making acts of the American Nation. The resolutions were seconded by J. K. Patterson in an eloquent tribute to the greatness of Senator Morrill, and were unanimously adopted by a rising vote of the convention.

The fourth report of the committee on methods of teaching agriculture was read by A. C. True, secretary of the committee. This report presented a syllabus of a course in zootechny, which was limited to the theory and practice of the production of the normal useful animal. Zootechny was divided by the committee into three main branches, (1) types and breeds of useful animals, (2) feeding, and (3) hygiene and management. An interesting discussion followed this report, in which some of the difficulties in separating instruction in technical agriculture from that in agricultural chemistry, economic botany, soil physics, and other related sciences were pointed out. The committee was continued.

Two papers were presented from the section on horticulture and botany. The first was by E. J. Wickson, on Climatology and horticulture. It was pointed out that while the botanists have studied the effect of various factors on plant growth, the horticulturists have done almost nothing to determine the relation between climate and horticulture. Some of the unexplained relations of environment to quality of fruit, development of color, and flavor of fruits under different environment and at different elevations were enumerated. These matters are frequently very important and were believed to afford a profitable field for research. Systematic investigation, it was thought, might assist in clearing up the vague condition of knowledge in this direction.

The other paper from this section was on Methods of seed testing and their relation to the farm and garden, by A. J. Pieters. The author spoke of the prevalence and evils of seed adulteration, resulting not only in diminished crops but in the introduction of injurious weeds. He showed by some actual examples the material financial loss from buying cheap seeds, and urged that experiment stations could do much to arouse an interest in and intelligent understanding of the subject. He believed that guaranteed seed would be put upon the market by seedsmen as soon as there was a demand for it. He described some of the simple methods of seed testing and their use by the small grower and the farmer.

Two papers were also presented from the section on college work. The first was by W. M. Liggett, on Agricultural education, practical and scientific. In this paper he described particularly the course of study at the Minnesota School of Agriculture, and mentioned the work which that institution is doing. The other paper treated of The principles underlying the formation of an agricultural course in the South, and was by C. E. Coates. The course in agriculture at the Louisiana State University was outlined, and the increasing success in securing students for the agricultural course was referred to. The ideas which have governed in elaborating this course and the principles which have been kept in mind in its formation were enumerated.

W. A. Withers presented an encouraging report from the committee appointed to attend the Second National Pure Food and Drug Congress, indicating that the outlook for legislation in the near future is hopeful.

No report was presented by the committee on graduate study, but A. C. True explained a plan for such study in the Department of Agriculture (E. S. R., 11, p. 1). This committee was continued, and J. E. Stubbs and A. C. True were appointed to fill the vacancies caused by the resignation of G. E. MacLean and Alston Ellis, who have severed their connection with the Association.

There was a quite general discussion of the subject of cooperation between the experiment stations and the divisions of this Department. Attention was called to the increasing amount of cooperation in recent years, and to the fact that Congress is recognizing the opportunity which the stations afford for extending the investigations of the National Department. As the work of the stations becomes more specialized and they take hold of the larger agricultural problems affecting whole regions of the country, there is greater interest manifested in arranging for cooperation with the Department and in securing funds from Congress for this purpose. In view of the increasing importance of the subject, it was suggested that the arrangements for cooperation between the Department and the stations would naturally assume a more formal character, and a committee of five was appointed to consider the basis and methods of such cooperation and report at the next meeting. The committee consists of E. A. Bryan, H. H. Goodell, W. A. Henry, H. J. Waters, and L. G. Carpenter.

A proposition from the section on mechanic arts, relative to the publication of abstracts of its papers, developed considerable discussion on the practicability of publishing in full or in abstract all the papers presented before the various sections. There was a feeling among a considerable number that all papers should be published, and that the assurance of publication would tend to improve the character of the papers presented.

A resolution was adopted to the effect that "this Association petition Congress that such measures be taken as shall secure the delivery of the public documents [of executive departments] to depository libraries at the earliest practicable moment, and that the executive committee be instructed to bring the matter to the attention of the proper committees of the two Houses."

The executive committee was instructed to secure a place upon the programme of the National Educational Association of 1900, for the presentation of a paper on the scope and mission of the land-grant colleges in our American system of education.

A committee, consisting of J. E. Stubbs, M. H. Buckham, J. K. Patterson, W. A. Henry, and H. H. Goodell, was appointed to consider the revision of the constitution of the Association and report at the next convention, the appointment of the committee being accepted by the Association as due notice of any changes the committee may recommend.

At one of the evening sessions A. G. McAdie, the local weather observer at San Francisco, gave an interesting address, illustrated with stereopticon views, on the climate of California.

Following the afternoon sessions on the last day of the convention, a reception was given the members of the Association by the State Floral Association of California in the parlors of the Occidental Hotel. A beautiful display of flowers was exhibited, some of the varieties or crosses representing the latest achievement of the originators.

An invitation was extended to the Association to hold its next meeting at New Haven or Middletown, Conn., next year marking the twenty-fifth anniversary of the establishment of the first experiment station in this country. Invitations were also read from the people of Jacksonville, Fla., and Saratoga Springs and Niagara Falls, N. Y. The matter was referred to the executive committee.

The officers elected for the ensuing year are as follows:

President, J. E. Stubbs, of Nevada; vice-presidents, E. W. Hilgard of California, J. M. Stone of Mississippi, E. E. Smiley of Wyoming, M. H. Buckham of Vermont, and M. A. Scovell of Kentucky; secretary and treasurer, E. B. Voorhees, of New Jersey; executive committee, H. H. Goodell of Massachusetts, W. M. Liggett of Minnesota, J. H. Washburn of Rhode Island, and Alexis Cope of Ohio; bibliographer, A. C. True, of Washington, D. C.

Section on college work.—Chairman, J. K. Patterson, of Kentucky; secretary, A. W. Harris, of Maine.

Section on agriculture and chemistry.—Chairman, L. G. Carpenter, of Colorado; secretary, C. D. Woods, of Maine.

Section on horticulture and botany.—Chairman, S. A. Beach, of New York; secretary, P. H. Rolfs, of South Carolina.

Section on entomology.—Chairman, H. Garman, of Kentucky; secretary, W. G. Johnson, of Maryland.

Section on mechanic arts.—Chairman, C. S. Murkland, of New Hampshire; secretary, F. P. Anderson, of Kentucky.

MEETINGS OF SECTIONS.

SECTION ON AGRICULTURE AND CHEMISTRY.

In this section three topics were selected which are of prime importance in the West, namely, alkali soils, irrigation, and range feeding of cattle. One session was devoted to each topic, and the papers and discussion were confined to the topic under consideration.

R. H. Loughridge discussed the alkali soils of the Pacific Coast and their utilization. He gave a clear disquisition on the general subject of alkali, and brought out the distinction between black and white alkali, which he recommended should be made in speaking of alkali. A third form, saline alkali, is found in southern California. He discussed the variation in the composition of alkali, and its effects upon soil and vegetation; and described the alkali regions of California, illustrating this by a map. The reclamation of black alkali land by the use of gypsum, as proposed by the California Station, was referred to. This has been successfully carried out at the substation at Tulare, Cal., wheat now being grown where formerly there was no vegetation except something like the saltbush; and large farms in central California have also been reclaimed by gypsum. "The rapidity of action of the gypsum is surprising. Experiments made in our laboratory show that where the gypsum is in sufficient amounts, and moisture is present, the change is within 24 hours. Whether it would be as quick as that upon lands I am unable to say, but in laboratory experiments the change was very rapid." The study of the vegetation on alkali lands, which is one of the features of the alkali work of the California Station, was thought to promise excellent results.

In a paper on Recent investigations by the Wyoming Experiment Station in alkali and irrigation, B. C. Buffum discussed the alkali soils of Wyoming, and reported upon the work which the station has done on the effects of the different alkali salts on seed germination and plant growth. He discussed the action of alkali, and the relation between the amount of moisture and this action, showing the connection between alkali studies and irrigation investigations in an alkali country. He showed by means of charts that alkali has a stimulating effect on the germination of seeds and on the subsequent growth, when the alkali salts, especially sodium carbonate, are not too high. He pointed out the relation which had been found between the absorption of alkali water by seeds, and osmotic pressure; and showed that the effect of alkali on germination of seeds is a physical and not a physiological one. In general, the number of seeds germinated at a given date was found to be inversely proportional to the osmotic pressure of the alkali solutions in which they were placed. The remedies for alkali soils were reviewed, such as leaching out the salts, preventing the accumulation of salts by controlling the evaporation, and growing useful plants which take it up. The possibility of the adaptation of plants to alkali soils was suggested.

A. Goss, of New Mexico, discussed the alkali soils of that Territory. In the Rio Grande Valley the water contains gypsum which would change any black alkali that might be present in the soil to white alkali. Hence only white alkali is found. Black alkali is found over restricted areas in New Mexico, notably in the Animas Valley. He described the "chico spots," containing considerable amounts of carbonate of soda, on which seeds will not germinate. The origin of these spots is attributed to the chico bush,[1] which accumulates the carbonate of soda near the surface. The speaker also discussed the plant food furnished by alkali, notably potash. Studies of the water of the Rio Grande have shown that irrigation furnishes the soil with more potash than an ordinary crop will remove.

F. W. Traphagen, of Montana, discussed the alkali of that State. The source of alkali in Montana is traced mainly to the marine shales. As a result of overirrigation the alkali rises and accumulates near the surface. This was illustrated by the results of experiments; in some cases 64 per cent of the alkali in the first 9 ft. of soil was concentrated in the first 2 ft. of soil by overirrigation. The value of washing as a means of removing alkali was shown by the amount of alkali which is being removed by the Yellowstone River, observations for 12 days showing an average of 400 tons per day. Data were presented to show the value of alfalfa as a preventive of alkali. "This crop has a remarkable power to prevent the rise of the alkali, and would seem to slowly remove it, for the very heavy crops, containing a considerable amount of mineral matter, a large portion of which is alkali salts, must remove very large quantities of alkali in the aggregate. My observations have caused me to believe that if a stand of alfalfa can be secured, and the water table kept low enough for all fields where such conditions prevail, the alkali problem is solved."

---

[1] Greasewood (*Sarcobatus vermiculatus*).

Other speakers brought out the value of alkali as a fertilizer, and for holding the water and retaining the soil moisture. With the rise of alkali, it was stated, there has been a rise of the ground water.

The discussion of the subject of irrigation was opened by L. G. Carpenter in a paper on Some of the general features of the problem of irrigation in the West. He discussed the question of water rights, and the difficulty of adjusting these matters equitably. He showed by charts the economy and waste in the use of irrigation water in practice on different farms. The amount of water used was said to be governed largely by the water supply rather than by the actual needs of the crop. "A comparatively small proportion, in many cases at least, is applied usefully; that is, to such a degree that the plant can use it and does use it in its growth. Much more passes away into the soil or air by evaporation from the soil." From a theoretical point of view, irrigation resolves itself into a question of soil moisture and its conservation. The fertilizing value of irrigation waters was referred to; and the effect of the temperature of the water on the temperature of the soil to which it is applied, and hence in controlling the growth of the plant under irrigation, was noted as a very important feature.

A. C. True and Elwood Mead spoke of the work which the Department of Agriculture has undertaken in irrigation investigations.

E. J. Wickson read a paper entitled Notes on irrigation of deciduous fruits, which embodied some of the more prominent facts learned from practice in the use of water for orchard fruits. He showed the advantages of irrigation, not only in the greater health, vigor, and productiveness of trees, but also in the appearance and quality of the fruit. He refuted the claim of some horticulturists that better fruit can be grown without irrigation. He maintained that "it is impossible to set up arbitrarily any exact standard of the moisture requirements of plants in terms of rainfall." The signs of need of irrigation, and the proper use of water to control growth and remedy unthrifty condition of trees were noted.

Other speakers called attention to the depletion of many of the western soils in humus, and the relation of humus to the retention of water. They advocated keeping up the humus by growing leguminous crops in place of summer fallow. A search for forage crops which are able to grow with a minimum amount of water was suggested as extremely desirable for semiarid regions.

Upon the third subject, Range feeding of cattle, a short paper by W. W. Cooke was read. C. D. Smith spoke on the Possibilities of developing high-class dairy cows from grade stock of the range type. He gave the results of experiments at the Michigan Station with good grade cows selected in the State and in the West. The results were held to show that feeding and care are very important factors and may do much to overcome the effects of type. "After all, one of the main questions in the dairy business is the careful, judicious feeding of the cows, and not primarily alone the selection of cows of a high type. I therefore say that among other possibilities of the Shorthorn and other cows of the range type comes a possibility of high production along dairy lines. No man can make of a [poor] cow a high-type dairy animal, but a good feeder may take the average range cow and expect to develop from that in a single year a herd of cows averaging 300 lbs. of butter." This paper developed considerable discussion, and it was contended that the statements regarding "range" cows should be qualified so as to exclude certain classes of range animals.

H. T. French presented the subject of Finishing range cattle in the stall. He referred to the changed conditions in the Northwest regarding the management of range cattle since the extensive introduction of sheep on the range. While formerly cattle could be finished on the range almost the year round, "now there are only a few months on that range that cattle are considered finished for the butcher." As a remedy, the growing of grasses, alfalfa, and clovers on which steers can be finished in the field, and stall feeding were suggested. Stall feeding of range steers unaccustomed to being handled was regarded as entirely practicable, and it was stated that steers so treated do well and take on fat very rapidly. Experiments by the speaker at the Oregon Station were cited in proof of this. The value of wheat, barley, and oats for fattening steers where corn can not be grown was discussed. It was believed that in the West these materials might be economically used.

H. P. Armsby gave a résumé of The present status of knowledge concerning the available energy of feeding stuffs. The available energy, or, as he preferred to call it, the net energy, is equivalent to the difference between the gross energy of the food and that of the excretory products. The calculation of energy from the digestible food materials was discussed, and the conclusion was reached that we have not yet progressed far enough to formulate feeding standards in terms of energy.

A paper entitled Notes on a preliminary catalogue of plants poisonous to stock was read by V. K. Chesnut. This paper developed considerable interest, as the subject is one of importance in range feeding and is receiving attention at several of the western stations.

SECTION ON HORTICULTURE AND BOTANY.

One of the chief horticultural features of the California meeting was a visit of the horticulturists, by special invitation, to the nurseries and gardens of Luther Burbank at Santa Rosa and Sebastopol. A most interesting day was spent with this famous originator in inspecting his work and studying his methods. To allow time for this visit only two sessions of the section were held, and as a result a number of the papers were read by title. Two of the papers of this section, by E. J. Wickson and A. J. Pieters, were read in general session (see p. 408).

An interesting discussion was aroused by a paper read before the section on Inspection of nursery stock and orchards, by Alexander Craw, quarantine officer of the California State Board of Horticulture. A historical review was given of the situation in the State of California as to insect pests, their spread and control; followed by a description of the present conditions, and the methods of inspection and fumigation followed. "Riverside, San Bernardino, and some other counties have a very complete system of orchard inspection and use printed charts, with the rows and cross rows of trees blocked out and numbered thereon. When a tree is found infested with a pest a designating mark is placed on it and at the intersection of the chart corresponding to where the tree stands. After the orchard is inspected the chart is turned over to the foreman of the fumigating crew and the infested trees can be readily located and treated. Orchards are fumigated after sundown, as the gas is more effective; so this work is done during the night. All fumigating should be performed then or in a shaded place. In districts where infection is more general the entire orchard is fumigated." The inspection of nursery stock brought into the State from other countries was described as very rigid. "I frequently notice trees in cases for the East infested with that serious and difficult to destroy scale, *Diaspis amygdali.* When this scale is found on stock for California it means the destruction of the plants or trees, as we never give it any quarters. In the case of the eastern trees, we can not stop them, as we operate under a State law, unless the trees and plants are infested with insects of such a character that they would endanger the State in passing through."

B. M. Lelong described the method of destroying injurious insects by insect parasites, the climate being too dry for the development of fungus parasites. A serious melon and cucumber pest was reported, the larvæ of which were found in much imported fruit of these plants. He believed there was practically no danger from fruit shipments from infested orchards, as the covering of the fruit is so soon destroyed.

A. J. McClatchie read a paper on Irrigation methods in orchards. He considered the subject under the three heads of (1) methods of applying the water, (2) amount of water, and (3) time of applying. Experiments made by the author at Phenix, Ariz., in irrigating a peach and apricot orchard in winter were reported, the object being to ascertain in how far this might replace the customary frequent irrigation in summer, when water is less abundant and evaporation greatest. Deep saturation in the winter gave satisfactory results, water settling to a depth of 25 ft., while in summer irrigation it reached only 3 or 4 ft.

below the surface. Roots of the trees were found abundantly 14 to 16 ft. below the surface, "showing that the water of at least the upper 20 ft. was available to the trees."

On invitation, N. A. Cobb, of the Department of Agriculture of New South Wales, gave an interesting talk on his work in that country.

The following papers were read by title: Making a garden herbarium and its uses, by A. D. Selby; The making of a horticultural herbarium, by J. Burtt Davy; Laboratory work for winter instruction in horticulture, by E. S. Goff; Horticultural field work for classes, by A. B. McKay.

SECTION ON MECHANIC ARTS.

Most of the papers presented before this section dealt with the subject of courses, methods of instruction, and laboratory work. The practical importance of industrials was the subject of a paper by W. F. Gilkison, which brought out considerable discussion. The author advocated abolishing the present exercise system in shopwork and substituting in its place the making of articles or appliances of some use.

A paper by C. L. Cory, on The electrical engineering laboratory in its relation to local engineering work, was a suggestive one and led to considerable discussion.

J. T. Faig read a paper on The teaching of machine drawing, and G. Gwinner treated the general subject of Teaching methods.

Some objections to early differentiation of engineering courses were presented by J. C. Nagle in a paper bearing that title.

W. T. Magruder introduced The agricultural engineer—the latest developed specialist.

SECTION ON COLLEGE WORK.

Neither the chairman nor the secretary of this section was present. The papers by C. E. Coates on The principles underlying the formation of an agricultural course in the South, and by W. M. Liggett on Agricultural education, practical and scientific, which were noted above as having been read in the general session of the convention, were presented before this section. In addition W. J. Spillman discussed the subject of The short dairy course, and J. H. Raymond, University extension in agriculture.

EXCURSIONS.

The day following the adjournment of the convention (Saturday) was occupied in a trip to Golden Gate Park and the Cliff House in the forenoon, and to the experiment station at Berkeley in the afternoon. The week following was devoted to excursions to different parts of the State where typical features could be studied. Special trains were provided for the party, and the long distances were traversed by night. On Monday the excursion was to Santa Rosa and Ukiah, on the California and Northwestern Railroad, stopping at the vineyards and winery of an Italian Swiss agricultural colony at Asti on the return trip, and reaching San Rafael in time for a banquet in the evening. The following day was spent in the vicinity of Fresno, in the San Joaquin Valley, where extensive vineyards, orchards, wineries, an ice plant, a raisin-packing establishment, and a number of beautiful estates were visited. An object lesson in irrigation was here presented, and an admirable illustration given of up-to-date farming in the extensive estate of Minnewawa, owned and superintended by Miss Eshleman. While a diversity of agricultural interests were represented on this estate, the dairy feature especially commanded admiration.

Wednesday morning the party reached Oroville, in the Sacramento Valley, where orchards of oranges, figs, and other fruits were visited. Later in the day stops were made at Yuba City and Woodland, where teams were in waiting to drive the visitors through the orchards and grain fields in the vicinity. Antioch, on Suisun Bay, was reached early Thursday morning, and the day was spent on the San Joaquin River, visiting grain and truck farms at several points along the river. An opportunity was afforded to see the large traction steam reapers and thrashers in operation in the fields.

Returning to San Francisco Thursday night, a fresh start was made Friday morning down through the beautiful Santa Clara Valley. A stop was made at Palo Alto, where Stanford University and the breeding stables were viewed. From San Jose trips were taken through orchards of olives, prunes, and other fruits, an oil mill where strictly pure olive oil is prepared, and a large fruit cannery. The Morse seed farm, one of the largest in the country, and operated entirely by Chinamen, was visited late in the afternoon; after which the party proceeded to Monterey.

Saturday morning a drive of some 16 miles was taken along the coast, which was greatly enjoyed; and later in the day a visit was made to the great beet-sugar factory at Salinas, which, when completed, will be the largest factory of the kind in the world.

The party then returned to San Francisco, arriving there Saturday evening. This completed the itinerary of an extremely interesting and enjoyable series of excursions, which will long be remembered with pleasure by all who participated in them and shared the bounteous hospitality everywhere extended.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Chemical analysis of rocks—determination of potassium and sodium, E. Bonjean (*Bul. Soc. Chim. Paris, 3. ser., 22 (1899), No. 14, pp. 691–693*).—Silica, iron oxid, alumina, lime, magnesia, and sulphuric acid are determined by means of fusion with alkaline carbonates. For the determination of potassium and sodium the material is fused with calcium carbonate (0.5 gm. of the carbonate to 1 gm. of the rock). The silica, iron oxid, alumina, and lime are eliminated by the ordinary methods. The solution, freed from these substances, is evaporated to dryness on a water bath and ignited to remove ammonium salts. The residue is taken up in water and magnesia precipitated as ammonium-magnesium phosphate. Ammonia is driven off and the ammonium phosphate precipitated by means of a 10 per cent solution of fresh neutral lead acetate added in slight excess. The excess of lead is removed by means of hydrogen sulphid. The filtrate from the lead precipitate is evaporated to dryness, ignited at a low red heat, taken up in water, acidulated with hydrochloric acid, and the potassium determined in the usual way, except that the platinum is precipitated by means of magnesium. The filtrate from the potassium-platinum chlorid is evaporated to remove the alcoholic ether, platinum precipitated with hydrogen sulphid, filtered, the filtrate evaporated to dryness, and the residue ignited at a red heat after the addition of sulphuric acid. The sodium is weighed as sulphate.

New process for the rapid determination of starch, M. D. Crispo (*Rev. Chim. Analyt. et Appl., 4 (1899), No. 9, pp. 289, 290*).—The author reviews the methods that have been proposed for the determination of starch, and states that none are suitable for rapid commercial work. He offers the following method: Treat 3.391 gm. of substance in a mortar with a little water, and then transfer to a 200 cc. flask, add 50 cc. of potash solution (6 gm. per 100), and heat the material (150 cc. volume) for an hour on the water bath. The solution is filtered, and, if necessary, refiltered, using an ordinary plaited filter, and then polarized. The result of polarimetric examination (with a 20 cm. tube) multiplied by 6 gives percentage of anhydrous starch. It is claimed that the potash completely dissolves the starch and that the solution is stable. The author states that this new process has not been given a thorough trial for the determination of the starch in cereals, but presumes that the gluten and other nitrogenous bodies will combine with the potash to produce products which are optically active. Among the results given are corn as containing 85.45 per cent of starch, and rye, 85.05 per cent.—H. SNYDER.

The determination of the digestible protein and the albuminoids of foods and feeding stuffs, B. SJOLLEMA (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 5, pp. 413–417*).—The author compared the use of commercial pepsin with that prepared from the stomach of swine according to Stutzer's method. The pepsin method used was as follows: Two grams of substance was digested for 48 hours in a water bath at 38 to 40° C. with 430 cc. of water, 1 gm. of pepsin, and 16 cc. of 10 per cent hydrochloric acid, adding 11 cc. of fresh acid at three different stages.

This was tested on a variety of feeding stuffs, and found to agree very satisfactorily with results from the use of the preparation from swine's stomach, indicating that commercial pepsin can be used in place of the latter.

In the determination of albuminoids in feeding stuffs like linseed cake, 1 gm. of substance was boiled with 50 cc. of water, and 50 cc. of 95 per cent alcohol added, then 50 cc. of cold water, 2 drops of cold saturated alum solution, and the prescribed amount of copper hydrate. Otherwise Stutzer's method was followed. The alcohol made the solution less slimy and more easily filtered. Trials with a number of different materials showed the modification to give the same results as the original Stutzer method for true albuminoids.

Detection of formaldehyde in milk, A. LEYS (*Jour. Pharm. et Chim., 6. ser., 10 (1899), p. 108; abs. in Chem. Ztg., 23 (1899), No. 66, Repert., p. 246*).—A colorless solution of phloroglucin (1 gm. in 1 liter), and potash solution (one-third "ordinary" strength) are used. A red color is produced if formaldehyde is present when 25 cc. of milk, 10 cc. of the phloroglucin solution, and 5 to 10 cc. of the potash are shaken in a test tube, the color disappearing after a few minutes. The Denigès test (E. S. R., 8, p. 459) is also recommended. Samples which give the reactions are distilled and the Denigès test applied again to make certain.

Recent progress in the field of agricultural chemistry, W. BERSCH (*Oesterr. Chem. Ztg., 11 (1899), No. 19, pp. 498–502*).—Recent articles relating to fertilizers, feeding stuffs, and soils are briefly reviewed.

Chemistry of soils and fertilizers, H. SNYDER (*Easton, Pa.: Chemical Publishing Co., 1899, pp. 277, pl. 1, figs. 35*).—The aim of this book is stated to be "to give, in condensed form, the principles of chemistry which have a bearing upon the conservation of soil fertility and the economic use of manures." It contains chapters on physical properties of soils; geological formation and classification of soils; chemical composition of soils; nitrogen of the soil and air; nitrification and nitrogenous manures; fixation; farm manures; phosphate fertilizers; potash fertilizers; lime and miscellaneous fertilizers; commercial fertilizers; food requirements of crops; and rotation of crops. Lists of problems, references, experiments, and review questions are also given. The book includes the results of recent investigations.

Investigations on Thomas slag, A. D. HERZFELDER (*Landw. Vers. Stat., 52 (1899), No 4, pp. 291–314*).—From the experiments reported the author concludes that it is tricalcium phosphate in Thomas slag which is soluble in citrate solution. The accuracy of the Wagner method is discussed.

The constitution of the ammonium-magnesium phosphate of analysis, F. A. GOOCH and M. AUSTIN (*Chem. News, 79 (1899), Nos. 2060, p. 233; 2061, pp. 244–246; 2062, pp. 255, 256*).—See E. S. R., 11, p. 107.

The mechanical precipitation of ammonium phosphomolybdate, F. WARSAGE (*Bul. Assoc. Belge Chim., 16 (1899), No. 7, pp. 343–345*).—A brief statement is made of the difficulties encountered when ammonium phosphomolybdate is precipitated. The author states that a complete precipitation can be secured in the cold by agitating the solution for 20 minutes. Brief directions are given for the preparation of the solution and the precipitation, and a table is appended showing the results secured by the new method (cold precipitation) and the old method (hot precipitation).—H. SNYDER.

Comparison of methods for detection of nitrates in water, L. GOBLET (*Bul. Assoc. Belge Chim., 16 (1899), No. 7, pp. 345–347*).—The author finds that Riegler's reaction (metadiamidobenzol and sulphuric acid) is the most sensitive; the presence of 0.000005 gm. of potassium nitrate in 10 cc. of water was capable of being detected.—H. SNYDER.

Gravimetric determination of sugar, G. MEILLÈRE and P. CHAPELLE (*Bul. Soc. Chim. Paris, 3. ser., 21–22 (1899), No. 10, p. 515*).—The reduction of the Fehling solution is carried out in a centrifugal tube. After heating in a concentrated salt bath the solution is whirled in the centrifuge, the clear liquid decanted, and the operation repeated twice with the addition of boiling water. The tube is heated at 150° C. for 5 minutes, cooled, and weighed.

A new "exact" method for determining fat in milk, A. A. BONNEMA (*Chem. Ztg., 23 (1899), No. 51, pp. 541, 542*).—The milk (10 cc.) is shaken in a "medicine bottle" with 1½ cc. of potash solution and then with 25 cc. of ether, cooled in water, and 2 gm. of tragacanth added, with vigorous shaking. The tragacanth takes up the water and forms itself into a ball. After cooling again, 10 cc. of the ether is poured off and evaporated, the fat weighed, and the percentage of fat in the milk calculated, taking the specific gravity into account.

A new method of estimating glycogen, E. PFLÜGER and J. NERKING (*Arch. Physiol. [Pflüger], 76 (1899), No. 11–12, pp. 531–542*).

Remarks on the article "A new method of estimating glycogen," E. PFLÜGER (*Arch. Physiol. [Pflüger], 76 (1899), No. 11–12, pp. 543–551*).

The quantitative determination of formaldehyde with peroxid of hydrogen, O. BLANK and H. FINKENBEINER (*Ber. Deut. Chem. Gesell., 32 (1899), No. 13, pp. 2142–2146*).

Detection of salicylic acid and boric acid in milk, G. BREUSTEDT (*Arch. Pharm., 237 (1899), No. 3, p. 170; abs. in Chem. Ztg., 23 (1899), No. 42, Repert., p. 158*).—A description of methods.

Direct measurement of the osmotic pressure of very dilute solutions of sodium chlorid, A. PONSOT (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 24, pp. 1447, 1448*).

A simple apparatus for use in the Kjeldahl method for nitrogen, F. PREGL (*Ztschr. Analyt. Chem., 38 (1899), No. 3, pp. 166, 167, fig. 1*).—An automatic mercury vent is used in the distilling flask, which is said to remove all danger from frothing and to do away with the necessity for a safety bulb of any kind to prevent the acid going over.

An electrical apparatus for the determination of the melting point of fats and waxes, N. CHERCHEFFSKY (*Chem. Ztg., 23 (1899), No. 57, p. 597, fig. 1*).—A German silver tube with proper electrical insulation from its metal support is made one of the terminals of a circuit, while a cup of mercury on a sand bath is made the other. The tip of the tube is coated with some of the melted fat or wax to be tested, and the tube is placed in the mercury and heated. When the film of wax melts, the electrical circuit is completed, the fact being announced by an enunciator. A thermometer shows the temperature of the mercury.—J. T. ANDERSON.

A new thermoregulator for electrically heated thermostats, E. PRIOR (*Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899), No. 9, pp. 701–703, fig. 1*).

Incandescent electric lamp as a source of heat in ether extraction, C. G. HOPKINS (*Jour. Amer. Chem. Soc., 21 (1899), No. 8, pp. 645–647, pl. 1*).—A battery of 20 extractors is illustrated, which are heated by five 110-volt electric lamps of 32-candlepower. The lamps are placed in a flat air bath, upon the top of which rest the ether flasks connected with the extractors.

A new "quartz-scale" polariscope, H. L. SAMSON (*Beet Sugar Gaz., 1 (1899), No. 7, pp. 8–10, figs. 3*).

A new low-pressure water-blast lamp, S. EPSTEIN (*Oesterr. Chem. Ztg., 2 (1899), No. 19, pp. 497, 498, fig. 1*).

BOTANY.

Native agricultural grasses of Kansas, A. S. HITCHCOCK and G. L. CLOTHIER (*Kansas Sta. Bul. 87, pp. 29, figs. 21, maps 29*).—The authors describe 29 species of the more important grasses, all of which are perennial except one, *Panicum crus-galli*. All of these are of sufficient importance to be included among the agricultural grasses of the State. The grass regions are divided into eight divisions, and the characteristic grasses of each given. These regions are wooded regions; sloughs, swales, and wet meadows; bottom land; prairies of eastern Kansas; upland plains of western Kansas; sandy regions; stony hills, and salt plains and alkali spots. The different species of grasses are figured and briefly described, and their distribution throughout the State, so far as represented by herbarium specimens in the station collection, are platted. Notes are also given on the relative economic value of the species.

Observations on the growth of plants in sunlight and in shade, BERTHELOT (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 3, pp. 139–144*).—The author gives the results of some investigations made upon crested dogtail grass (*Cynosurus cristatus*), in which the differences observed in plants grown in the shade and in sunlight are shown. One lot of plants which had grown in natural meadow conditions exposed to the sun was harvested May 28. Another lot, cut at the same time, had grown under similar conditions except that it was continually under the shade of an elm tree; and a third lot, which was the aftermath from a previous cutting on June 3, was grown in the sun and cut on August 6. The average weight of the different lots is given, as well as the dry matter. Analyses are quoted in which the proportionate amounts of roots, stems, and leaves are shown, and also analyses in which the ash and some of the organic constituents are given.

Plants grown in the sun contain the maximum amount of carbon, that of the aftermath being somewhat less than in the first cutting. Phosphorus and sulphur are found most abundant in plants grown in the shade. The nitrogen content in each of the three cases was almost the same. Plants grown in the shade often appear more vigorous than others, but it is said to be due to the suppression or retardation of the functions of reproduction.

Modification of the respiration of plants by alternation of temperature, W. PALLADIN (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 23, pp. 1410, 1411*).—The general law that the amount of carbon dioxid given off by plants increases in proportion to the temperature has been investigated, and the author finds that within certain limits it holds good. His experiments further show that intensity of respiration may vary considerably at any given temperature, providing the plants have some time previous to the beginning of the experiment been subjected to different extreme temperatures.

Experiments with etiolated stems of *Vicia faba* are reported, in which the extremities of the plants were cut off and placed in 10 per cent solutions of saccharose. One lot of these was exposed to a temperature of 17 to 20° C., a second to a low temperature ranging from 7 to 12°, and a third to a high temperature of 36 to 37.5° C. After several days the three lots were subjected to an average temperature of 18 to 22° and their respiration simultaneously determined. It was found that the amount of carbon dioxid given off by the plants which had been kept at the medium temperature was the lowest. Those subjected to the low temperature showed an increase of 40 per cent, and those which had received a high temperature in a previous part of the experiment gave off 53 per cent more carbon dioxid than those at the medium temperature. The cause of this phenomenon the author does not attempt to explain.

Anatomical and physiological characteristics of alpine plants produced by the alternation of extreme temperatures, G. BONNIER (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 19, pp. 1143–1146*).—In a previous article (E. S. R., 10, p. 608) the author showed the possibility of producing alpine forms of plants by a day and night alternation in temperature. At that time the plants had not developed sufficiently to complete the study.

In the present paper he compares the anatomy and physiology of the germander plants in his experiments. It appears that the plants which resulted in the alternation of temperature were comparable in every way to those produced in high mountain regions. The stems and petioles of the leaves had their protective tissues more differentiated and were more rapidly developed. The leaves were smaller and much thicker, their palisade tissue much more developed, and they very frequently exhibited a red coloration due to anthrocyanin, which is quite frequently produced in alpine plants. The carbon dioxid assimilation was considerably in excess in plants grown under these conditions. The flowers produced were relatively larger and much higher colored.

Vernal phenomena in the arid region, T. D. A. COCKERELL (*Amer. Nat., 33 (1899), No. 385, pp. 39–43*).—The author reviews the theory relative to life zones as laid down by C. Hart Merriam, in which it is stated that the "northward distribution of terrestrial animals and plants is governed by the sum of the positive temperatures for the entire season of growth and reproduction and the southward distribution is governed by the mean temperature of a brief period during the hottest part of the year." The author states that the mean temperatures, even in January and February, are high enough to stimulate growth in those plants which have been introduced from more humid regions, but the native vegetation remains backward nothwithstanding the warmth. He gives tables to show the date of blooming of quite a number of peach, plum, and apricot trees, as well as of a considerable number of native plants.

It appears that with one or two exceptions native vegetation is backward notwithstanding the warm weather, but after the period of the latest killing frosts is passed it comes out with remarkable rapidity. At Mesilla Park the domestic honeybee is frequently seen in January, while the native bees seldom appear until late in March. The author states in conclusion that—

> "Throughout the arid region where the sky is clear and radiation great the development of plants and insects is controlled largely by the distribution of the frosts throughout the year. The climate of this region is peculiar and presents a barrier to the ingress of plants and animals from without. For tropical and subtropical species the winters are too cold. For species of moist temperate regions the late frosts following warm spells are usually destructive. It is a curious anomaly that in a locality having more than tropical summer temperatures plants of the temperate zone should fail on account of frosts.'

Notes on the maximum thermal death point of Sporotrichum globuliferum, B. M. DUGGAR (*Bot. Gaz., 27 (1899), No. 2, pp. 131–136*).—While engaged in a study of an entomogenous fungus, *Sporotrichum globuliferum*, experiments were made for the determination of the maximum thermal death point of this fungus under varying conditions. Cultures were made on nutrient agar in slanting tubes. When exposed for 24 hours at temperatures of 35°, 37.7°, and 40.5° C. the spores were effectually inhibited in growth. On the other hand, a few hours after germination had begun they were able to withstand considerably longer exposure to these temperatures. Three hours' exposure to temperatures of 46.1° and 51.6° was sufficient to destroy nearly all growth of the spores. The mycelium in the agar tubes was submitted for various lengths of time, ranging from 1 to 24 hours, at temperatures from 37.7 to 51.6°, in which it appears that the mycelium is quite resistant except to the higher temperatures and longer exposures.

Spores exposed to dry heat for from 1 to 6 hours at temperatures from 46.1 to 60° C. were in no wise injured. The maximum amount of dry heat which the spores of this fungus will resist during a single exposure was not ascertained. When exposed for 3 hours to a temperature of 51.6° on 4 successive days no growth resulted. Mycelium cultures on insects which were exposed from 1 to 24 hours at temperatures of 46.1° and 56.1° were affected but slightly, if at all.

Improvement of plants by selection, H. J. Webber (*U. S. Dept. Agr. Yearbook 1898, pp. 355–376, pls. 2, figs. 2*).—The object of this paper is to discuss the fixation of desirable variation by methodical selection and the gradual improvement of plants resulting from the cumulative effect of selecting through many generations. The methods of selection are discussed at some length and results as illustrated by the improvement of sea-island and other cottons shown. Some of the limitations of selection are pointed out and statements given relative to the development of new races by selection, as has been done in the case of the wild parsnip, *Anthriscus sylvestris*, and other plants. Notes are given on the improvement by selection of cuttings, slips, buds, etc., and illustrations drawn from work conducted by members of the Division of Vegetable Physiology and Pathology on violets are given.

A synopsis of the genus Sitanion, J. G. Smith (*U. S. Dept. Agr., Division of Agrostology Bul. 18, pp. 21, pls. 4*).—An attempt has been made to characterize the numerous forms that have generally been grouped under *Sitanion hystrix* or *Elymus sitanion*. In this synopsis 23 species, most of them new, are recognized and described.

Sand-binding grasses, F. Lamson-Scribner (*U. S. Dept. Agr. Yearbook 1898, pp. 405–420, pls. 3, figs. 9*).—The author describes some of the principal grasses which are distinctively sand binders, both those growing near the seashore and those which are natives of the interior. Among those best adapted to this purpose are the beech or the marram grass, sea lyme grass, bitter panic grass, creeping panic grass, seaside blue grass (*Poa macrantha*), Redfield's grass (*Redfieldia flexuosa*), sand grass (*Calamovilfa longifolia*), yellow lyme grass, and sand blue grass (*Poa leckenbyi*). Other grasses which are not true sand binders but will grow in sandy situations are Johnson grass, *Arundo donax*, some of the bamboos, and wheat grasses.

Forage plants for cultivation on alkali soils, J. G. Smith (*U. S. Dept. Agr. Yearbook 1898, pp. 535–550, figs. 4*).—The author states the effect of alkalis on plant growth, quoting extensively from Wyoming Station Bulletin 29 (E. S. R., 8, p. 568) and California Station Bulletin 105 (E. S. R., 7, p. 717).

Descriptions are given of various saltbushes native to Australia which have proved more or less valuable for forage on alkali soils. In addition to the Australian species, a number of indigenous saltbushes are described. Notes are given on other plants of somewhat similar character.

Production of Johnson grass for forage, T. A. Williams (*Breeders' Gaz., 35 (1899), No. 26, pp. 775, 776*).—This grass is highly recommended for a hay grass, being more esteemed for that purpose than for pasture. On account of the habit of growth it should not be used in any rotation.

Corn plants, F. L. Sargent (*Boston: Houghton, Mifflin & Co., 1899, pp. V+106, figs. 32*).—An untechnical work designed to be supplemental to the use of text-books in secondary schools. It gives in considerable detail the life histories of the different cereals and suggests the part each has had in the world's economy.

Contributions to the knowledge of Mortierella van tieghemi, H. Bachmann (*Ber. Schweiz. Bot. Gesell., 1899, No. 9, p. 36*).

The structure of the caryopsis of grasses with reference to their morphology and classification, P. B. Kennedy (*U. S. Dept. Agr., Division of Agrostology Bul. 19, pp. 44, pls. 8*).—An historical review and summary of the previous investigations on this subject is given, together with a general description of the fruit, in which the various parts are described. Detailed descriptions are given of the fruits of the different grasses, representatives being given of each of the 13 tribes recognized by Hackel in his arrangement of the grasses. The relationship and systematic connection of the tribes are discussed and a bibliography of the subject appended.

Concerning the anatomy of water-secreting organs, M. VON MINDEN (*Stuttgart, 1899, pp. 76, pls. 7; abs. in Bot. Ztg., 2. Abt., 57 (1899), No. 20, pp. 308, 309*).

The physiological characteristics of the cell, F. SCHENCK (*Physiologische Charakteristik der Zelle. Würzburg: A. Stuber, 1899, pp. VIII + 123*).

The influence of inorganic salts upon the formation of conidia by Aspergillus niger, A. YASUDA (*Bot. Mag. [Tokyo], 13 (1899), pp. 85–91*).

A preliminary note as to the cause of root pressure, R. G. LEAVITT (*Amer. Jour. Sci., 4. ser., 7 (1899), No. 41, pp. 381, 382*).—An attempt is made to explain, by Van't Hoff's interpretation of osmotic pressures, some of the hitherto poorly understood phenomena, such as the increased absorption due to heat as shown by the experiments of Sachs, variation in tree pressures noted by Clark, etc.

A preliminary arrangement of the species of the genus Bacillus, F. D. CHESTER (*Delaware Sta. Rpt. 1898, pp. 100–137*).—The author gives an arrangement of the species of the genus Bacillus following the table of characters and abbreviations used in a previous memoir on the genus Bacterium (E. S. R., 10, p. 519). In all 143 species are described at more or less length and an index to the more important literature of the species is appended.

Edible and poisonous fungi of Middle Europe, G. BRESADOLA (*I funghi mangerecci e velenosi dell' Europa media, etc. Milan: U. Hoepli, 1899, pp. 152, pls. 112*).

Fungi in greenhouses, H. WEBSTER (*Rhodora, 1 (1899), No. 5, pp. 83, 84*).—Notes on some fleshy fungi in greenhouses.

Alinit, the new soil bacteria, B. DURFEE (*Amer. Florist, 14 (1899), No. 580, pp. 1453, 1454*).—Notes the use of Alinit in floriculture. Experiments with asters and carnations are reported. The test with asters was a complete failure, while some advantage to one pot of carnations is reported. On the other plants no effect of inoculation was apparent.

Experiments with Nitragin, R. T. HENNINGS (*K. Landt. Akad. Handl., 38 (1899), No. 1, pp. 14–21*).—No effect or only slight effects were obtained in two different experiments with peas.

Concerning the results obtained by Nitragin inoculation, FRANK (*Landw. Vers. Stat., 51 (1899), No. 6, pp. 441–445*).—The author sums up for the Prussian Ministry of Agriculture the evidence relative to the use of Nitragin as a means of inoculating leguminous crops. Under certain circumstances the substance may be used with advantage, but in many experiments negative results are reported. In soils poor in nitrogen and in which no organisms capable of nitrogen assimilation are present favorable results are likely to follow, but where nitrogen and organisms are plentiful its use is not recommended.

The bacteria of the soil with special reference to soil inoculation, R. S. MACDOUGALL (*Trans. and Proc. Bot. Soc. Edinburgh, 21 (1897), pt. 1, pp. 25–40*).—Gives an account of pot experiments with Nitragin cultures in sterilized soil in which the advantage of using the proper kind of cultures for each crop is shown. Notes are also given on nitrifying organisms and their action.

The influence of organic substances upon the work of nitrifying organisms, S. WINOGRADSKY and V. OMELIANSKY (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), Nos. 10, pp. 329–343; 11, pp. 377–387; 12, pp. 429–440*).

Bud variation, L. BEISSNER (*Seperat. Niederrhein. Ges. Nat. u. Heilkunde, Bonn, 1898, pp. 30–42; abs. in Jour. Roy. Micros. Soc. [London], 1899, No. 3, pp. 295, 296*).—The author enumerates the various kinds of bud variation which occur especially in woody plants, resulting in pyramidal or columnar forms, pendent and weeping forms, dwarf forms, forms of deeply divided or highly colored leaves, etc. The danger of confusing the variations which result from unfavorable or other vital conditions with true bud variations is pointed out, and the limited knowledge of the conditions which determine bud variation is commented upon.

Bud variation in plants, R. M. KELLOGG (*Proc. Michigan Hort. Soc., 1897, pp. 121–134*).—The principal causes of bud variation are pointed out and several specific cases are cited.

The causes of variation in cultivated plants which give us new varieties, H. AYERS (*Missouri Hort. Soc. Rpt., 1898, pp. 21-35*).—A popular presentation of the subject.

A study of the methods of seed dispersal, K. SAJO (*Prometheus, 10 (1899), No. 499, pp. 481-485, fig. 1*).—Comparative studies are given between the seed of *Pinus austriaca* and *P. sylvestris.*

ZOOLOGY.

Birds as weed destroyers, S. D. JUDD (*U. S. Dept. Agr. Yearbook 1898, pp. 221-232, figs. 7*).—The most important weeds which are prevented by birds from seeding are ragweed, pigeon grass, smartweed, bindweed, crab grass, lamb's-quarters, and pigweed. Birds are most actively engaged in feeding upon weed seeds during the winter months. The birds which are most effective in this work are about 20 species of sparrows and finches, horned larks, blackbirds, cowbirds, meadow larks, doves, and quails. The English sparrow is reported as especially useful in destroying the seeds of crab grass and dandelion. Three-fourths of the dandelions which bloom on the Department lawns during April and May are said to be mutilated by birds. The native sparrows are active in this destruction of the dandelion.

The common goldfinch is praised as an unusually valuable bird in this particular work. Horned larks are said to feed to a considerable extent upon sorrel. The blackbirds are found to eat large quantities of the seeds of wild sunflowers, sorrel, mustard, chickweed, and thistle during the fall. The quail and mourning dove are also noted as weed destroyers. In the crop of one mourning dove were found 7,500 seeds of *Oxalis stricta.* About 50 species of birds are noted as destroyers of somewhat more than 60 species of weeds.

Manitoba birds of prey and the small mammals destroyed by them, G. E. ATKINSON (*Trans. Hist. and Sci. Soc. Manitoba, 1898, No. 53, pp. 16, figs. 7*).—This paper treats of the feeding habits of the Cathartidæ, Falconidæ, and Strigidæ, with special reference to the Manitoba species of these families. Nearly all the species considered are believed to be more beneficial than injurious, and some of them are said to feed exclusively upon injurious species of animals. Of the mice and gophers which are most frequently found in the stomach of these birds, the author mentions *Arvicola riparius*, *A. gapperi*, *Spermophilus franklini*, *S. tridecimlineatus*, *S. richardsoni*, and *Thomomys talpoides.* Estimates are given of the number of mice per acre and the amount of damage done by mice and gophers.

The danger of introducing noxious animals and birds, T. S. PALMER (*U. S. Dept. Agr. Yearbook 1898, pp. 87-110, pl. 1, figs. 6*).—The author calls attention to the many cases of accidental and intentional introduction of mammals and birds into new countries. In most cases these animals when intentionally introduced were supposed to be distinctly beneficial in the destruction of injurious insects and other animals, but while the importations seemed to be successful at first, the imported animals have almost without exception proved to be in the end as bad pests as were those pests which they were intended to exterminate.

Brief descriptions are given of a number of these intentional importations, including such animals as the rabbit, mongoose, stoat, weasel, flying fox, English sparrow, starling, and mina, all of which animals proved decidedly injurious. Various attempts have been made to introduce into this country the skylark, green linnet, black thrush, and the great titmouse. Neither one of these latter named species has become very numerous in this country, but all are likely to prove injurious in case they should become abundant.

The author calls attention to various legislative restrictions which have been adopted in other countries against the importation of animals which may become injurious and urges that the time has come when the United States may well pass some general law of this sort.

Observations on the normal and pathological histology and bacteriology of the oyster, W. A. HERDMAN and R. BOYCE (*Proc. Roy. Soc. [London], 64 (1899), No. 407, pp. 239-241*).—This paper is an abstract of an extended account of the authors' investigations with oysters. A portion of the work was previously reported (E. S. R., 10, p. 522). The primary object of the investigation was to study the oyster under unhealthy conditions, but this rendered necessary much histological work. The principal conclusions concerning the greening of oysters and the possibility of infection through oysters follow:

> "A diseased condition we found in certain American oysters very soon brought us into contact with the vexed question of the 'greening' of oysters, and one of the first results we arrived at was that there are several distinct kinds of greenness in oysters. Some of them, such as the green Marennes oysters, and those of some rivers on the Essex coast, are healthy; while others, such as some Falmouth oysters, containing copper, and some American oysters rebedded on our coast, and which have the pale-green 'leucocytosis,' . . . are not in a healthy state.
>
> "Some forms of greenness (e. g., the leucocytosis) are certainly associated with the presence of a greatly increased amount of copper in the oyster, while other forms of greenness (e. g., that of the Marennes oysters) have no connection with copper, but depend upon the presence of a special pigment, 'marennin.'
>
> "We are able, in the main, to support Ray Lankester in his observations on Marennes oysters; but we regard the wandering amœboid granular cells on the surface of the gills as leucocytes which have escaped from the blood spaces, and have probably assumed a phagocytic function.
>
> "We see no reason to think that any iron which may be associated with the marennin in the gills, etc., is taken in through the surface epithelium of the gill and palps, but regard it, like the rest of the iron in the body, as a product of ordinary digestion and absorption in the alimentary canal and liver.
>
> "We do not find that there is any excessive amount of iron in the green Marennes oyster compared with the colorless oyster, nor do the green parts (gills, palp, etc.) of the Marennes oyster contain either absolutely or relatively to the colorless parts (mantle, etc.) more iron than colorless oysters. We therefore conclude that there is no connection between the green color of the 'Huîtres de Marennes' and the iron they may contain.
>
> "On the other hand, we do find by quantitative analysis that there is more copper in the green American oyster than in the colorless one; and more proportionately in

the greener parts than in those that are less green. We therefore conclude that their green color is due to copper. We also find a greater quantity of iron in those green American oysters than in the colorless; but this excess is, proportionately, considerably less than that of the copper.

"In the Falmouth oysters, containing an excessive amount of copper, we find that much of the copper is certainly mechanically attached to the surface of the body, and is in a form insoluble in water, probably as a basic carbonate. In addition to this, however, the Falmouth oyster may contain a much larger amount of copper in its tissues than does the normal colorless oyster. In these Falmouth oysters the cause of the green color may be the same as in the green American oyster.

"By treating sections of diseased American oysters under the microscope with potassium ferrocyanid and various other reagents, we find that the copper reactions correspond in distribution with the green coloration; and we find, moreover, from these micro-chemical observations that the copper is situated in the blood cells or leucocytes, which are greatly increased in number. This condition may be described as a green leucocytosis, in which copper in notable amount is stored up in the leucocytes.

"We find that an aqueous solution of pure hæmatoxylin is an extremely delicate test for copper, just as Macallum found it to be for iron.

"Experiments in feeding oysters with weak solutions of various copper and iron salts gave no definite results, certainly no clear evidence of any absorption of the metals accompanied by 'greening.'

"Although we did not find the *Bacillus typhosus* in any oysters obtained from the sea or from the markets, yet in our experimental oysters inoculated with typhoid we were able to recover the organism from the body of the oyster up to the tenth day. We show that the typhoid bacillus does not increase in the body or in the tissues of the oyster, and our figures indicate that the bacilli perish in the intestine.

"Our experiments showed that sea water was inimical to the growth of the typhoid bacilli. Although their presence was demonstrated in one case on the twenty-first day after addition to the water, still there appeared to be no initial or subsequent multiplication of the bacilli.

"In our experiments in washing infected oysters in a stream of clean sea water the results were definite and uniform; there was a great diminution or total disappearance of the typhoid bacilli in from 1 to 7 days.

"The colon group of bacilli is frequently found in shellfish as sold in towns, and especially in the oyster; but we have no evidence that it occurs in mollusca living in pure sea water. The natural inference that the presence of the colon bacillus invariably indicates sewage contamination must, however, not be considered established without further investigation. . . .

"We have shown also the frequent occurrence, in various shellfish from the shops, of anaërobic spore-bearing bacilli giving the characteristics of the *B. enteritidis sporogenes* recently described by Klein."

A text-book of agricultural zoology, F. V. THEOBALD (*Edinburgh and London: W. Blackwood & Sons, 1899, pp. XVII + 511, figs. 225*).—In this volume the author discusses the general principles of zoology and gives consideration to all the orders of the animal kingdom. Those orders which are of special economic importance are treated more fully than the groups which are not distinctly related to agriculture. Among the subjects treated may be mentioned the Ciliata which are found in the intestines of various domestic animals and man; the Sporozoa, sometimes parasitic in vertebrate animals; the various parasitic flat and round worms; and annelids. In the order Orthropoda, the author gives most attention to those insects, myriapods, and arachnida which are the enemies or friends of agriculture. In discussing the mammals the author gives a detailed account of the horse. In the appendix, lines of treatment are suggested for insect pests and for diseases caused by worms.

The fauna of Cuba, W. MARSHALL (*Die Thierwelt Cubas. Leipsic: C. E. M. Pfeffer, 1898, pp. 17; separate from Ztschr. Naturw., 71 (1899), pp. 219–236*).—The paper gives a general account of the native mammals, birds, reptiles, amphibians, fishes, mollusks, insects, and crustacea of the Island of Cuba. The author calls attention to the presence of large numbers of wild dogs, cats, horses, hogs, goats, and rabbits which are injurious to most cultivated crops and to poultry.

Natural history of the Tres Marias Islands, Mexico (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No 14, pp. 97, pl. 1, figs. 2*).—This bulletin contains the following items: General description, mammals, birds, and a partial bibliography of the Tres Marias Islands, E. W. Nelson; reptiles of the Tres Marias Islands, L. Stejneger; notes on the Crustacea of the Tres Marias Islands, Mary J. Rathbun; and plants of the Tres Marias Islands, J. M. Rose.

Results of a biological survey of Mount Shasta, California, C. H. MERRIAM (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 16, pp. 179, pls. 5, figs. 46*).—This bulletin contains an account of the itinerary of an expedition in the neighborhood of Mount Shasta, with a discussion of the general geographical features of the region, the forest conditions, the effects of forest fires and of slope exposure, and a study of the life zones found represented upon this mountain. Some observations are made upon the boreal fauna and flora of Shasta as compared with corresponding faunas and floras of the Sierra and Cascades. Annotated lists are given of the mammals, birds, and plants which were noted during the expedition.

The economic importance of some common birds, E. B. WILLIAMSON (*Jour. Columbus Hort. Soc., 13 (1898), pp. 33–44*).—The author discusses the feeding habits of a number of common birds of Ohio which may be considered beneficial to agriculture.

The relation of birds to horticulture, W. W. COOKE (*Colorado State Bd. Hort. Rpt. 1898, pp. 45–53*).—Popular notes on the feeding habits of some common birds.

Birds on the farm, H. H. HEATON (*Iowa State Agr. Soc. Rpt. 1898, pp. 458–461*).—The economic relationship of a number of common birds is discussed, including the house wren, the rose-breasted grosbeak, Baltimore oriole, tree sparrows, crows, woodpeckers, English sparrows, and the meadow lark. The tree sparrows were observed feeding voraciously upon various weed seeds.

Is the sparrow the friend or foe of the gardener and florist? W. N. CRAIG (*Amer. Florist, 14 (1899), No. 570, pp. 1204–1206*).—Relates the insect-eating habits of the English sparrow, and concludes that the benefits from this bird outweigh its injuries.

The woodpecker (*Bul. Bot. Dept. Jamaica, n. ser., 6 (1899), No. 4, p. 58*).—The woodpecker is reported as feeding on cocoa beans.

Observations on owls with particular regard to their feeding habits, T. H. MONTGOMERY (*Amer. Nat., 33 (1899), No. 391, pp. 563–572*).—Observations upon the short-eared owl (*Asio accipitrinus*) and the long-eared owl (*A. wilsonianus*).

Animals which are injurious to the sugar beet, with descriptions of their life habits and remedies for controlling them, W. MÜLLER (*Thierische Zuckerrüben-schädlinge, Beschreibung, Lebensweise und Vertilgung. Berlin: Paul Parey, 1893, pp. 90, figs. 42*).—This is a sort of handbook recording all the animal depredators of the sugar beet, including mammals, birds, insects of various orders, myriapods, and nematodes. Many of the insects which are treated are figured, as well as the myriapods and nematodes, and remedies are suggested in each case.

The extermination of rabbits by means of plate traps (*Deut. Landw. Presse, 26 (1899), No. 44, p. 498, fig. 1*).—A brief account of the use and effectiveness of this sort of trap.

Rabbit plague in vineyards of Stuttgart, J. HOFFMANN (*Jahreshefte Ver. Vaterl. Naturk. Württemberg, 55 (1899), pp. 425–431*).—Since 1896 numerous complaints have been made in this region concerning the destruction of beans, peas, and other garden plants, as well as young grapevines, by rabbits. Upon investigating the matter, it was found that the rabbits which were doing the damage were descendants of tame rabbits which had escaped and which had come to resemble in form, size, and color the ordinary wild rabbit. The soil in this particular locality was unfavorable for the digging of burrows, and as a result the rabbits had made short burrows, especially under rubbish or stones.

Gopher destruction (*Rpt. Dept. Agr. Northwest Territories, 1898, pp. 36–38*).—A brief discussion of the use of strychnin and bisulphid of carbon as remedies against these animals.

Revision of the jumping mice of the genus Zapus, E. A. PREBLE (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 15, pp. 39, pl. 1, figs. 4*).—This bulletin contains a brief history of our knowledge of the genus Zapus and a monographic account of the genus, including one Asiatic species. The species of the genus, except the one, belong to North America. Notes are given in connection with each species on the habits of the animals.

Observations on the common toad, G. L. ROPE (*Zoologist, 4. ser., 3 (1899), No. 27, pp. 97–102*).—Gives the habits of *Bufo vulgaris*.

The classification of Tæniidæ, A. RAILLIET (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 1, pp. 32–34*).—This paper contains a discussion of the relationship of the genera of this family.

A contribution to the knowledge of earthworms, W. MICHAELSEN (*Zool. Jahrb., Abt. Syst., 12 (1899), No. 2, pp. 105–144, figs. 2*).—A general account of the habits and life history, with descriptions of new species.

Earthworms, M. C. HOLMES (*Sci. Amer. Sup., 47 (1899), No. 1228, pp. 19601, 19602, figs. 3*).—Anatomical and physiological observations on earthworms, with notes on their habits and biological relations.

The beet-root worm (*Pop. Sci., 33 (1899), No. 5, p. 102, figs. 6*).—Popular notes are given on *Heterodera schachtii*.

Nematode worms injurious to cereals, J. JABLONOWSKI (*Kisérletügyi Közlemények, 2 (1899), No. 4, pp. 169–197, figs. 10*).—This article contains a detailed description of the habits and methods of attack of *Tylenchus devastator* and *T. scandens*. Among the remedies which are recommended by the author may be mentioned deep plowing and soaking the seed grain in a ¾ per cent solution of blue vitriol and water for 24 hours.

METEOROLOGY.

Monthly Weather Review (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 27 (1899), Nos. 4, pp. 139–186, figs. 3, charts 11; 5, pp. 187–241, pls. 6, figs. 9, charts 8; 6, pp. 243–285, charts 9*).—In addition to the usual reports on forecasts and warnings and on weather and crop conditions, and meteorological tables and charts, No. 4 contains special contributions on Sun spots and Hawaiian eruptions, by C. J. Lyons; A talk on elementary meteorology (illus.), by G. M. Davison; Long-range weather forecasting in Canada, by J. Gun; Climate and crop service publications, by J. Berry; Normal precipitation in the region of the Great Lakes, by A. J. Henry; and Text-books on botany, by F. V. Coville; and notes by the editor on pamperos and cyclonic storms, spool kites and kites with radial wings (illus.), newspaper fakes, universities and meteorology, ball lightning, empirical generalizations for South Carolina, radiant heat for the prevention of frost, the present state of long-range forecasting, characteristics of tornadoes, death of Mariano Bárcena, no increase in tornadoes, no change in the climate of April, rains of sand, dust, and mud, the prediction of tornadoes and thunderstorms, international courtesy, recent earthquakes, National Geographic Society, the weather service of Jamaica, West Indies, and daily international exchange with Mexico.

No. 5 contains special contributions on Monthly reports of the Weather Bureau service in the West Indies, by W. B. Stockman; The utilization of fog, by F. A. Carpenter; The flood of January, 1880, at Basseterre, St. Kitts, West Indies, by W. H. Alexander; Derecho, not tornado, of May 16 in Ohio, by J. W. Smith; Balloon ascensions on March 24, 1899, in France, by F. H. Bigelow; Climatology of the Isthmus of Panama, including the temperature, winds, barometric pressure, and precipitation (illus.), by H. J. Abbot; Spurious tornado photographs, by A. J. Henry; The meteorological service of Canada, by R. F. Stupart; An advance in measuring and photographing sounds (illus.), by E. F. Sharpe; and Rainfall and temperature in Nicaragua, by A. P. Davis; and notes by the editor on the Pacific Coast division of the Canadian meteorological service, "scientific aids" in the Department of Agriculture, and records by the Milne seismograph (illus.).

No. 6 contains special contributions on Extraordinary rainfall in Texas, by H. A. Hazen; Some physical features and flood conditions of the James River Valley, by E. A. Evans; Records by the kite corps at Bayonne, N. J., by H. L. Allen; and The precipitation over the Pacific Northwest and the possibility of high water in the Columbia from the melting snow in the mountains, by B. S. Pague; and notes by the editor on climatological data for Canada, the annual summaries of the climate and crop service, the climate adapted to tobacco, the duration of the growing season for 1898, ribbon lightning, unnecessary tornado alarms, the camphor barometer, an objectionable new meteorological term ["snow tornadoes"], Weather Bureau men as university lecturers, the conflict of man with the climate, widespread area of drought or cold, rainfall at high stations, physics and meteorology in the universities, and the climate and crop service in Puerto Rico.

Report of the meteorologist, W. H. BISHOP (*Delaware Sta. Rpt. 1898, pp. 247-262*).—Monthly summaries of observations at six different places in Delaware on temperature, pressure, precipitation, relative humidity, and prevailing winds during the year ended June 30, 1898, and a summary of observations on temperature and precipitation during the calendar year 1897 are given and the data are briefly discussed. The summary for 1897 is as follows:

Annual summary of meteorological observations in Delaware, 1897.

Locality.	Temperature.			Total rainfall.	No. days on which 0.01 in. or more of rain fell.
	Highest.	Lowest.	Mean.		
	Deg. F.	*Deg. F.*	*Deg. F.*	*Inches.*	
Newark	94 (Sept. 10, 11).	6.5 (Jan. 25)	52.6	43.99	[illegible]
Middletown	97 (Sept. 11)	6 (Jan. 26)	53.3	47.98	[illegible]
Dover	94 (June 30)	8 (Jan. 26)	53.7	43.43	124
Milford	97.5 (Sept. 11)	9.5 (Jan. 26)	56.2	46.62	416
Seaford	95.5 (Sept. 10)	8 (Jan. 26, 31)	55	44.59	110
Millsboro	94 (Sept. 11)	3 (Jan. 31)	54.2	50.14	130

Ninth annual report of the New York Weather Bureau, 1897 (*Rpt. New York State Dept. Agr., 5 (1897), II. pp. 1-424, charts 28*).—This report includes daily and monthly summaries of observations on temperature at some 103 stations in 54 counties of the State, on precipitation at 131 stations, and on atmospheric pressure at 10 stations, and a review of the crop conditions during the year. The meteorological conditions during 1897 are summarized as follows:

"The average atmospheric pressure (reduced to sea level and 32° F.) for the State of New York during 1897 was 30.05 in.; the highest monthly mean pressure, 30.15 in., occurring in September, and the lowest, 29.94 in., in July. The highest barometer was 30.87 in. at Albany on March 1, and the lowest was 29.06 in. at Oswego on November 9, giving a range of 1.81 in. within the State. The highest local monthly mean pressure was 30.18 in. at Albany in October, the lowest being 29.92 in. at Buffalo, Rochester, and Oswego in July. The greatest local range was 1.69 in. at Albany, and the least, 1.56 in., at Buffalo and Erie. The mean annual range for all stations was 1.63 in. The greatest departures of monthly means from the normal were +0.08 in. in April, September, and October, and —0.06 in May.

"The mean annual temperature for the State was 46.4°, as derived from the records of 81 stations; the mean temperature of January, the coldest month, being 22.3°, and of July, the warmest month, 72.1°. The highest local annual mean was 52.6° at Brooklyn, and the lowest was 40.7° at North Lake, Herkimer County. The highest local monthly mean was 75.1° at Canajoharie in July, and the lowest was 13.9° at Saranac Lake in January. The maximum temperature reported during the year was 102° at Avon on July 5 and 10, and the minimum was 28° below zero at Saranac Lake on February 28, giving an annual range of 130° within the State. The average daily range for the year was 19°; the greatest local value being 25° at Oxford, while the least was 12° at Arkwright. The mean annual temperature of the State, as derived from the records of 22 stations possessing records of 10 years or more, was very slightly above the normal. Only Honeymead Brook and Plattsburg Barracks reported deficiencies of temperature.

"The average total precipitation over the State for the year was 40.30 in., as derived from the records of 121 stations. The maximum local precipitation was 59.26 in. at Setauket, while the minimum was 19.85 in. at Mt. Morris. The greatest monthly average for the State was 6.88 in. in July, the least being 1.10 in. in March. The greatest local monthly precipitation was 18.18 in. at Setauket in July, and the least was 0.13 in. at Poughkeepsie in October. The total depth and distribution of precipitation over the State are shown in the fourth chart of this report, and the average daily amounts by the sixth chart. The average precipitation during 1897 at 27 stations possessing records for previous years was 1.49 in. above the normal amount. Deficiencies were reported from 12 stations, the greater number of which were located in western and central New York. The amounts exceeded any annual rainfall previously recorded at Honeymead Brook and Setauket, while at Cortland the rainfall was the least on record. The average total snow fall at 53 widely distributed stations was 59.9 in. The heaviest snow fall, exceeding 100 in., occurred on the highlands east of Lakes Ontario and Erie, the maximum local amount being 145 in. at North Lake. On the coast and in the central valleys the total depth ranged from 25 to 40 in.

"The average number of days on which the precipitation amounted to 0.01 in. or more was 127. The number was largest near the Great Lakes and over the Northern Plateau, and least in the southeast and near the Central Lakes.

"The average number of clear days for the State was 118, of partly cloudy days 113, and of cloudy days 134, giving an average cloudiness of 53 per cent."

New work in the Weather Bureau, W. L. MOORE (*U. S. Dept. Agr. Yearbook 1898, pp. 81–86*).—A brief account of the extension of the work of the Weather Bureau during 1898 along the following lines: Additional stations of observations in the arid and subarid West and in the principal cotton-producing regions of the

South; the establishing of 17 aerial meteorological stations; the inauguration of a tentative West Indian daily cablegraphic meteorological service.

Meteorological observations, J. E. Ostrander and A. C. Monahan (*Massachusetts Hatch Sta. Met. Buls. 127, 128, 129, pp. 4 each*).—These bulletins give the usual summaries of meteorological observations, with general notes on the weather during the months of July, August, and September, 1899.

Meteorological report, J. Dryden (*Utah Sta. Rpt. 1898, pp. XX, XXI*).—This is a monthly summary of observations on temperature and precipitation during 1891–1897. The mean temperature during 1897 was 46.5° F., the average for the 7 years being 46.4°. The precipitation during 1897 was 17.45 in., the average for the 7 years being 15.22 in.

The velocity and force of the wind (*Rev. Sci. Paris, 4. ser., 12 (1899), No. 14, p. 443*).—A brief reference to work of Köppen on this subject.

Cyclones, hurricanes, and tornadoes, F. H. Bigelow (*U. S. Dept. Agr. Yearbook 1898, pp. 525 534*).—A brief discussion of the origin and characteristics of these 3 classes of storms.

The terrestrial atmosphere, E. Tassilly (*L'Atmosphère terrestre. Paris: Société d'Éditions Scientifiques, 1899, pp. 110*).

The use of kites in the exploration of the upper air, C. F. Marvin (*U. S. Dept. Agr. Yearbook 1898, pp. 201–212, pl. 1, figs. 9*).—The standard kite and apparatus used by the Weather Bureau in explorations of the upper air are described and detailed directions for building and flying a tailless kite of modern type are given.

The kite as an instrument of meteorological research, C. F. Marvin (*Jour. Franklin Inst., 148 (1899), No. pp. 241–259, figs. 6*).

Diurnal variation in atmospheric electricity, A. B. Chauveau (*Compt. Rend. Acad. Sci. Paris, 129 (1899), No. 13, pp. 500, 501; abs. in Rev. Sci. Paris, 4. ser., 12 (1899), No. 15, p. 472*).

Investigations on the influence of forests on floods (*Centbl. Gesam. Forstw. Wien, 25 (1899), No. 10, pp. 434–437*).—A brief account is given of the action of a committee of the Association of Forestry Experiment Stations appointed to formulate plans for investigations on this subject. An outline plan of observations was adopted. This includes, in addition to the usual meteorological observations, measurements of the flow of streams and observations on precipitation, evaporation, soil moisture, drainage, and position of ground water.

WATER—SOILS.

Soil moisture, J. T. Willard and R. W. Clothier (*Kansas Sta. Bul. 89, pp. 22, charts 5*).—This is an account of experiments on soil moisture during 2 years in continuation or extension of previous experiments along the same line (E. S. R., 9, p. 138).

"The experiments described are of two types, those to test the effects of the addition of certain fertilizers to soils, with reference to soil moisture, and those to show the effects of tillage.

"Experiments with soil in pots, tried under the most rigid conditions available, showed that the rate of evaporation of water from soils is not sensibly affected by the addition to the soil of relatively large amounts of the substances ordinarily used as fertilizers, nor by certain others.

"Experiments with outdoor plats where both evaporation and drainage came into play, showed no decided effect from the fertilizers except with the plat to which unleached ashes were applied, which lost water more readily than any of the others."

The substances experimented with in pots included muriate of potash, salt, magnesium chlorid, sulphate of potash, kainit, carnallite, and superphosphate at the rate of 904 lbs. per acre, slaked lime at the rate of 12 bu. per acre, and barnyard manure at the rate of 28 tons per acre. In the plat experiments the substances used were muriate of potash, salt, magnesium chlorid, sulphate of potash, sodium nitrate, potassium nitrate, ammonium sulphate, superphosphate, and gypsum at the rate of 500 lbs. per acre, lime and wood ashes at the rate of 2,000 lbs. per acre, and manure and leaf mold at the rate of 40,000 lbs. per acre.

"Experiments to test the relative efficiency of different kinds of culture in conserving soil moisture showed that simple plowing while the soil was in good condition was as efficacious as plowing followed by planking, rolling, harrowing, or subsurface packing. Disking was found to be a good means of saving moisture, but was not equal to plowing.

"The importance of plowing stubble ground as early as possible while moisture is still in the soil was shown by experiments in 2 years. Early plowing left the ground in good condition, as regards soil moisture, for wheat seeding, while late-plowed ground was dangerously dry.

"The efficiency of the dry soil or dust mulch, and its superiority in the long run over a straw mulch, were strikingly shown."

In these experiments it was found that a sampling tube cutting a one-inch core was much less likely to choke and gave more accurate samples than one having a smaller diameter.

Oklahoma soil studies, J. H. BONE (*Oklahoma Sta. Bul. 42, pp. 26, figs. 8*).—In this bulletin an account is given of experiments during 3 years on the influence on soil moisture of plowing, subsoiling, cultivation, rolling, and manuring; data on the moisture content of upland and bottom lands, mechanical analyses, specific gravity, water-holding capacity, and rate of evaporation of different kinds of soil; and humidity and rainfall of 1898 are also reported and discussed. The moisture content was calculated from determinations made in samples taken in the usual way, the results being given in tables and diagrams.

"Soil plowed in March contained more moisture than that plowed about the middle of April. Shallow plowing did not maintain as much moisture in the soil as deep plowing. Subsoiled land contained more moisture than land not so treated. The yield of corn on a plat subsoiled in the spring was less than on a plat not subsoiled. Stubble should be plowed as soon after harvest as is convenient, and harrowed occasionally until sown to wheat. . . .

"The frequency of the cultivation of crops depends upon the season. Plats having two cultivations gave larger yields than others having nine cultivations. . . . Poor cultivation affects Indian corn more than it does Kafir corn.

"Increasing the supply of decayed vegetable matter is desirable for most Oklahoma soils. In one case there was an average difference of 2.5 per cent of soil moisture in the first foot of soil during the period of most active growth in favor of the soil manured and subsoiled.

"Rolling did not tend to conserve soil moisture or increase the crop yield. Rolled soil is blown by winds more readily and is not in condition to receive the rainfall to the best advantage.

"Bottom land did not dry out so completely as upland, nor did it hold as much moisture when full. . . .

"The soil moisture was much higher during 1898 than during 1897. Upland prairie contained a yearly average of 18.5 per cent in 1898 and 16.6 per cent during 1897.

Upland plowed soil to the depth of from 3 to 12 in. contained 18.2 per cent of moisture during 1898 and 16.6 per cent during 1897."

Science of soils, P. V. OTOTSKI, editor (*Pochvovyedyeniye. St. Petersburg: Soil Comm. Imp. Free Econ. Soc., 1899, No. 1; rev. in Selsk. Khoz. i Lyesov., 193 (1899), June, pp. 716–713*).—Of the articles in the first number of this new periodical two are of especial interest: (1) The science of soils and forestry, by G. F. Morozov, and (2) the soil zones of European Russia, in connection with the salt (alkali) content and the character of the forest vegetation, by G. N. Vysotski. In the latter article the author points out the relation of the salt content in the subsoils to the soil zones. As is well known, the soils of the plains of European Russia can be divided, according to the classification of Sibirtzev, into zones, from the north to the south, in the following order: (1) "Podzols" (more or less pure, fine silica; the German *Bleisand*), (2) gray forest soils, (3) chernozem, and (4) soils of the dry (desert) steppes. In the same direction a gradual increase of the amount of soluble salts is observed in the subsoils. In the first zone no such salts are found; the second zone is characterized by the presence of calcium carbonate; in the third zone there is observed besides lime, gypsum, and in the fourth zone are found besides these salts common salt and its usual associates. In correspondence with this each zone is characterized by its particular vegetation. The first zone is the region of mixed forests, the second of oak forests, the third of steppe bushes, and the fourth is distinguished by the vegetation peculiar to alkali lands.—P. FIREMAN.

On the waters of the salt lake of Urmi, R. T. GÜNTHER and J. J. MANLEY (*Proc. Roy. Soc.* [*London*], *65* (*1899*), *No. 419, pp. 312–318*).—The results of chemical and physical examinations of the water of this Persian lake are reported.

Bacteriological examinations of water samples, F. D. CHESTER (*Delaware Sta. Rpt. 1898, pp. 50–52*).—Notes are given on bacteriological examinations of 2 samples of water from which several bacteria were isolated. Two of the species were of especial interest since the presence of colon bacillus indicated an infection with fæcal matter, and the *Bacillus ærogenes* indicated a contamination with milk refuse or other household waste.

The study of the soil, A. DE VILLÈLE (*Rev. Agr. Reunion, 5* (*1899*), *No. 7, pp. 303–306*).

The soluble mineral matter of soils, T. H. MEANS (*U. S. Dept. Agr. Yearbook 1898, pp. 495–504*).—A general discussion of this subject under the following heads: The weathering of rocks and formation of soluble matter, absorption of salts by soils, conditions favoring the formation of alkali, kinds of alkali, effect of irrigation upon alkali, and methods of removing alkali.

The movement and retention of water in soils, L. J. BRIGGS (*U. S. Dept. Agr. Yearbook 1898, pp. 399–404*).—This subject is briefly discussed under the following heads: Surface tension of water, capillary movement of water, and the influence of texture of soils upon movement of water. A technical discussion of this subject has been given in a bulletin of the Division of Soils of this Department (E. S. R., 9, p. 732).

Soil temperatures at Riga, G. SCHWEDER, Jr. (*Die Bodentemperatur bei Riga. Riga, 1899, pp. 24*).

On the soil relations of the North German flat lands, G. F. BURGUY (*Inaug. Diss., Berlin, 1899, pp. 51*).

The soil relations of the Prussian flat lands, a geological-agronomic sketch, H. GRUNER (*Die Bodenverhältnisse des preussischen Flachlandes; eine geologisch-agronomische Skizze. Berlin: Paul Parey, 1898, pp. 20*).

Control and fixation of shifting sands, J. GIFFORD (*New York, 1898, pp. 14; reprinted from Engineer. Mag., Jan., 1898*).

The reclamation of drifting sand dunes, J. MCLAREN (*Forester, 5 (1899), No. 10, pp. 222, 223*).—Gives an account of experiments in Golden Gate Park, San Francisco. The sand was first bound with *Calamagrostis arenaria*, after which a large number of trees were planted, the most satisfactory ones being *Acacia latifolia*, *A. lophantha*, the Monterey pine, the Monterey cypress, and the tamarisk and several species of Eucalyptus.

The progress of marsh culture during late years, C. VON FEILITZEN (*K. Landt. Akad. Handl., 33 (1899), No. 3, pp. 154–167*).

The practical bearing of some of the field and pot experiments conducted at the Rhode Island Station, H. J. WHEELER (*Rhode Island Sta. Bul. 53, pp. 51–63*).—A summary of the results of direct practical value obtained in investigations on potato scab (E. S. R., 10, p. 967); the poisonous or unsatisfactory action of ammonium sulphate as a fertilizer (E. S. R., 9, p. 937); the effect of acid soils on the growth of plants (E. S. R., 10, p. 939); the distribution of acid soils in Rhode Island (E. S. R., 10, p. 938); the assimilability of the nitrogen in nitrate of soda, sulphate of ammonia, and dried blood on an acid soil before and after liming (E. S. R., 10, p. 937); and the fertilizer requirements of different kinds of soil (E. S. R., 10, p. 937).

Soil bacteria in their relation to agriculture, F. D. CHESTER (*Delaware Sta. Rpt. 1898, pp. 59–100, figs 2*).—This is the full technical review of investigations on this subject, a popular summary of which was given in Bulletin 40 of the station (E. S. R., 10, p. 334). This paper "contains all references, and the detailed results of studies of the bibliography of soil bacteriology, exclusive of the subject of nitrogen assimilation, which will be considered in a future report."

FERTILIZERS.

The preservation and relative value of the nitrogen of barnyard manure, C. RAGOYSKI (*Inaug. Diss., Leipsic, 1899; abs. in Chem. Ztg., 23 (1899), No. 64, Repert., p. 235; Ztschr. Landw. Versuchsw. Oesterr., 2 (1899), p. 391; Ann. Agron., 25 (1899), No. 5, pp. 244–248; Jour. Chem. Soc. [London], 75 (1899), No. 441, II, p. 512*).—The experiments here reported were made with 6 kg. lots of an artificial manure consisting of 61.7 per cent of cow dung, 26.7 per cent of liquid manure, and 11.6 per cent of straw. The lots of manure were kept for 56 days in glass cylinders either alone or treated with various preservatives—a mixture of sulphuric and hydrofluo-silicic acids (a by-product from the manufacture of aluminum), calcium carbonate, lime and soil, and soil alone.

The untreated manure lost 36.6 per cent of its nitrogen in 56 days. The addition of 1 per cent of the acid mixture reduced the loss to 4.7 per cent. This is a greater saving than can be accounted for by the fixing of the ammonia by the acids, and is attributed in part to the action of the hydrofluo-silicic acid in checking biological processes in the manure. Lime was very effective in preserving the nitrogen, but its action was irregular. In one case with lime used in connection with a covering of soil there was an actual gain of nitrogen; in another the loss was only 7 per cent. When lime was used in connection with soil mixed with the manure the loss was 17.6 per cent. Soil alone used as a covering to the manure reduced the loss to 18.8 per cent; mixed with the manure the loss was 22.3 per cent.

An examination of the nitrogenous matter of the manure by Stutzer's copper hydroxid method showed an increase of 25.6 per cent in the insoluble (albuminoid) nitrogen in manure treated with 1 per cent of the acid mixture, 33 to 38.5 per cent with lime and soil, and 41.2 per cent with soil alone mixed with the manure. Pot experiments with mustard, however, did not indicate that this nitrogen was unassimilable.

The author concludes that only the nitrogen of the liquid manure was available to the plants.

It was observed that the more highly nitrogenous the manure the less the amount of water required to produce a unit of dry matter in the crop.

P. P. Dehérain questions the accuracy of these results on account of the smallness of the samples of manure experimented with. He also points out that while only the nitrogen of the liquid manure was utilized in the time over which the experiment extended, that of the feces and straw would undoubtedly have become available in time.

Plat experiments with legumes, W. S. SWEETSER (*Pennsylvania Sta. Rpt. 1897–98, pp. 120–133*).—This article is a report on plat experiments with legumes conducted for the purpose of comparing the amount of total dry matter, ash, nitrogen, phosphoric acid, potash, and lime in the different crops. Crimson clover was grown on 3 different plats and timothy on 1 plat for comparison. Each crop is briefly described, and the results are tabulated. The amounts of dry matter and fertilizing substances produced per acre by the various crops, considering the entire plant, are given in the table below:

Yields of forage plants per acre (tops and roots).

	Total yield.	Dry matter	Ash.	Organic matter	Nitrogen.	Phosphoric acid.	Potash.	Lime.	Nitrate of soda furnishing same amount of nitrogen.
	Lbs	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*
Flat pea	41,412	9,073	906	8,167	239.8	49.8	161.8	122.2	1,495 7

Note on phosphates, J. JOFFRE (*Bul. Soc. Chim. Paris, 21 (1899), No. 10, pp. 511–513*).—In previous experiments (E. S. R., 10, p. 218) in the laboratory the author showed the low solubility of apatite and other forms of tricalcium phosphate both in pure water and in water containing carbon dioxid. The present article reports the results of tests of the fertilizing value of different phosphates with white mustard grown in sand or mixtures of sand with peat and calcium carbonate. The comparative effectiveness of the different phosphates thus found is shown in the following table:

Comparative fertilizing effect of different phosphates on white mustard.

	Sand.	Artificial soil.
Without phosphate	100	100
Apatite	100	112
Tricalcium phosphate (bone ash)	150	142
Tricalcium phosphate, gelatinous	246	197
Monocalcium phosphate	321	359

Analyses of commercial fertilizers, J. L. HILLS, C. H. JONES, and B. O. WHITE (*Vermont Sta. Buls. 69, pp. 41–51; 70, pp. 55–68; 71, pp. 71–116*).—These bulletins report results of inspection of fertilizers in Vermont during the spring of 1899, comparing the results with those obtained in previous years.

"The station has analyzed 137 brands, the output of 18 companies, all drawn from dealers' stocks, all this year's goods.

"Three-fourths of the brands were up to or above guaranty, one-fourth fell short somewhat, while one-tenth failed to furnish a commercial equivalent of their guaranties. A few cases of deficiency were serious. The percentage of failure to meet claims is greater than has been found of late years.

"While as a rule the quality of the crude stock used was good, there were some cases which seem open to criticism. Two-fifths of the brands carried no water-soluble nitrogen. Laboratory methods seem to indicate that somewhat inferior forms of nitrogen were used in certain cases, notably in some low-grade goods and by some companies. The phosphoric acid was in some cases quite largely in the insoluble or reverted forms, indicating apparently either imperfect manufacture, old goods, or more or less use of (agriculturally) inferior forms of this ingredient. Sulphate of potash is claimed to be present in nine-tenths of the brands, but was actually found in less than one-eighth of the entire number.

"The average selling price approximated $28.75, and the average valuation $17.39. Two dollars in every five paid for fertilizers met costs of manufacture and sale. The same amount of plant food which cost a dollar might have been bought at retail for cash at the seaboard for 56 cts. in average low-priced goods, for 61 cts. in average medium-grade goods, and for 66 cts. in average high-priced goods. In one-third of the entire number of brands a dollar was charged for amounts of plant food which might have been bought in the manner above stated for 55 cts. or less. 'Cheap fertilizers' are usually the most expensive to buy.

"The average composition of the brands sold is slightly lower than last year. Selling prices have dropped and plant food is as cheap as it ever was. Notwithstanding these facts, buying mixed goods on time is still a far more costly method of getting plant food than is home mixing or buying on special order.

"The comparison of analyses of 133 brands for 5 years shows in some essential evenness and in others considerable variation in composition."

Manures in Egypt and soil exhaustion, G. P. FOADEN and W. C. MACKENZIE (*Jour. Khed. Agr. Soc. and School Agr., 1 (1899), No. 4, pp. 129–170*).—A general discussion of this subject, special attention being given to the fertilizing value of Nile mud, barnyard manure, sebakh coufri (remains of ancient villages), bones, nitrate-bearing clays, and sewage, and to the demand on the fertility of the soil of cotton, "berseem" (Egyptian clover), "berseem-bagazi" (alfalfa), sugar cane, wheat, barley, maize, beans, and potatoes.

Straw and peat for litter (*L'Ing. Agr. Gembloux, 10 (1899), No. 1, pp. 37–39*).—Their comparative merits are discussed.

Manurial value of ammonium sulphate, J. MUIR (*Jour. Gas Lighting, 74 (1899), pp. 163–168, 223–227, 287–292, 359–364; abs. in Jour. Soc. Chem. Ind., 18 (1899), No. 9, p. 846*).—A prize essay summarizing the information on this subject.

General fertilizer experiments, E H. HESS (*Pennsylvania Sta. Rpt. 1897–98, pp. 146–153*).—This is a summary of results obtained during 1897 in combined fertilizer and rotation experiments begun at the station in 1883 (E. S. R., 9, p. 823).

Commercial fertilizers, H. J. WHEELER, B. L. HARTWELL, and C. F. KENYON (*Rhode Island Sta. Bul. 54, pp. 67–85*).—This bulletin discusses fertilizer inspection in Rhode Island, makes suggestions regarding the purchase and sale of fertilizers, gives a schedule of trade values of fertilizing materials, explains the terms used in fertilizer analysis, and reports analyses and valuations of 13 samples of fertilizers.

Analyses of commercial fertilizers, M. B. HARDIN (*South Carolina Sta. Bul. 43, pp. 30*).—This includes statements regarding the composition and valuation of fertilizers, directions for taking samples, the law and regulations governing the sale of fertilizers in South Carolina, and analyses and valuations of 327 samples of fertilizers inspected during the season of 1898–99.

Fertilizers and fertilizer analyses, H. H. HARRINGTON (*Texas Sta. Bul. 51, pp. 24–38*).—The text of the law providing for the inspection of fertilizers and commercial poisons recently passed by the legislature of Texas, and discussions of the nature, function, valuation, and use of fertilizers, and analyses of 15 samples of fertilizing materials, including bat guano and bat-guano ash, mineral phosphates, acid phosphates, bone meal, tankage, cotton-hull ashes, sulphate of ammonia, kainit, and barnyard manure.

Commercial fertilizers, B. H. HITE and T. F. WATSON (*West Virginia Sta. Bul. 57, pp. 12*).—This bulletin gives a schedule of trade values of fertilizing materials and tabulated analyses and valuations of 149 samples of fertilizers.

Commercial fertilizers, H. A. HUSTON and W. J. JONES (*Purdue Univ. Spec. Bul., May, 1899, pp. 8*).—This bulletin discusses the extent of the fertilizer trade in Indiana and gives the text of the amended fertilizer law which went into effect April 28, 1899; notes on valuation, and tabulated analyses and valuations of 386 samples of fertilizers legally on sale in Indiana in May, 1899. The amended law provides for the taking of samples of fertilizers actually found in the market. Heretofore only analyses of samples supplied by the manufacturer have been published.

FIELD CROPS.

Cotton experiments, B. C. PITTUCK (*Texas Sta. Bul. 50, pp. 21*).—Variety, fertilizer, and distance experiments were continued in 1898 (E. S. R., 10, p. 342). No fertilizers were added in 1898, the residual effect of the applications made in 1897 being observed. The data for the different experiments are tabulated. Short descriptions are given of 31 varieties of cotton grown either in the variety or fertilizer tests and the same classified with regard to quality.

Twelve varieties were tested at the station and also at the Beeville Substation. Beck Big Boll has given the largest average yield of seed cotton for a period of 3 years at the station, 1,390 lbs. per acre. This variety also gave the largest money returns of the varieties tested in

1898, though the largest yield of seed cotton in 1898 was afforded by Dixon Improved, 1,390 lbs. per acre. At the Beeville Substation the largest yields of seed cotton of varieties tested in 1898 were made by Nancy Hanks, Gilbert Lamb Wool, and Hawkins Extra Prolific; and the largest money returns by Hawkins Extra Prolific, Griffin Drouth Proof, and Nancy Hanks, in the order named.

The residual effect of the fertilizers in 1898 was much greater than the original effect in 1897, the increase over the control plats varying from 0.77 to 65.9 per cent, while in 1897 the increase over the controls varied between 0.77 and 11.8 per cent. The largest yields of seed cotton were obtained on the plats which had been fertilized with cottonseed meal at the rate of 500 lbs. per acre. The plats fertilized with either boneblack or bone meal followed quite closely. Plats fertilized with wood ashes gave the best results among those which had received potash and lime fertilizers and plats fertilized with barnyard manure and acid phosphate the best among those receiving complete fertilizers. There was but little difference in the average yields of seed cotton of 5 varieties whether they were planted in rows 3 by 2, 4 by 2, or 4 by 3 ft. apart, but a considerable decrease in yield followed when the cotton was planted in rows 5 ft. apart and 3 ft. distant in the rows.

Varieties of cotton, J. S. NEWMAN, D. R. COKER, and H. HAMMOND (*South Carolina Sta. Bul. 42, pp. 8*).—Data for tests of 18 varieties of cotton at the station, 4 in the upper pine belt in Darlington County, and 8 on heavy clay soil on Beech Island, are reported.

Texas Oak, Bates Improved Prolific, and Drake Cluster, in the order named, gave the largest yield of lint per acre at the home station. Considerable variation in the earliness of the different varieties is shown. King Improved had yielded 92 per cent of its entire crop up to October 27, while Peterkin Improved had yielded up to the same period but 69 per cent. Bates Improved Prolific had the largest proportion of lint to seed cotton, 37.6 per cent. Ginned samples of the different varieties were classified by experts as "fully middling," "good middling," and "fully good middling," with the exception of Kennard and Jackson Limbless, which were graded as "barely good middling."

Jones Improved gave the best yield of the 4 varieties tested in the upper pine belt region, 468.58 lbs. of lint per acre; and African, King, and Truitt, in the order named, the largest yields of seed cotton of the 8 short staple varieties tested at Beech Island.

Experiments with nitrate of soda on forage crops, E. B. VOORHEES (*New Jersey Stas. Bul. 136, pp. 28–31*).—Experiments were made in fertilizing corn, oats, peas, barnyard millet, cowpeas, and soy beans with nitrate of soda, on a fair quality of clay loam in a good state of cultivation. Five groups of 2 plats each were used. They had previously received fertilizers at the rate of 200 lbs. of acid phosphate and 100 lbs. of muriate of potash per acre. One plat of each group was left unfertilized; the other was fertilized at the rate of 75 lbs. of nitrate of soda at the time of seeding and 75 lbs. later. The dates of seeding the different crops, total yields per acre, cost of increased yield, etc., are shown in tabular form. The results show a much larger increase from fertilizer with cereals than with legumes, the increase varying from 10.9 per cent with cowpeas to 52.5 with oats and peas. The nitrate had a tendency not only to increase the yield of the different crops, but to hasten the period of development. The cost of the increase with nitrate of soda amounted to only one-fourth its average value in the case of corn, millet, and oats. For the cowpeas and soy beans, however, the cost was considerably higher and left a profit only in the case of the cowpeas.

Experiments with different forms of nitrogen on white potatoes, G. A. MITCHELL (*New Jersey Stas. Bul. 136, pp. 26–28*).—An experiment was made to determine the relative value for potatoes of different forms and varying amounts of nitrogen fertilizers on light sandy soil poor in physical condition. Twenty plats, each $\frac{1}{20}$ acre in extent, were used, and from 150 to 350 lbs. of nitrate of soda, 120 to 280 lbs. of sulphate of ammonia, and 340 to 800 lbs. of cotton-seed meal per acre, applied separately to the different plats. The quantity of fertilizer used per acre on each plat and yields from the different plats are tabulated. Owing to the poor physical condition of the soil the yields in all cases were low, not exceeding in any instance 95 bu. per acre. The nitrate of soda was the most effective form of fertilizer used, the increased yield from this material being 84 per cent, while that from ammonia was 77 and from cotton-seed meal 38 per cent greater than the control plat.

Experiments with wheat, corn, and potatoes, H. J. PATTERSON ET AL. (*Maryland Sta. Bul. 62, pp. 187–205*).—The experiments consisted of variety tests with wheat; culture experiments with corn; and variety, culture, and spraying experiments with potatoes.

Wheat.—The best yields in a test of 30 varieties in 1898 were made by Lebanon 35.4 bu., Currell Prolific 35.3 bu., and Dietz 34.5 bu. per acre. Data for the yields of 80 varieties tested since 1889 are given. Fultz has given the largest average yield of any of the varieties tested for 7 years, 36.1 bu. per acre.

Corn.—Data of tests to determine the relative value of deep and shallow cultivation, different numbers of cultivations, wide and narrow rows, and planting in drills and checks are tabulated for each year from 1883 to 1898, as is also the rainfall for the growing season. The average yields for this period are slightly in favor of deep cultivation. Corn drilled in rows 3¾ ft. apart and 22½ in. distant in the row has given increased yields each year of the test over corn planted in hills 3¾ ft. distant each way and 2 stalks in a hill. Only inconclusive results have been obtained in the other tests.

Potatoes.—Holton Rose and Carman No. 3 gave the best yields of 52 varieties tested in 1897, 263.6 and 252.9 bu. per acre, respectively; while the 3 leading varieties in 1898 were Vigerosa, 134 bu., Early Vaughn, 132 bu., and Bovee, 131 bu. per acre.

Potatoes sprayed with Bordeaux mixture have given increased yields over unsprayed potatoes each year from 1893 to 1898, and but little difference has been observable whether early or late spraying was practiced. Deep cultivation and narrow rows have given slightly better yields than shallow cultivation and wide rows. No decisive results either way have been obtained in the test of early *vs.* late and ridge *vs.* flat cultivation.

Experiments in the seeding of sainfoin and lucern (*Jour. Bd. Agr.* [*London*], *6* (*1899*), *No. 1*, *pp. 39–44*).—The results, and in some cases the tabulated details, are given of experiments carried out in several places in England to determine (1) "the relative values of sainfoin and lucern, (2) the effect of sowing these seeds broadcast and with a drill, and (3) the relative results obtained by sowing them alone or mixed with grass and clover seed." The nature of the different soils is noted in each instance. In general heavier crops were secured with both sainfoin and alfalfa when they were mixed with grasses and clovers than when they were sown alone. Not much difference was noticeable in the yields from plats sown broadcast and those that were drilled. The data as to the relative yields of the two plants on different plats are conflicting.

The sugar beet in Maryland, H. W. WILEY (*Maryland Sta. Bul. 61*, *pp. 169–186*).—A detailed historical account is given of the sugar beet in Maryland, with notes on the possibility of its successful culture in some portions of the State. Tabulated analytical data show the sugar content and percentage of purity of the crop grown in the State in cooperative tests during the season of 1898. The average weight of 31 samples of sugar beets grown in 1898 was 22 oz., average sugar content 10.4 per cent, and average coefficient of purity 76 per cent.

In the present state of the industry the author believes that "Maryland can not successfully compete in the manufacture of beet sugar with the more favorable localities of the United States."

Utah sugar beets in 1898, L. FOSTER and J. STEWART (*Utah Sta. Bul. 59*, *pp. 93–129*).—This bulletin summarizes the results of 5 years' experiments with sugar beets in Utah, suggests future lines of work that may be profitably undertaken with this crop, discusses the development of the sugar-beet industry, process of manufacture, and beet-sugar factory conditions in Utah; and gives the analyses and other data for 316 samples of sugar beets grown in cooperative experiments throughout the State in 1898.

The beets grown in 1898 had an average sugar content of 15.82 per cent and a purity of 86.89 per cent. The average sugar content for all the beets grown in the State during the 5 years' experimentation is 14.66 per cent, and the average purity 84.85. Several of the samples analyzed in 1898 had been grown on slightly alkali soils. The sugar content and purity of all of these samples were high.

The authors consider that experiments in this line have now progressed sufficiently to demonstrate the suitability of Utah for sugar-beet culture, and in future the station will confine its investigations to special problems in their culture or in the use of sugar-beet factory by-products.

The progress of "moor culture" in Prussia, H. HEINE (*Fühling's Landw. Ztg.*, *48* (*1899*), *Nos. 14, pp. 550–554; 15, pp. 567–571*).—A history of the improvement of moor lands in Prussia, with a description of the methods employed.

The influence of methods of sowing on the growth of the grain (*Landw. Wchnbl. Schleswig-Holstein, 49* (*1899*), *No. 32, pp. 593–595*).—A popular discussion on how the growth of cereals is affected by the time and methods of seeding.

How commercial fertilizers should be used on clay, loam, sand, and marsh soils, K. DE VRIEZE (*Hoe kunstmest gebruikt moet worden op klei-,leem-,zand- en veengronden. Groningen: J. B. Wolters, 1899, 4. enl. ed., pp. VIII+116*).

The improvement of cultivated plants, J. H. MANSHOLT (*Orgaan Ver. Oudleer. Rijks. Landbouwschool, 11* (*1899*), *No. 134, pp. 143–147*).—A discussion of the different methods employed.

Field experiments in 1897–98 (*Bul. Agr.* [*Brussels*], *15* (*1899*), *No. 4, pp. 179–204*).—Results of cooperative experiments in testing varieties of oats, potatoes, and rye in the various provinces of Belgium are given in tabular form.

Belgian agricultural cooperative societies (*Jour. Bd. Agr.* [*London*], *6* (*1899*), *No. 1, pp. 22–27*).

The Holtdorf culture experiments in 1897–98, WOLCKENHAAR (*Landw. Wchnbl. Schleswig-Holstein, 49* (*1899*), *No. 36 pp. 675–678*).—Partial data are given for variety tests with rye, winter oats, wheat, oats, and potatoes. The best yields of the late varieties of potatoes were made by Silesia, 30,050 kg. per hectare; and Professor Maercker, 28,450 kg. per hectare, followed by Queen of the South, Professor Sidam, Professor Kühn, and Schwan, all with yields exceeding 20,000 kg. per hectare.

Experimental work in field and garden, A. LOW (*Trans. Massachusetts Hort. Soc. 1899, pt. 1, pp. 21–31*).—This is a paper read before the Massachusetts Horticultural Society, in which the author gives his results obtained in variety and culture experiments with garden peas, sweet corn, potatoes, and several miscellaneous crops for green manuring. Alaska was the earliest garden pea, Quincy Market the earliest variety of sweet corn, and Early Fortune one of the earliest and most satisfactory potatoes tested. In a comparison of the relative values of seed potatoes from different localities the best yields were usually from seed obtained from the more northern districts. Of 10 varieties of potatoes tested, Carman No. 1, Carman No. 3, Enormous, and Uncle Sam proved the most hardy against blight.

Arrowroot, A. J. BOYD (*Queensland Agr. Jour., 4* (*1899*), *No. 5, pp. 335–339, fig. 1*).—This gives directions for growing the crop and handling the bulbs, together with a description of the machinery used in working up the crop.

Culture of winter barley on sandy soils, W. BESELER (*Deut. Landw. Presse, 26* (*1899*), *No. 58, p. 668*).—A brief report on a culture experiment with winter barley on sandy soil.

The cultivation of broom corn, D. JONES (*Queensland Agr. Jour., 4* (*1899*), *No. 6, pp. 424–426; 5* (*1899*), *No. 1, pp. 1–7, figs. 5*).—A discussion of the characteristics of the more desirable varieties of broom corn now being grown in Queensland, with directions for its culture and a description of the machinery employed.

Sweet and bitter cassava, S. BOYCE (*Florida Agr., 26* (*1899*), *No. 40, p. 690*).—Notes on the different physical characteristics of sweet and bitter cassava, with detailed directions for extracting the poisonous principles of bitter cassava before it is used as food.

Cassava and velvet beans, G. E. PYBUS (*Florida Agr., 26* (*1899*), *No. 39, pp. 596, 597*).—Cultural suggestions based on the results of the author's experience in growing these plants.

Corn culture, P. THIELE (*Der Maisbau. Stuttgart: Eugen Ulmer, 1899, pp. 152, figs. 61*).—This work is intended as a guide to the culture, care, and improvement of corn and is based on studies made by the author in the corn-growing districts of Hungary. Besides dealing with the ordinary cultural operations, the uses of corn and its improvement by selection are discussed and descriptions given of 30 different varieties of corn with illustrations of the ear and kernels in each case. The machinery used in cultivating, shelling, and grinding corn are also described and illustrated, as well as cribs for storage, etc.

Report on experiments in the cultivation and preparation of flax in Demyan district, in the Government of Novgorod, in the years 1896–1898, A. P. MARG (*Selsk. Khoz. i Lyesov., 192 (1899), Feb., pp. 363–388*).

Suggestions on the improvement of flax culture, KUHNERT (*Mitt. Deut. Landw. Gesell., 14 (1899), No. 14, pp. 221–226*).

The culture of sisal hemp (Agave sisalana), A. TERRACCIANO (*Bol. R. Orto Bot. Palermo, 2 (1898), No. 3–4, pp. 91–111*).

Russia's flax and hemp crops of 1898 (*U. S. Consular Rpts., 1899, No. 229, p. 230*).—Statistics on area and yield for the years 1896-1898.

Millets, T. A. WILLIAMS (*U. S. Dept. Agr. Yearbook 1898, pp. 267–290, figs. 6, pls. 2*).—This is a popular article giving descriptions of cultivated varieties of millets, their uses, feeding value, and fertilizing value. Cultural methods are suggested and injuries resulting from feeding millet discussed.

The author separates the different varieties into 3 groups, namely, foxtail, barnyard, and broom corn millets. Under foxtail millets, Common millet (*Chætochloa italica*), German millet (*C. italica*), Golden Wonder millet (*C. italica*), and Hungarian millet (*C. italica* var. *germanica*) are given as standard varieties of the group. Under barnyard millets, Shama millet or jungle rice (*Panicum colonum*), Sanwa millet (*P. frumentaceum*), and barnyard millet (*P. crus-galli*) are described. Under broom-corn millets Manitoba, Californian Beauty, French, Turkish, Broom corn, White French, Chinese White, Japanese White, Red French, and Japanese Red are mentioned.

Study on sugar cane, H. PELLET (*Sucr. Indig., 53 (1899), Nos. 15, pp. 444–447; 16, pp. 479–481*).

Yields of beets as affected by light (*Beet Sugar Gaz., 1 (1899), No. 8, pp. 18, 19*).—This article summarizes the results which have been obtained in growing sugar beets in partial darkness and in light. Light increases the percentage of sugar in the beet and decreases the nonsugar and water constituents.

Germany's beet-sugar industry from 1877 to 1899, H. W. DIEDERICH (*U. S. Consular Rpts., 1899, No. 226, pp. 471–474*).—A tabular compilation of statistics bearing on the beet-sugar industry of Germany during the past 20 years.

The sugar industry in Roumania, A. E. MISLIN (*Oesterr. Chem. Ztg., 2 (1899), No. 17, pp. 458–464*).—This is a communication from the experiment station at Bucharest on the growing of sugar beets, including the time of seeding, distance of planting, size of seed, use of fertilizers, varieties, and meteorological data; and the technology of beet-sugar manufacture.

Some figures from two Westmoreland sugar estates, P. H. GREG (*Jour. Jamaica Agr. Soc., 3 (1899), No. 9, pp. 521–533*).—Data on the yields per acre, juice in canes, value of product, etc.

Tobacco culture, J. M. PRIEGO (*El cultivo del tabaco. Madrid: M. G. Hérnández' Sons, 1899, pp. 133*).—The work treats of the tobacco plant in general and discusses soils, climate, cultivation, varieties, and their degeneration, cost of production, and the different products obtained.

Improving the quality of tobacco by means of fertilizer applications, A. STUTZER (*Tropenpflanzer, 3 (1899), No. 6, pp. 260–263*).

Tobacco, T. H. SHARP (*Jour. Jamaica Agr. Soc., 3 (1899), No. 9, pp. 550–554*).—Popular articles on the culture of tobacco, written for the purpose of assisting the tobacco industry in Jamaica.

Culture of tobacco in Tunis, F. MALET (*Rev. Cult. Coloniales, 4 (1899), Nos. 30, pp. 343–347; 31, pp. 360–370; 5 (1899), Nos. 32, pp. 13–20; 33, pp. 56–61; 34, pp. 113–117*).—Extract from the *Bulletin de la Direction de l'Agriculture* of Tunis, dealing largely with the meteorology and tobacco soils in the neighborhood of Cape Bon, with notes on the cultural practices observed in these regions and on the export of tobacco.

The world's wheat supply, J. B. LAWES and J. H. GILBERT (*London: Spottiswoode & Co., 1898, pp. 16*).—Criticism of the statements of Sir W. Crooks relative to this subject. The article is a reprint of the authors' letter to *The London Times* of December 2, 1898.

Trials of rust-resisting wheats, A. C. MACDONALD (*Agr. Jour. Cape Good Hope, 15 (1899), No. 4, pp. 229–235*).—In continuation of previous investigations the rust-resistant qualities of Medeah, Italian, and Rietti wheat were tested. The experiment with Rietti was a failure owing to late sowing. In 13 cases Medeah was free from rust, slightly attacked in 4, and more or less affected in 9 others. Italian is reported free from rust in 17 cases, more or less affected in 23, and destroyed in 2 instances. This wheat is said to withstand drought well, but the grain is said to be too hard.

Course in practical agriculture; the food plants of warm countries and of the colonies, HEUZÉ (*Cours d'agriculture pratique; les plantes alimentaires des pays chauds et des colonies. Paris: Librairie de la Maison rustique, 1899, 2. ed., pp. 381, figs. 58*).—This treats of rice, sorghum, dolich bread, fruit, etc.

HORTICULTURE.

Field experiments with nitrogenous fertilizers, E. B. VOORHEES ET AL. (*New Jersey Stas. Bul. 136, pp. 31*).—Fertilizer experiments were made to determine "under field conditions the relative usefulness of the 3 distinct forms of nitrogen, viz, nitrate, ammonia, and organic, for crops belonging to that class in which rapid and continuous growth are important factors in determining the profits to be obtained in the growth of the crop." Detailed data for tests with beets, tomatoes, muskmelons, potatoes, sweet potatoes, and forage crops are given. The experiments with potatoes and forage crops are noted elsewhere in this issue (pp. 439, 440). The experiments were carried out both at the station and on farms in different parts of the State. In all cases the plats under experiment were well fertilized with the manurial elements, phosphoric acid and potash, previous to the application of the nitrogen.

Beets.—The soil upon which the test with table beets was made was a well-drained, sandy loam which had been cropped with table beets for nearly 10 years and had received a yearly dressing of 20 tons of barnyard manure and 1 ton of complete commercial fertilizer per acre. This same amount of fertilizer was again applied the season of the test. The object of the experiment was "to learn whether it would be profitable to add nitrogen in its most active form to the crop grown upon a soil thus abundantly supplied with plant food." Five plats each $\frac{1}{10}$ acre in size were used. One plat was used as a control. The others received 40, 50, 60, and 70 lbs., respectively, of nitrate of soda. The plants were set the last week in March and the fertilizer applied in three equal dressings April 22 and May 10 and 21. Harvesting began May 27 and continued until June 25. The number of bunches gathered from the various plats on the different dates of picking, selling price per bunch, and the value of the crop are given in tabular form, and the data are discussed.

The earliness of the crop was greatly hastened by the use of the nitrate. At the first picking the average yield of bunches from the nitrate plats was 63 per cent greater than on the check plats. At the gathering 4 days later this yield was 135 per cent greater and at the third gathering, June 3, 17½ per cent greater than on the check plat. From that time on the yields of the different plats were about equal. The different amounts of the nitrate increased the extra earliness of the beets from 10.1 per cent in the case of the plat receiving the least nitrate to 23.7 per cent in the case of the plat having the greatest amount, though not in a regular ratio. The largest prices were received for the earliest gathering, and the greatest net gain per acre, $27.10, was obtained from the plat fertilized at the rate of 700 lbs. of nitrate of soda per acre.

Tomatoes.—The test was made on sandy loam soil in a good state of cultivation and of fair quality. Four tenth-acre plats were used. One plat was used as a check, one received nitrate of soda at the rate of 150 lbs. per acre, one dried blood at the rate of 200 lbs. per acre, and one sulphate of ammonia at the rate of 120 lbs. per acre. Half the fertilizers were applied at the time of planting and the remainder 3 weeks later. Data as to date of picking, yield, selling price at the different dates of picking, etc., are tabulated. The largest yield of early tomatoes, the greatest number of prime fruits, the largest total yield, 21,695 lbs., and the largest money returns, $215.52 per acre, were furnished by the plat fertilized with nitrate of soda. The plat fertilized with sulphate of ammonia stood second, with a yield of 19,384 lbs. and a money value of the crop of $186.79; and the plat fertilized with dried blood last, with a yield of 12,898 lbs. and a money value of the crop of $121.67. The check plat gave a total yield of only 5,894 lbs. This had a money value of $51.02. The largest percentage of imperfect fruit on the fertilized plats was found where dried blood was used. The author believes the results show that nitrate of soda, applied in reasonable amounts, not to exceed 150 lbs. per acre, has a favorable influence on both the early maturity and the total yield of the crop rather than an unfavorable one as is sometimes believed.

Muskmelons.—The object of the work with muskmelons was (1) to compare the relative effects upon the yield and quality of crop of nitrate, ammonia, and organic forms of nitrogen, and (2) the effect of increasing amounts of these materials. Ten plats of light sandy loam soil, each $\frac{1}{10}$ acre in size, were used. Plat 1 was used as a check; the remaining plats were divided into 3 groups of 3 plats each. Plats 1 of each group received 15, 25, and 35 lbs., respectively, of nitrate of soda; plats 2, 12, 20, and 28 lbs., respectively, of sulphate of ammonia; and plats 3, 20, 33, and 47 lbs., respectively, of dried blood. "The actual nitrogen applied in the different forms was the same for each group." Half the fertilizers were applied at planting time and the remainder about 3 weeks later.

The largest average yield, 115 per cent increase over the check plat, and the greatest number of marketable fruits, were obtained from the plats receiving nitrate of soda, the smallest application giving the largest total yield and greatest money returns. The average yields obtained from the plats receiving dried blood were 91 per cent greater than the yield from the check plat and about 4 per cent greater than the average yield from plats fertilized with sulphate of ammonia. The effects of the fertilizers on earliness were conflicting in the different groups, nitrate of soda standing at the head in the first and third groups, and dried blood in the second.

Sweet corn.—The plan of this experiment was similar in character and purpose to that with melons, the number of plats, their arrangement, and the amount of fertilizers used on each plat and the method of application being the same. The weight and number of ears of corn grown on each plat, weight of stalk, cost of fertilizers, and total value of crop are given in tabular form. "The average increased yield [of ears] from the use of nitrate of soda was 21.1 per cent; from sulphate of ammonia, 25.4; and from dried blood, 34.9 per cent." And this yield was greatest, with but one exception, in group 3, which received the heaviest applications of fertilizers. The yield of stalks was increased by the use of nitrogen in every instance except on the plat which received the smallest application of nitrate of soda. The best average yields were made on the plats receiving sulphate of ammonia, and the yield of plats in group 2, which received medium amounts of fertilizer, was larger than in groups 1 or 3. The earliness of the crop was somewhat retarded by unfavorable weather. Notwithstanding this, the application of the fertilizers was profitable in all cases except with the smaller amounts of nitrate of soda and sulphate of ammonia in group 1. The author believes that aside from the determination of the most available forms of nitrogen, the experiment demonstrates the value of an abundance of all forms of fertilizer for this crop.

Sweet potatoes.—The relative effects of nitrate of soda and cotton-seed meal on the growth of sweet potatoes on a light sandy soil which lacked "'condition' and was poor in respect to physical character" was investigated. Two plats, each one-half acre in extent, which had been well fertilized with phosphoric acid and potash, were used. One plat was fertilized with nitrate of soda at the rate of 200 lbs. per acre and the other with cotton-seed meal at the rate of 456 lbs. per acre. The results are tabulated. The yield of "firsts" was 18.7 per cent greater and of "seconds" 22.8 per cent greater on the plat fertilized with nitrate of soda than on the plat receiving the cotton-seed meal.

Chemical studies of Oregon fruits—points on prune dipping, G. W. SHAW (*Oregon Sta. Bul. 56, pp. 8*).—It is said to be an almost universal custom in the State to dip prunes into a boiling solution of lye just previous to drying, to hasten the operation of drying, and to cleanse them and render the skin less tough. Results are given of experiments in dipping prunes in lye of different strengths, and of analyses with reference to alkalinity of 27 samples of concentrated lyes found in Oregon markets.

> "Prunes of normal size were subjected to treatment in a 1.25 per cent solution of lye for 20 seconds, and on removal from the solution were found to be well checked; but small prunes were very imperfectly checked, many of them not being affected at all. Increasing the time seemed only to cause the prune to crack deeply or the skin to roll up, leaving the flesh badly exposed. A trial with a solution of double the strength used at first, 2.5 per cent alkalinity, only caused the skin to roll up worse and the cracks to be made deeper and failed to produce a well-checked fruit."

The practical bearing of these experiments, in the opinion of the author, is "to enforce the idea of preliminary grading of fruit or, still better, the necessity of keeping trees in such a healthy condition as will permit them to bear only fruit of normal size."

No general rule can be given with regard to the use of lyes because of the great variation in strength of the different brands. Potash lyes, as a rule, are preferred to soda lyes because of their more ready solubility in the case of sprays and their easier removal from dipped fruit. Tables show the net weight, price per can, percentage alkalinity as soda, actual alkali per can, and the actual alkali purchased for 10 cts. for a number of different brands of lye. Great variation in the weight of cans, percentage alkalinity, etc., was found between different brands.

Pollination of pomaceous fruits, M. B. WAITE (*U. S. Dept. Agr. Yearbook 1898, pp. 167–180, figs. 13*).—This article consists largely of a review of the principal results of the author's work on pollination of the pear (E. S. R., 6, p. 47).

Experiments in cross pollination of the apple and quince are reported. The apple blossom and its adaptation for cross pollination are described. It was noticed in western New York that ordinarily there were not enough insects to insure complete pollination when the main body of the orchards come into bloom. To obviate this difficulty it is recommended that hives of bees be kept in the vicinity.

"The methods followed in the work on the apple were the same as in the experiments with pears . . . [and], in a general way, the results were similar. . . . The division of the varieties into self-fertile and self-sterile sorts was not nearly so well marked. Crossing gave decidedly better results in all cases than self-pollination."

Experiments with Norton Melon, a variety producing fruit of the choicest quality, indicated that high quality is not necessarily associated with self-sterility. Cross fertilized apples were larger, more highly colored, and better supplied with seed than those self-fertilized. Experiments with the quince showed no such striking benefits from insect visits as in the case of the pear and apple.

Soils and fertilizers for pineapples (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 472, 473*).—It is stated that a sandy loam soil, rich in humus and having a hardpan clay subsoil, is absolutely unsuitable for pineapple culture in Australia, which is contrary to the experience of the Florida Station (E. S. R., 7, p. 214). It is stated also that in Australia, where the climate is subject to heavy rainfalls at certain periods of the year and at other times to comparatively long periods without rain or with only a small rainfall, the effect of the heavy rains on such a soil would be to saturate it completely, and as the water would have no means of escape it would stagnate and kill the plants. Perfect drainage is found to be essential to successful pineapple culture. It is further stated that the soil recommended for Florida conditions would dry out very rapidly, since after the moisture in the foot or so of soil has become exhausted the hardpan would absolutely prevent its being replaced by capillary action. The same soil would, however, be adapted to pineapples if it were not underlaid by hardpan.

Fertilizer experiments now in progress in Queensland indicate that pineapples are much benefited by applications of a mixture of soluble nitrogenous and phosphatic manures, but, contrary to the results obtained by the Florida Station, up to the present time potash has had little if any effect.

A method for the rapid propagation of the strawberry by layers and cuttings, C. GAZEAU (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), May, pp. 113-119*).—A method of propagating strawberries is described which, it is claimed, is especially suited to the rapid propagation of a variety from a few plants. In the spring, as soon as the first runner shows its terminal bud with its rosette of leaves, it is layered, leaving only the terminal leaves exposed. The runner proper is thus protected from accidents and the weather. It also does not lose by evaporation any of the sap that it receives from the mother plant. The bud itself is in intimate contact with a fine, moist, and well compacted soil, conditions much more favorable to rapid making of roots than are found in ordinary field culture. In about 12 days the bud has rooted and thrown out a runner which is a prolongation of the primary runner, and after a few days this also is layered as before. This operation is repeated for each new bud that appears. These may be six or eight or even more. The mother plant generally throws out eight or nine runners, each of which is treated in the same way. As soon as the buds of the primary runners have struck roots, they in turn form adventitious buds and throw out secondary runners which are also layered. The first few weeks the number of plants increases in arithmetical progression, but later, obviously, in geometrical progression.

When there is no longer room to make more layers, cutting must be resorted to. When the terminal rosette shows two well-formed leaves the runner is sectioned close to its mother plant and the cuttings are planted out. In the author's experience cutting was not so successful as layering; the plants are not so vigorous and do not multiply so rapidly, cutting yielding only about 35 per cent as many plants as layering in the same time. The mother plants are set 2 meters apart each way, preferably the preceding fall, in a deeply worked and heavily manured propagating bed. The growing season may be lengthened by starting the plants in a cold frame. Intense culture must be given and frequent waterings with a nitrogenous manure water. By massing plants that are to be used for propagation, the area to be cultivated and, consequently, the cost of cultivating is reduced to a minimum. Plants propagated by this method are exceedingly vigorous and yield an abundant harvest of very large fruit the following season, whereas by the ordinary method of propagation they do not yield until the second year.

Detailed cultural directions especially suited to this method are given throughout the article.

Hybrid coffee (*Gard. Chron., 3. ser., 25 (1899), No. 642, p. 240*).—The report of the Government gardens and parks in Mysore for 1897–98 states that the existence of hybrid coffee plants on several estates in southern India appears now to be an established fact.

> "These new forms are reported to combine, more or less, the characteristics of *Coffea liberica* and *C. arabica*, and are only found in localities where the 2 species have been cultivated and propagated together. They have not been introduced by the planters as new varieties, but were unknown prior to the introduction of the West African species *C. liberica*. It is therefore reasonably inferred that these intermediate plants are true hybrids. The most remarkable thing about them is their immunity from coffee-leaf disease, a condition which can only be attributed to enhanced vitality in the constitution of the hybrid. This is a discovery of much importance to the planter and will encourage him to pursue the operation of crossing on methodical lines with a view to raising improved strains of seed."

A small coffee plat consisting of 135 bushes, comprising 2 species and 1 variety, has been planted. Systematic hybridizing operations will be commenced as soon as these plants flower, which it is expected will be next season.

Irrigation of the vine during a late drought, A. MÜNTZ (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 25, pp. 1189–1193*).—During a period of drought late in the season a test was made of the practicability of pumping water a considerable distance upgrade for irrigating a vineyard. The water was pumped 1,500 meters and raised 40 meters. The application was equivalent to 220 mm. of rain. The increase in yield was on the average from 25 to 30 per cent.

Analysis of the must showed that as a result of watering the water content of the fruit was increased and the sugar content decreased, but the relative decrease of sugar was much less than the relative increase in the size of the fruit—that is, there was a total increased production of sugar. The acid content was also considerably increased.

The cost of the irrigation in this case was about 60 francs per hectare, while the returns were from 200 to 250 francs per hectare more than from a check plat not watered.

The replanting of vineyards with American vines, J. M. GUILLON (*La reconstitution du vignoble. Cognac: Vve. G. Berauld, 1899, pp. 17*).—A general discussion of the subject. The three requirements for American vines used in replanting vineyards are that they be resistant to chlorosis and the phylloxera, and that the variety be adapted to the soil in which it is planted. Each of these requirements is discussed in detail from a practical standpoint. To insure resistance to chlorosis on soils having a lime content of not more than 15 per cent, use Riparia; 20 per cent, Riparia-Rupestris; 25 per cent, Rupestris; 35 per cent, Riparia-Berlandieri, Rupestris-Berlandieri, or Vinifera-Rupestris; above 35 per cent, Berlandieri or Vinifera-Berlandieri.

Rose culture in Oregon, G. COOTE (*Oregon Sta. Bul. 58, pp. 11, pls. 7*).—Popular directions are given for making and propagating midsummer and fall cuttings and Manetti stocks; for propagating by budding; and for planting, pruning, and disbudding roses. Brief notes are also given on the more usual insects and diseases affecting roses, with suggestions for their control.

High standard roses have not been successfully grown at the station, owing to the sudden variations in temperature which are liable to occur during the winter months. Some of these varieties, however, when grown on native wild stocks and covered in winter by a coating of snow have done well. Of the varieties thus grown La France, John Hopper, La Rhine, Gloire de Dijon, Gloire de Lyonnaise, and Queen of Morocco are noted as the best. Gloire de Dijon when grown on native brier was found to lose its climbing habits and made but little wood growth. Maréchal Niel was short lived, lasting only three or four years. Common Sweet Brier, worked close to the ground, is recommended as stock for this variety.

Can perfumery farming succeed in the United States? E. S. STEELE (*U. S. Dept. Agr. Yearbook 1898, pp. 377-398, figs. 7*).—The statistics of the trade in alcoholic perfumery are given and the methods of extracting essential oils briefly described. Experiments indicate that the rose, rose geranium, citrus fruits, and lavender can be successfully grown for perfumery in this country, so far as climate and soil are concerned. Notes are given on thyme, rosemary, orris or iris root, bitter almond, umbelliferous aromatics, violet, cassie or opopanax, tuberose, jasmine, and the following native perfumery plants: Sassafras, wintergreen, sweet birch, red cedar, wild ginger, sweet golden-rod, large-flowered magnolia, sweet bay (*Magnolia virginiana*), and yellow jasmine (*Gelsemium sempervirens*). From an economic point of view it is believed that the difficulty in the way of producing perfumery materials in this country is lack of information and experience and the cost of labor. Nevertheless it is believed that new industries in this class are feasible in particular localities.

Green asparagus out of season, J. FOUSSAT (*Rev. Hort. et Vit., 31 (1899), No. 9, pp. 199-202*).—Directions for forcing asparagus.

The cabbage crop (*Florida Agr., 26 (1899), No. 40, p. 610*).—The nitrogen content of different varieties of cabbage is noted and directions given for fertilizing cabbage, making the seed bed, sowing the seed, cultivation, and protection from insects, with suggestions as to best varieties to plant.

Dwarf tomatoes, W. J. GREEN (*Amer. Gard., 20 (1899), No. 250, p. 687*).—Cultural notes. The author advocates staking this crop.

Some tomato trials (*Amer. Gard., 20 (1899), No. 250, pp. 684, 685, fig. 1*).—Results with varieties of tomatoes in the *American Gardening* trial grounds are noted. The stake method of training with the continual removal of all lateral or side branches has given the most satisfactory results. The following varieties in the order named succeeded best in 1899: Stone, Royal Red, Crimson Cushion, Matchless, Trucker Favorite, Perfection, Thorburn Novelty, and a yellow sort, Golden Jubilee.

The softening of peas on boiling, A. J. SWAVING (*Landbouw. Tijdschr., 6 (1899), pp. 353–357*).—The author reports experiments on the effect of different soils and fertilizers on the composition of peas, with especial reference to their becoming soft on boiling.

Mushrooms, J. HOBSON (*Amer. Gard., 20 (1899), No. 245, p. 610*).—The preparation of the mushroom bed is discussed and precautionary measures to be observed in watering and otherwise caring for the crop noted.

Vegetable physiology applied to fruit-tree culture, G. BELLAIR (*Rev. Hort., 71 (1899), No. 16, pp. 376, 377*).—The value of proper lighting, the distance to set different vines and orchard fruits apart, and methods of their pruning to secure access of light are popularly discussed.

New nursery methods, N. E. HANSEN (*Nat. Nurseryman, 7 (1899), No. 8, pp. 89, 90*).—Paper read before the Philadelphia meeting of the American Pomological Society. In order to avoid a repetition of the widespread destruction of nursery stock and young orchards following the severe freezes of last winter, the author advises the adoption of the Russian method of using pure *Pyrus baccata* as stock.

A year among the orchards of Nova Scotia, C. H. HOOPER (*Author's ed.; repr. from Jour. Roy. Hort. Soc. England, 23 (1899), pt. 1, pp. 20, figs. 4*).—Paper on the present status of the fruit industry in Nova Scotia read before the Royal Horticultural Society of England at its meeting January 31, 1899. The grafting and pruning of apple trees; fertilizing, management, and spraying of orchards, and picking, packing, and shipping the fruit are especially considered, and notes given on the culture of cranberries, varieties of different fruits commonly grown in Nova Scotia, and on the Nova Scotia School of Horticulture and Fruit Growers' Association.

Special method for cleft grafting apples, pears, plums, and cherries, J. BORD (*Belg. Hort. et Agr., 11 (1899), No. 16, pp. 246, 247*).—The author advocates cleft grafting these fruits in September and October instead of in the spring, and notes the successful results obtained by himself in cleft grafting at this time.

The sand cherry as a stock, N. E. HANSEN (*Garden, 56 (1899), No. 1450, p. 176*).—Notes on the characteristics and value of this native western fruit as stock, with an account of the work in selection now being carried on with it at the South Dakota Station.

Pruning of trees and other plants, W. SAUNDERS (*U. S. Dept. Agr. Yearbook 1898, pp. 151–166.*)—A popular article discussing the general principles and practices of pruning and their specific application to the pruning of hedges, street trees, trees for timber, flowering shrubs, raspberries, blackberries, gooseberries, currants, apples, pears, plums, cherries, peaches, nectarines, and grapes.

Fertilizers for fruit trees (*Agr. Gaz. New South Wales, 10 (1899), No. 7, pp. 607–609*).—Fertilizer formulas for apples and pears, stone fruits, and citrus fruits.

Pears adopted by the Congrès Pomologique of France (*Garden, 55 (1899), No. 1440, pp. 440–442*).—A continued article. Complete pomological descriptions are given of a large number of varieties of pears.

The banana in cultivation and commerce, A. L. PINART (*Garden, 56 (1899), No. 1448, pp. 141, 142*).—Translated from *Bulletin de la Société d'Acclimatation.*

Camphor culture in Florida (*Florida Agr., 26 (1899), No. 35, p. 552*).—Notes on experimental plantings by private individuals in southern Florida, which have thus far yielded encouraging results.

Small fruits in 1897, G. C. BUTZ and J. P. PILLSBURY (*Pennsylvania Sta. Rpt. 1897–98, pp. 87–100*).—Variety tests and descriptive notes of strawberries, blackberries, currants, and gooseberries. In a comparative test of matted row and hill culture for strawberries, the hill system produced berries much more uniform in size, of finer flavor, and more highly colored. With the matted-row system fruit was from 1 to 6 days earlier and the plants remained in bearing from 1 to 4 days longer.

Utilizing surplus fruits, G. B. BRACKETT (*U. S. Dept. Agr. Yearbook 1898, pp. 309–316*).—This is a popular article treating in a practical way with the processes of drying or evaporation, canning, and extracting the juice of fruits. The treatment of the fruit by the several processes is described. Evaporation is considered the most economical process for the preservation of fruits. Among the minor points touched upon are the evaporation of cores and skins and the production of "chops," cider, orchard brandy, vinegar, fruit juices, unfermented wine, fruit sirups, and jellies. It is recommended that fallen fruit be utilized by turning the hogs into the orchard to forage upon it.

Artificial fertilization of coffee-tree flowers for the purpose of obtaining hybrids (*Planting Opinion, 4 (1899), Mar. 18; abs. in Rev. Agr. Réunion, 5 (1899), No. 7, pp. 319–321*).—Liberian coffee trees are recommended to be planted among Moka varieties to facilitate cross fertilization of the flowers by insect visits. The resulting hybrids are said to produce coffee of excellent flavor and a tree more resistant to diseases.

Tea from seed to cup in southern India, T. BROWN (*Planting Opinion, 4 (1899), Nos. 33, pp. 631, 632; 34, pp. 670, 671; 35, pp. 687, 688*).—The subjects of grafting, pruning, topping, picking the crop, removing blossoms, and the like are popularly considered.

Vanilla (*Queensland Agr. Jour., 4 (1899), No. 6, pp. 477–483, figs. 4*).—This article deals with the cultivation, pollination, fertilizing, and harvesting of vanilla; drying and preparing the pods for market, and the London prices for vanilla in 1898.

The present condition of grape culture in California, G. HUSMANN (*U. S. Dept. Agr. Yearbook 1898, pp. 551–562*).—This is a sketch of the rapid development of grape growing in California. It is believed that the industry is established on a firm basis and promises still greater development as the merits of California wines become known.

Subirrigation on vines by brush ditches, L. DEGRULLY (*Prog. Agr. et Vit., 16 (1899), No. 36, pp. 269–274, figs. 3*).—The details of making brush ditches and the advantage of using such ditches in connection with subirrigation by means of tiles are discussed at some length. Brush ditches when properly made last about 10 years. An instance is noted of a vineyard irrigated in this manner in which the least yield for 20 years in succession had been at the rate of 173 hectoliters per hectare and the greatest 183 hectoliters per hectare.

Resistant vines, G. HUSMANN (*Pacific Rural Press, 58 (1899), No. 14, p. 213*).—The author recites his experiences with different varieties of resistant grapes, and on this basis makes suggestions as to desirable varieties for planting for white and red wines.

Green manures in vineyards, DORRY (*Vigne Amer. et Viticult. Europe, 23 (1899), No. 9, pp. 281–283*).—The author discourages the use of green manures in vineyards, as the harm they do in taking up soil moisture more than counterbalances their fertilizing value.

Coloring grapes (*Garden, 55 (1899), No. 1439, p. 419*).—Directions for putting color and finish on ripening bunches of grapes. It is stated that the essentials to well-finished fruit are an abundant food and moisture supply at the roots, avoidance of overcropping, and a very liberal supply of fresh air night and day.

Notes on the self-fertility of cultivated grapes, S. A. BEACH (*Proc. Soc. Prom. Agr. Sci., 1898, pp. 162-167*).—The data of this article have also appeared in Bulletin 157 of the New York State Station (E. S. R., 11, p. 248).

Tests of methods of preserving fruits (*Gartenflora, 48 (1899), No. 17, p. 464*).—Fruit was (1) packed in turf dust in boxes and the boxes stored in a cellar; (2) in turf dust in boxes after being wrapped in tissue paper; (3) wrapped in tissue paper, packed in turf dust in boxes, and the boxes buried in the ground 18 in. deep, and (4) wrapped in tissue paper and laid on racks in a fruit storage cellar. Fruit thus preserved was exhibited at the agricultural fair held in Frankfurt, Germany, June 8-13, 1899. Wrapping in tissue paper and packing in turf dust gave the best results, all fruits considered; and this method is thought to be a valuable means of prolonging the keeping periods of desirable market fruits, especially apples.

The walnut, J. B. NEFF (*Pacific Rural Press, 58 (1899), No. 12, p. 182*).—Notes on the growing, pruning, and diseases of walnuts.

Cultivation of the English walnut (*U. S. Spec. Consular Rpts., 15 (1899), pt. 2, pp. 153-167*).—Notes on the culture, yield, and exports of English walnuts to the United States from Austria-Hungary, France, Germany, and Italy.

Commercial chestnut culture in the United States, G. H. POWELL (*Amer. Gard., 20 (1899), Nos. 220, pp. 178, 179, fig. 1; 223, pp. 238, 239, fig. 1; 225, p. 280; 226, pp. 295, 296, figs. 2; 235, p. 444; 242, p. 559, figs. 2*).—A general discussion of the history and present status of the industry in the United States, types of cultivated chestnuts, chestnut culture, and varieties.

The improvement of plants, A. HEMSLEY (*Gard. Chron., 3. ser., 26 (1899), No. 662, pp. 186, 187*).—The author's experience in the improvement of mignonette, Chinese primulas, cinerarias, pelargoniums, begonias, and carnations is given in more or less detail.

Centaurea ragusina, H. T. MARTIN (*Gard. Chron., 3. ser., 26 (1899), No. 664, p. 223*).—Culture notes.

Decorative and cactus dahlias, L. BARRON (*Amer. Gard., 20 (1899), No. 247, pp. 638, 639, figs. 3*).—Discussion of the characteristics of these two classes of dahlias.

Commercial fertilizers in the culture of geraniums, V. BOUTILLY (*Rev. Cult. Coloniales, 5 (1899), No. 37, pp. 177-179*).—The yields of geranium essence obtained on 9 plats differently fertilized are tabulated and discussed. Superphosphate of lime proved the most efficient fertilizer of the different materials employed.

Perfumes from plants, F. W. BURBRIDGE (*Garden, 56 (1899), No. 1444, pp. 59-62*).—A catalogue of the plants most generally grown for their fragrance, and especially of those having sweet-scented leaves as well as flowers.

Hybridization, F. A. WAUGH (*Amer. Gard., 20 (1899), No. 234, pp. 431-435, figs. 4*).—This paper contains a catalogue of important hybrids among ornamental plants and fruits, the author's statement of the general laws of hybridity and of hybridism, and practical suggestions to plant breeders.

Bulb growing in the State of Washington, A. SIMON (*Amer. Florist, 14 (1899), No. 576, pp. 1357, 1358; Florists' Exchange, 11 (1899), No. 24, p. 626*).—Experiments in raising flowering bulbs have been carried on for 6 to 8 years at Orcas Island, San Juan County, Wash., with results indicating that the soil and climatic conditions of this region are adapted to the industry. Western Washington is said to have plenty of moisture in the growing season, a period which extends usually from October to the July following, and the ground rarely freezes to the depths the bulbs are planted. This is followed by a rainless period of 60 to 90 days in mid-season. The bulbs are found to mature in a remarkably short time. This is believed to be due to the facts that from the time the bulbs are planted or commence their fall growing until after the blooming period, there is no cessation in growth on account of frost, and that the bulbs get thoroughly ripened off before the growing period commences again. It is stated that larger and better developed blooms and 50 per cent more stock is obtained than in Holland.

Causes of imperfect or deformed flowers in Bermuda lilies, A. F. WOODS (*Gardening, 7 (1899), No 163, p. 297*).—The development of brown sunken spots on the petals is stated to be due to weak bulbs. Splitting of flowers on one side is often caused by the work of the aphis on young buds of plants which have been forced rapidly.

Orchid roots (*Garden, 56 (1899), No. 1442, pp. 21, 22*).—Notes on the habits of growth of roots of various orchids.

A monograph of Cypripedium, F. DES BOIS (*Les Cypripedium; leur monographie. Gand: E. Meyer, 1898, pp. 544*).—This is said to be a work essentially for gardeners, being rather a voluminous compilation than a systematic study. The names and descriptions are generally given as originally published without an attempt to discriminate synonyms.

Soil vs. climate in the culture of roses (*Gard. Chron., 3. ser., 25 (1899), No. 633, p. 81*).—It is contended that climate has far more to do with the successful culture of the rose than does the soil. This opinion is supported by arguments drawn from the culture of the plant in a number of localities in the British Isles and on the Continent.

History of the sunflower, ROZE (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), June, pp. 505–512*).—Extensive historical notes

Early sweet peas, R. T. BROTHERSTON (*Gard. Chron., 3. ser., 25 (1899), No. 636, p. 132*).—Notes on numerous varieties.

Shading violets, P. H. DORSETT (*Amer. Florist, 14 (1899), No. 576, p. 1364*).—It is recommended that violets be shaded from the time they are set out until October. The light should be strong but well diffused during the growing season.

The Kei apple (Aberia caffra), F. M. BAILEY (*Queensland Agr. Jour., 4 (1899), No. 6, p. 468, pl. 1*).—Botanical, cultural, and culinary notes. The plant is recommended for hedge making.

Moving large trees without a wagon, E. ANDRÉ (*Rev. Hort., 71 (1899), No. 14, pp. 325–328, figs. 4*).—The method consists in lifting the tree from the ground by means of derricks, mounting on rolls, and moving as a building is moved. The method is especially adapted for use on hillsides and wet ground.

FORESTRY.

Notes on some forest problems, G. PINCHOT (*U. S. Dept. Agr. Yearbook 1898, pp. 181–192, pls. 1*).—The author briefly mentions some of the phases through which the public estimation of forestry has passed, introductory to a short discussion of what he believes to be the true character and proper field of forestry in the United States. At first, forestry was understood to relate to trees, but more to the individual tree than to forests. The economic management of forests and conservative lumbering is a more recent understanding of the subject, and to this must be added the effect of forests on the water supply.

The subject as described by the author may be divided into two divisions: Forestry in wooded regions, and in the treeless regions. In the wooded regions, forestry has to do with the protection and preservation of forests, but, most of all, with their use. In the drier regions of the West, the duties of the forester include the protection of the mountain forests, not only for the purpose of wood, but also on account of the effect of forests on the water supply, and also tree planting in the plains and treeless valleys.

The work that the Government is carrying on in forestry is briefly outlined, and some of the obstacles to conservative lumbering are stated. Among these obstacles the principal ones are lack of definite information and the effect of heavy taxes on forest lands. The subjects of forest grazing, tree planting in the plains, and forest fires are briefly reviewed.

Influence of spacing on the growth of certain trees, A. JOLYET (*Bul. [Min. Agr. France] 18 (1899), No. 2, pp. 286–291*).—The author reports the effect of planting spruce, pine, and larch trees at distances of 1, 1½, and 2 meters apart. The trees when planted were 3 and 4 years old, and the measurements were made in the spring of 1898 after having been planted from 12 to 14 years. The average spread ot the different trees, their circumference, and height are given. It appears from the figures given that a distance of about 2 meters gives the best results, especially with spruce. This distance seems particularly to favor increase in diameter. The effect on height is not definitely shown.

The restoration of mountain covering, T. P. LUKENS (*Forester, 5 (1899), No. 7, pp. 151–155*).—The author comments upon the trees available for the restoration of mountain covering in southern California, and describes their characteristics, growth, and habitat. Of the trees best suited to this purpose the tuberculated or knobcone pine (*Pinus tuberculata*) is considered especially available on account of some of its peculiarities of growth. The habit of the tree in holding its cones for many years, or, in fact, until the death of the tree, when the seeds are liberated, renders it peculiarly adapted to reforesting burned areas, and it is in these regions that the tree seems to be most abundant.

Another tree which is well adapted to this purpose is the *Sequoia gigantea*, and an instance is cited in which Sequoia seeded simultaneously with pines, firs, and Libocedrus after about 7 years had attained a marked advantage in growth over the others. Among other trees adapted to mountain covering the author mentions the silver firs (*Abies concolor* and *A. magnifica*) and the silver pine (*Pinus ponderosa*).

Growing forest-tree seedlings, W. B. ALWOOD and J. L. PHILLIPS (*Virginia Sta. Bul. 88, pp. 15–55*).—The horticultural department of the station has for a number of years been growing forest and ornamental trees for resetting in the campus and station grounds. In 1896 cooperative experiments were undertaken in connection with this Department in which it was desired to study the effect of climate on several species of forest trees grown from seeds collected from different parts of the country. The species tested were black walnut, bur oak, hackberry, honey locust, boxelder, green ash, and white ash. The more important data concerning the growth of the different species during the 2 years in which the experiments were conducted are given in tabular form. While no very constant differences due to change of locality are observed, in some cases the trees grown from southern seed were considerably longer in maturing in the fall and consequently were more injured by frost.

It is stated that the growing of forest-tree seedlings may be easily accomplished. Seeds of the silver maple or other early-ripening species must be gathered and sown at once. The late-ripening species should be sown in autumn or stratified and planted in the spring. All forest-tree seedlings should be grown in mellow loam soil so as to encourage the development of a strong root system, and transplanting should be made at the end of the first or second year into nursery rows. Most forest trees should be permanently planted when they have attained a height of from 5 to 8 ft.

The redwood forests of California, H. GANNETT (*Forester*, *5* (*1899*), *No. 7*, *pp. 148-150*, *figs. 2*).—The author describes the redwood (*Sequoia sempervirens*), its distribution throughout the Pacific coast, and the extent of its forests. The tree is said to be, to a considerable degree, exempt from injury by forest fires on account of the small amount of resin contained in the wood. Where the redwood forests have been cut off but few seedlings are found, and the author states that probably by the progressive drying of the climate the environment is not now favorable to the growth of the redwood, and with the clearing away of the present forests the lumber value of this species will disappear.

The Douglas spruce in northern Oregon, H. S. GRAVES (*Forester*, *5* (*1899*), *No. 3*, *pp. 52-57*, *pls. 2*).—The Douglas spruce is said to be found from tide land to an elevation of between 5,000 and 6,000 ft. above sea level. Scattering trees occur near the coast but only begin to reach their normal development above the recent sea deposits. On the eastern side of the Cascade Range the author has not observed the tree at a less elevation than 2,800 ft. In Washington and Oregon the Douglas spruce is probably the most rapid growing of coniferous trees, and the author summarizes a number of measurements made during 1896 to ascertain the rate of growth and reproduction.

Notes are given on the habit of the tree, its tolerance toward shade, reproduction, and growth. When growing in open situations Douglas spruce develops a large spreading crown, which gives the tree a broad, conical aspect. In dense stands, however, the trees are very tall, shed their lower branches early, and form long, clear boles with narrow compact crowns. The largest tree measured by the author was 13 ft. in diameter and was estimated to be over 300 ft. in height. While there is no apparent difference botanically between them, lumbermen recognize 2 types of spruce—a red and a yellow. The author states that yellow spruce is old and mature and generally found in dense forests, on good soil, and in favorable situations. The trees have long, clear, full trunks, narrow crowns, and a fine-grained, yellowish wood. The red spruce has a comparatively large crown, deeply corrugated bark, and coarse-grained, reddish wood. For the most part the red spruce is found on the eastern slope of the Cascades while the yellow variety is confined to the Pacific slope.

From tables in which average measurements of a number of plats are given it appears that the tree reaches its maximum rate of growth in height between its twentieth and thirtieth years, during which period it is shooting up 2.4 ft. per year. The mean annual growth in height for the first 30 years is 1.9 ft.; the rate of growth in diameter is very regular; it reaches its maximum about its thirtieth year and continues at the rate of 0.24 in. per annum until the tree is about 50 years old, after which the rate decreases. From the figures given, a fully stocked plat should contain between 2,000 and 3,000 twenty-year-old trees per acre. With the increased growth the number of trees decreases until at the age of 83 years one plat contained 150 trees, which is about 0.7 that of a fully stocked area. The annual increase of growth in such a forest is a little more than 2 cords per acre.

Work of the Division of Forestry for the farmer, G. Pinchot (*U. S. Dept. Agr. Yearbook 1898, pp. 297–308, pls. 3, figs. 2*).—The Division of Forestry, in its relation to the farmer, has two important lines of work, namely, the introduction of suitable trees for planting in the treeless portions of the West and the better handling of wood lots on farms in the regions where trees now grow. The Division of Forestry has undertaken to give practical advice as how best to secure the advantages of proper management and a copy of the agreement between the Department and the owner of a wood lot is given. The working plan for a wood lot at Oakland, N. J., is appended.

The profession of forestry, G. Pinchot (*Forester, 5 (1899), No. 7, pp. 155–160, pls. 4*).—An address delivered before the students of Yale University.

The need of forestry experiment stations, W. R. Lazenby (*Proc. Columbus Hort. Soc., 13 (1898), pp. 15–17*).—A popular address on forestry.

Forestry experiment stations, Loren (*Allg. Forst u. Jagd. Ztg., 65 (1899), No. 4, pp. 113–121*).—An address outlining the organization of forestry stations in Germany and briefly summarizing their investigations.

Forestry in the United States (*Mitt. Deut. Landw. Gesell., 11 (1899), No. 11, Beilage, pp. 50–56*).—A résumé is given by the German Embassy of the forests and forestry conditions of the United States.

Forest administration in Bengal, E. G. Chester (*1897–98, pp. 90*).—A report is given on the extension and constitution of the State forests, their management, gross yield and output of forest produce, financial results, forest administration, etc. Under the subject of management of State forests, working plans are discussed, and the general subject of forest protection, improvement, and exploitation is considered in detail.

Forestry in New South Wales, W. S. Campbell (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 958–961*).—The author reviews the forestry conditions of New South Wales, calling attention to some of the valuable timber and also the necessity of its proper conservation.

On the forests of Dean, F. Bailey (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, pp. 292–300*).—Extracts are given from a report by H. C. Hill on the above forests, in which the working plan for high meadow woods is outlined and suggestions given for the management of the forest as a whole.

Establishment of State model forests for Scotland, F. Bailey, R. C. Munro Ferguson, and R. Galloway (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, pp. 201–222*).—A letter addressed to the president of the Board of Agriculture, setting forth the views of the society on this subject.

Working plan for the forests of the Raith Estate, F. Bailey and G. U. MacDonald (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, pp. 223–278; Summary in Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 115–121*).—Gives working plans for the management of the forest in the interest of the charcoal production. This is said to be the first plan put into operation in Scotland.

The relation of forest preservation to the public welfare, J. B. COLLINS (*Forester, 5 (1899), No. 6, pp. 127–129*).—An address before Montana State University.

What shall we do for the forest? (*Forester, 5 (1899), No. 6, pp. 129–133*).—A symposium of 4 papers on this subject, as follows: An object lesson of forest destruction, E. L. Berthoud; The need of forest legislation in Colorado, H. Michelsen; The advisability of forest culture, and The increasing interest in forest preservation.

The lumberman's view of the forest (*Forester, 5 (1899), No. 6, pp. 133–135*).—Two papers—(1) Forest destruction, H. B. Ayres, and (2) Conservation, E. M. Griffith.

Trees in cities and some of the causes of their destruction, P. NYPELS (*Ann. Soc. Belge Micros., 23 (1898), pp. 75–143, pl. 1*).

On the influence of cutting and different degrees of light upon the stand of forest trees, SCHWAPPACH (*Ztschr. Forst u. Jagdw., 31 (1899), No. 5, pp. 259–293*).

The decay of trees, A. C. FORBES (*Gard. Chron., 3. ser., 26 (1899), No. 656, p. 66*).—Notes are given on some of the causes of decay in forest trees. That decay is often not an immediate cause of the death of the tree is shown by citing examples of oaks and yews known to be more than 1,000 years old, although nothing remains of the tree trunk but a shell. It is stated as a fact that almost all examples of very old trees are either pollards or pollard-like in their stem and growth. The commercial value of clean boled sound trees, greater liability to destruction by winds, and tendency to weakening of root system are given as causes of the destruction of many trees.

The basket willow, E. HERSEY (*Bul. Bussey Inst., 2 (1899), pt. 8, pp. 429–436*).—Gives an account of experiments on the cultivation of *Salix purpurea* and *S. viminalis* for basket osiers, etc. Directions are given for the preparation of the soil, planting, cultivation for various purposes, and methods of handling the crop. It is also stated that many of the roots possessed no root hairs, but seemed to be enveloped in mycelium. From this it is thought the plant lives, partly at least, through the symbiotic action of the mycorrhiza.

Some timber trees of Queensland, J. W. FAWCETT (*Queensland Agr. Jour., 4 (1899), No. 5, pp. 382–387, pls. 3*).—Notes are given describing a number of species of Casuarina and giving their distribution and uses.

A short key to the hitherto known species of Eucalyptus, J. G. LUEHMANN (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 523–536*).—A key is given for the more ready determination of the 140 species of this important timber tree of Australia.

A review of the characters valuable for the classification of the Eucalyptus, R. TATE (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 544–552*).—The author reviews the various systems of classification that have been adopted and gives an arrangement of the species based on the shape and structure of the fruits.

The mesquite tree and its pods, T. STEEL (*Rpt. Australasian Assoc. Adv. Sci., 7 (1898), pp. 946, 947*).—A brief note is given calling attention to the mesquite (*Prosopis dulcis*) and its pods and analyses are given of samples, comparisons being made with pods from the honey locust, *Gleditschia triacanthos*.

Recent investigations in Prussia in regard to the quality of timber, W. SOMERVILLE (*Trans. Roy. Scottish Arbor. Soc., 15 (1898), pt. 3, pp. 279–291*).—This is a translation of a portion of A. Schwappach's work upon this subject and treats of the investigations made of the specific gravity and resistance to crushing of timbers grown in Prussia. In all, timber from 263 trees was studied, the varieties being Scotch fir, Norway spruce, silver fir, white pine, and beech.

Natural reforestation in the Southwest, J. W. TOUMEY (*Forester, 5 (1899), No. 7, pp. 145–147, fig. 1*).—The author calls attention to some of the problems to be considered in the southwestern portions of the United States, particularly California and Arizona, where the denuded lands may be gradually covered with tree growth. Several instances are cited in which through natural agencies this has been secured, and the successful reforestation in this region will depend largely upon the prevention of forest fires and close cropping by stock, particularly sheep.

Fourth annual report of the chief fire warden of Minnesota, C. C. ANDREWS (*1898, pp. 148, pls. 24*).—A statement is given on the practical working of the Minnesota fire-warden law. During the year covered by the report there were 51 forest fires and 67 prairie fires reported. Of the former, 78 per cent were extinguished by the State officers. The present condition of the forests in a number of counties of the State is pointed out, and their ultimate value, if properly managed, is shown.

The report contains summaries showing the condition of a number of private forests in this country and the forestry conditions in a dozen or more European States.

Forestry legislation of Switzerland (*Bul. Soc. Cent. Forst. Belg., 6 (1899), No. 7, pp. 435-441*).—A brief summary of the Swiss laws relating to forestry.

The Massachusetts Forestry Association, A. CHAMBERLAIN (*Forester, 5 (1899), No. 10, pp. 219-221*).—Notes the organization and aims of this association.

SEEDS—WEEDS.

Effect of alkali on seed germination, J. STEWART (*Utah Sta. Rpt. 1898, pp. XXVI-XXXV, dgms. 8*).—As a part of the preliminary work on the study of alkali problems, the author conducted a series of experiments with wheat, oats, rye, barley, alfalfa, peas, and red and white clover, to test the effect of different amounts and different kinds of alkalis upon their germination. Shallow tin plates containing 400 gm. of sand were prepared, to which were added varying quantities of carbonate of soda solution representing a percentage of alkali ranging from 0.05 to 4 per cent. In another lot sodium sulphate and in a third sodium chlorid were substituted for sodium carbonate. In general it was noted that the sodium sulphate is less injurious than either of the other alkalis, but in nearly every case 1 per cent of the white alkali was fatal to germination. With the white and red clovers white alkali proved as injurious as the black. Although sodium carbonate is conceded to be the most injurious of the three compounds tested, the chlorid, in its injurious effects, stands very close to it. In every case but one 0.5 per cent of either carbonate or chlorid proved fatal to germination.

In reference to their ability to withstand alkalis, the cereals generally surpassed the legumes, although peas are nearly as hardy as the cereals, and in black alkali proved stronger than either wheat or oats. In their germinative power the cereals stand in the following order: Oats, wheat, rye, and barley, oats being the weakest. This relation holds good for all three kinds of alkali tested. The relative power of the legumes to resist effects of different alkalis varies slightly. In the black alkali the relation was: Alfalfa, white clover, red clover, and peas, the alfalfa being the weakest. With the sodium sulphate and sodium chlorid the relation is the same, except that the alfalfa and white clover change places. It was further found that alfalfa is able to withstand the effects of large amounts of sodium sulphate better than red clover, although with small amounts of sulphate the red clover appeared the stronger. It is stated as worthy of mention that even in soils free

from alkali the alfalfa and white and red clovers exhibited a much smaller power of germination than either of the other kinds of seeds. The author states that the results of this preliminary experiment would simply indicate that cereals would prove a much surer crop on alkali soils than legumes.

The effect of ferments on the germination of old seed, A. THOMSON (*Gartenflora, 45 (1896), p. 344; abs. in Centbl. Agr. Chem., 28 (1899), No. 5, p. 352*).—A report is given of experiments on the germination of a number of cereals taken from the economic collection of the University of Dorpat, these seeds being from 20 to 25 years old. They were divided into lots of 100 each and soaked for 24 hours in diastase or pepsin solutions, after which they were well washed with distilled water and germinated. The pepsin and one of the diastases were commercial preparations, and the second diastase was extracted from freshly germinated barley.

The experiments showed that barley which gave a germination of 4.5 per cent germinated 35 per cent when treated with a 5 per cent diastase solution and 48 per cent with a 10 per cent diastase solution. A 5 per cent pepsin solution raised the percentage of germination from 4.5 to 10 per cent. Oats which had a germination of 16 per cent germinated 47 per cent when treated with a 5 per cent diastase solution and 54 per cent with a 10 per cent disastase, while a 5 per cent pepsin solution increased the germination to 39 per cent. A small-grained maize, which possessed a germinative energy of 3 per cent, germinated 49 per cent when treated with a 5 per cent diastase solution and 38 per cent with a 5 per cent pepsin solution. Rye and wheat which showed no germination when soaked in water gave no indication of germinating after treatment with the ferments. Peas which germinated 5 per cent germinated 22 per cent when treated with a 5 per cent diastase solution. White clover when untreated germinated 17 per cent, and 50 per cent when soaked with a diastase. Yellow clover with a germination of 7 per cent gave 13 per cent when treated with diastase.

Report of the seed-control station in Lund (Sweden) for the year 1898, B. JONSSON (*Malmö, 1899, p. 19*).—The report presents the usual account of the work done in analyzing seed samples, of which 1,621 were examined during the year. An investigation of the influence of the germination bed on the germination of seeds is also reported. The Jacobsen germination apparatus (E. S. R., 10, p. 12) was used. The highest results were obtained for all seeds tested when the disks of felt were sterilized, put on warm, and changed daily, the paper being left unchanged. When the felt disks were changed as before and the filter paper changed every fifth day, somewhat lower results were obtained, viz, for *Dactylis glomerata* 89.6 per cent against 97.2 per cent, for *Festuca rubra* 74 per cent against 85.2 per cent, for timothy 72.2 per cent against 80.8 per cent, etc. When neither felt disks nor filter paper were changed, the germination of the seeds mentioned was 88, 40, and 74 per cent, respectively.—F. W. WOLL.

The eradication of charlock (*Jour. Bd. Agr.* [*London*], *6* (*1899*), *No. 1, pp. 17–21*).—A report is given of a number of experiments conducted in various parts of England for the eradication of charlock (*Sinapis arvensis*). In several of the experiments the effect of 1 to 6 per cent solutions of copper sulphate in qualities varying from 10 to 100 gal. per acre was tested on fields of barley and oats. It seems from these experiments that copper sulphate will destroy the charlock without injury to the cereal crops or seeds sown with them, such as vetches and mangels. The strength of solution, it is said, should not exceed 2 per cent, and from 25 to 50 gal. per acre should be applied. Similar experiments were conducted in which sulphate of iron was applied in strengths of 13 to 20 per cent to an oat field. The charlock was destroyed by this treatment, although it is thought that the strengths of solutions were too strong to be used on a large scale. Whichever method of treatment is adopted, 1 or 2 applications should be made while the cereal crop is quite small. The solutions may be sprayed by hand, but experience has shown that horsepower sprays are more economical. The application should be made during fine weather, when there is no immediate prospect of rain, and a second application, following the first by a short interval, will frequently be found advantageous.

Experiments in which the charlock was in full flower among oats 18 in. high were unsuccessful. At this time 4 per cent solutions of copper sulphate at a rate of 50 gal. per acre did not kill all the flowers, the weeds being protected to a considerable extent by the oat plants.

Experiments on charlock spraying in 1899, J. HORNSBY (*Agr. Gaz.* [*London*], *50* (*1899*), *No. 1314, p. 232; Farm and Home, 18* (*1899*), *No. 918, p. 335*).—An account is given of a series of experiments conducted upon two fields of barley for the eradication of charlock (*Sinapis arvensis*), in which solutions of copper sulphate and iron sulphate were tested, different quantities and strengths of solutions being compared. The iron sulphate was used in strengths of 7½ and 10 per cent at the rate of from 32 to 40 gal. per acre without effect. The solutions of copper sulphate used were 2, 3, 4, and 5 per cent, the quantity employed varying from 16 to 40 gal. per acre. The first series of experiments were made when the plants were just beginning to show the flower buds. Many of the plants at this time were quite small, possessing only five or six leaves. Another series of experiments was conducted later, in which 2 and 4 per cent solutions of copper sulphate at the rate of 72 and 85 gal. per acre were sprayed over the fields when the charlock was coming into flower, and a still further lot was sprayed with 72 gal. of a 4 per cent solution to test whether the weed would be killed when forming its seed, and also to ascertain the effect on white clover which had been sown with the barley.

In all these experiments the copper sulphate treatment was very efficient, fully 85 per cent of all plants of charlock being destroyed without any permanent injury to the barley or clover. As a result of these experiments the author recommends spraying charlock at the rate of 40 gal. per acre with a 2 per cent solution when the plants are small, or, if the charlock is in full flower, at the rate of 60 gal. per acre with a 4 per cent solution. The quantity to be used was also found to vary with the atmospheric conditions at the time of spraying.

Grass seed and its impurities, G. H. HICKS (*U. S. Dept. Agr. Yearbook 1898, pp. 473–493, pls. 5, figs. 2*).—The author points out some of the difficulties met with in securing good grass seed and suggests various ways in which the quality might be improved. Illustrated descriptions are given of a number of the more common grass seeds and the impurities usually accompanying them. Among those described are Kentucky blue grass, rough-stalked meadow grass, wood meadow grass, timothy, orchard grass, fescues, English rye grass, awnless brome grass, meadow foxtail, redtop, and bent grasses.

Seed testing and selection, J. ATKINSON (*Breeders' Gaz., 35 (1899), No. 16, p. 483*).—Brief directions for seed testing and selection.

Report of seed testing during 1898, BEINLING (*Wchnbl. Landw. Ver. Grossherz-Baden, 1899, No. 10, pp. 122–125*).

Effect of inductive electricity on the germination of seed, F. E. AHLFVENGREN (*Öfvers. K. Svenska Vetensk. Akad. Forhandl., 1898, No. 8, pp. 22, fig. 1; abs. in Bot. Centbl., 79 (1899), No. 2, pp. 53, 54*).—Experiments with a large number of seeds of economic plants showed that electricity exerted a beneficial influence on the germination of many varieties. Old seed and those requiring a long time for germination were either not influenced at all or very slightly. In accordance with the conclusions of Kinney (E. S. R., 9, p. 54), maximum, minimum, and optimum strengths of current were observed.

Weeds in cities and towns, L. H. DEWEY (*U. S. Dept. Agr. Yearbook 1898, pp. 193–200, figs. 5*).—The characteristics of city weeds are pointed out, and among those most widely dispersed are the cocklebur, tall ragweed, rough pigweed, burdock, and fine-leaved sneezeweed (*Helenium tenuifolium*). Some of the effects of weeds are mentioned and suggestions given for their eradication.

Eradicating the Canada thistle, T. SHAW (*Breeders' Gaz., 35 (1899), No. 26, pp. 776, 777*).—Salting and repeated cutting recommended for its eradication.

The life history of Cuscuta, G. WILSDORF (*Fühling's Landw. Ztg., 48 (1899), Nos. 14, pp. 544–550; 15, pp. 561–567*).—Investigations are reported on the germination, experiments with seedlings, methods of attacking host plants, haustoria, vegetative growth, and reproduction of a number of the more common economic species of Cuscuta.

Dodder affecting alfalfa, E. SCHRIBAUX (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 34, pp. 229–236; Rev. Gén. Agron. [Louvain], 8 (1899), No. 8–9, pp. 373–377*).—The author describes *Cuscuta gronovii* and states that it is frequently present in American clover and alfalfa seed.

Spraying for mustard, F. T. SHUTT (*Canad. Hort., 22 (1899), No. 9, pp. 345–347*).—Notes the effect of comparatively strong solutions of fungicides on this weed.

DISEASES OF PLANTS.

Work in vegetable physiology and pathology, A. F. WOODS (*U. S. Dept. Agr. Yearbook 1898, pp. 261–266*).—A brief review is given of the investigations carried on by the Division of Vegetable Physiology and Pathology. Among some of the more important results which have been ascertained, mention is made of the three-years' test for rust resistance of some 900 varieties of wheat. The varieties found to be most resistant to orange leaf rust are the winter wheats Turkey, Mennonite, Pringle No. 5, Rieti, and Odessa, and the spring wheats Haynes Blue Stem and Saskatchewan Fife. The Durum and Poulard wheats are said to be very resistant to rust, but, on account of their high gluten content, are so far mainly used for macaroni. In this investigation it has been found that the leaf rusts which have been chiefly hitherto studied are not nearly so destructive to the crops as the black stem rusts of wheat and oats. It has been further demonstrated that the uredo or summer stage of *Puccinia rubigo-vera tritici* lives over the winter, and the same has been proved true of the corresponding form on rye. The black stem rust of wheat is said to occur on squirrel-tail grass (*Hordeum jubatum*), but, so far as known, does not winter in its uredo form in this country. Orchard grass and tall oat grass are now known to be hosts for the black stem rust of oats, and, as a consequence, the oat crop may be infected from these grasses. A full presentation of this and other investigations is promised shortly.

In addition to the work on rusts mention is made of a number of other important diseases, among them investigations on a destructive disease of bulbs on the Pacific Coast; sooty mold of the orange and lemon, which follows attacks of the mealy wing or white fly and may be combated by parasitic fungi; leaf-spot disease of violets; and studies in plant breeding.

Rice blast and a new smut on the rice plant, A. P. ANDERSON (*South Carolina Sta. Bul. 41, pp. 14, figs. 1*).—Numerous inquiries received from various sources led the author to investigate the cause of blast or blight of rice. Most of the information given in the bulletin is from correspondence with a number of the leading rice growers of the State. The disease characterized as blast or blight seems to be manifest in two forms. According to one correspondent the rice-stalk borer is probably the cause of one form of the disease, while the other is apparently of unknown cause. Both diseases attack the upland as well as lowland rice, frequently damaging the crop to a very considerable extent. Another correspondent divides the disease into what he designates as "direct" and "indirect" blast. The first is characterized by the heads appearing dead when emerging from the sheath. The second form is less easily distinguished, and will probably not be recognized until the rice, instead of being of a bright golden color, is seen to be assuming a dark tan appearance. This latter form seems to be due to imperfect aeration of the roots, and was in one case corrected by withdrawing the water from the crop and thoroughly draining the land. The direct blast, from the symptoms given, the author believes to be due to a fungus, which will require further study.

Samples of rice flower, much darker than normal, were submitted to the author for an opinion as to the cause, and upon examination it was found that the flour contained large numbers of black spores. A study of these spores proved them to be *Tilletia corona*, a species of smut described first as occurring on species of grass near Washington, D. C. Comparisons are made between this fungus and *T. horrida* from Japan, from which the author is led to believe that the two are apparently identical. The different characters of the fungus spores are given, and the author expresses the belief that the infection takes place through the young seedlings being affected as soon as the seed germinates. There appears to be no record showing that rice has ever been treated with fungicides, but the author suggests that possibly the treatment given for the prevention of wheat and oat smuts would be beneficial in preventing this disease.

A preliminary report upon treatment for rice smut, E. WALKER (*South Carolina Sta. Bul. 41, pp. 15–31, fig. 1*).—A report is given upon a number of experiments made to test the effect on rice seed of various treatments which were expected to prove beneficial in preventing attacks of the rice smut. All attempts made to germinate the spores have thus far failed, and the effect of the treatment upon them is inferential from that which results in treating oats and wheat.

In experiments made, two series of vessels containing the seeds for germination were arranged, and the seeds were soaked in one-half per cent solution of copper sulphate, 1 per cent solution of potassium sulphid, ½ per cent solution of bromin water, ½ per cent solution of formaldehyde, scalded 3 seconds in boiling water, and then soaked 24 hours in cold water. Two additional lots were also soaked 24 hours in cold water and soaked 24 hours in a 1 per cent solution of pyoktanin. The effect of these various treatments on the germination and subsequent growth is stated, from which it appears that the treatment did not in any way interfere with the germination, and in the case of the bromin water it was thought to slightly accelerate it. A number of the treatments caused rather a feeble and weak growth after germination. This was particularly true of soaking in a solution of pyoktanin and copper sulphate. As a preliminary to this experiment, the author separated the heavy seed from the light and diseased ones by throwing them in water, and he recommends this as one of the treatments to be adopted for the prevention of the smut. Until definite information is known concerning the effect of these fungicides upon the spores, no positive recommendations can be made.

Bacteriosis of potatoes occurring near St. Petersburg in 1898, K. S. IWANOFF (*Ztschr. Pflanzenkrank., 9 (1899), No. 3, pp. 129–131*).—The author notes having observed in July, 1898, that the stems and leaves of many potato plants were affected, the stems showing brown streaks and patches and the leaves becoming wilted and brown. The disease first manifested itself upon the leaf blades and later the stems were affected. By August 15 it had spread quite widely and the crop in the affected fields was greatly diminished, the tubers being small and few.

A study of the disease led the author to the conclusion that it was due to bacteria and he isolated small, short, oval-cylindrical, active bacteria, 1.5μ by 0.5μ in size. Numerous other organisms were found but they were mostly if not all believed to be saprophytic. Among them are enumerated *Fusarium solani*, *Rhizoctonia solani*, *Verticillium albo-atrum*, several bacteria, and yeasts.

Attention is called to the great similarity existing between this disease and its cause and that described by Smith in Bulletin 12 of the Division of Vegetable Physiology and Pathology of this Department (E. S. R., 8, p. 895) as due to *Bacillus solanacearum.* The investigations have not been carried far enough to establish their identity.

The presence of the cucurbit wilt due to *Bacillus tracheiphilus* (E. S. R., 7, p. 311) and *Cercospora resedæ* on *Reseda odorata* are affirmed. Both proved very injurious to their host plants.

The parasitism of yeasts in relation to sorghum blight, RADAIS (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 7, pp. 445–448*).—After briefly quoting the position of several investigators relative to the cause of sorghum blight, the author states that stems of sorghum affected with blight were received from Algeria, from which a small ovoid budding yeast was separated and cultivated in a pure state. The yeast, which is a true saccharomycete, was cultivated on various media and its characteristics are given. Sorghum plants which were grown in the greenhouse and inoculated with cultures of this yeast presented the characteristic appearance shown by sorghum blight. The investigations show that the yeasts are able to develop in the living cells of sorghum and produce the red color characteristic of sorghum blight in the tissues of the plant.

The author believes that the results of his experiments confirm the hypothesis of Palmeri and Comes that the sorghum blight is due to the parasitic action of some saccharomycete. At the same time it is said that these investigations do not necessarily disprove those of Burrill, Kellermann, and Swingle who have claimed that the disease was due to bacteria, but merely show that yeasts may also be considered as a cause of sorghum blight. The red coloration exhibited in the disease is claimed to be due to the chromogenetic function of diseased cells.

Concerning the prevailing Monilia epidemic of fruit trees, FRANK and KRÜGER (*Landw. Jahrb., 28 (1899), No. 1–2, pp. 185–216, pls. 3*).—The authors give an account of a serious outbreak of *Monilia fructigena* on various fruit trees, it having been especially destructive to cherries. A description of the fungus and its appearance on different fruit trees are given. The various tissues attacked are mentioned and the behavior of the fungus in them described. The relation between weather, soil, and exposure, and the disease are discussed at some length, as is the life history and development of the fungus. Historical and geographical notes are given relative to the outbreak of the epidemic. A related and sometimes associated fungus, *Clasterosporium amygdalearum*, is also described. Notes are given on experiments for the prevention of the disease. The authors recommend collecting all mummified fruits and other refuse, pruning all dead twigs, and burning this refuse. Thorough spraying with Bordeaux mixture or similar fungicides is advised, and the ground under diseased trees may be dusted with lime to considerable advantage.

Brown rot of prunes, A. B. CORDLEY (*Oregon Sta. Bul. 57, pp. 15, figs. 7*).—A report is given upon a serious disease of prunes caused by the brown rot (*Monilia fructigena*). This fungus, which is known upon a number of other hosts, is described and some of the differences as manifested on the prune are pointed out. In the case of its attack upon cherries and peaches, a small circular brown spot is said to appear at the point of infection, and this rapidly spreads until the whole fruit becomes affected. In apples, pears, and quinces, the disease spreads in much the same way, but more slowly. In prunes, the disease may affect the entire fruit and still produce but little external evidence of its presence. Such prunes, when opened, will exhibit a brownish rotten appearance due to the work of the fungus. On account of this peculiarity, many prunes are placed in a drier with the impression that they are in good condition, but all such fail to produce a good quality of dried fruit.

It has been frequently claimed that the germ tube of this fungus is unable to penetrate uninjured epidermal tissues, and the author states that the disease rarely attacks an uninjured prune until the ripening process is well under way. This is probably due not alone to the resistant epidermis of the prune, but also to the small amount of moisture in the atmosphere during the summer months. Observations made during two seasons have shown in nearly every instance that prunes infested with the brown rot early in the season had first been attacked and the epidermis broken by the larvæ of the peach-twig borer (*Anarsia lineatella*). Investigations have been conducted to ascertain the manner in which the fungus passes the winter, from which it appears that the spores are carried over to a large extent in the mummy fruits. Among the remedies suggested for the prevention of this disease are the destruction of mummy fruits and thorough spraying of the trees with Bordeaux mixture.

Brunissure of the vine and other plants, A. F. WOODS (*Science, n. ser., 9 (1899), No. 223, pp. 508-510*).—The author briefly reviews the statements of Viala and Sauvageau describing brunissure of the vine and the California vine disease which is said to be due to *Plasmodiophora vitis* and *P. californica*. Subsequent to these investigations Debray claimed the parasite belonged to a new genus and gave it the name *Pseudocommis vitis*. The directions given for the study of this organism are to slowly clear sections or tissues in dilute eau de javelle. The protoplasm of the host cell is said to be dissolved, while the plasmodia remain for a long time unattacked. These may be stained with iodin or other stains, bringing out their structure very sharply.

The author of the present paper has studied a number of plants, among them the grape, lily, tobacco, tomato, rose, hyacinth, and spirogyra, and he states that under the microscope a slight plasmolysis of the cells may be observed, which may increase or afterwards disappear. The chloroplasts swell and become colorless, uniting with each other and usually with the rest of the protein into an amorphous, almost transparent mass. This in turn contracts into a single vacuolated plasmodium-like structure or into several such structures in each cell. They are highly refractive and remain without much change for several hours or disappear, according to the strength of the reagent. In this stage they may be coagulated with alcohol or iodin, stained, and permanently mounted. Changes of this kind are not produced by a mixture of 5 per cent sodium chlorid and 1 per cent sodium hydrate or by either acting alone.

In the author's opinion his observations indicate quite clearly that the supposed *Pseudocommis vitis* is nothing but micro chemical reaction brought about by the oxidation and the influence of alkali upon the protein contents of the cell, especially upon the chloroplasts.

Notes on some destructive fungi, C. B. PLOWRIGHT (*Gard. Chron., 3. ser., 25 (1899), pp. 392, 393, figs. 2*).—Notes are given on a willow-destroying fungus (*Cryptomyces aureus*), elm-tree parasite (*Polyporus ulmarius*), and of an alder parasite (*Ditopella fusispora*).

The willow parasite first appears on the young twigs where the shining black patches surrounded by a very distinctly marked bright yellow border contrast very strikingly with the smooth green bark. On the older twigs the yellow zones are not so distinct, and upon the still older branches they are practically obliterated. The diseased patches extend in a centrifugal manner so that the branches become denuded of their bark and the outer segment of the wood tissues dead and blackened by the fungus. The affected branches die after a time and seriously affect the appearance of the shrubs.

The elm-tree fungus is said to be a true parasite, and its method of growth results in the hollowing out of the trees. It is a perennial, and although the host plant is seriously affected it continues to live for a number of years.

The alder parasite is found upon dead alder twigs while they are still attached to the trees. The bark of the affected branches assumes a bright reddish-brown hue contrasting strikingly with the greenish hue of the living twigs. The line of demarcation between dead and live tissues is very abrupt. The fungus is also known to be a wound parasite, gaining entrance through any broken ends of the twigs. The dead twigs may remain all the year and probably more than a single season, but the perfect fungus will be encountered only during the winter months.

On the parasitism of Ximenia americana, E. HECKEL (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 22, pp. 1352, 1353*).—The author reports experiments with 2 lots of seed of this plant, in which 1 lot was germinated in pots and the other allowed to germinate in the soil under other plants. In the first case the haustoria not being able to affix themselves to the roots of neighboring plants, seized upon the stem and seed of the plant itself, establishing a sort of autoparasitism. In the second case the haustoria were carried to the roots of neighboring plants and fastened upon them. The phenomena of parasitism, it is said, has heretofore been unknown for this family of plants.

Treatment of plant diseases in 1897, F. D. CHESTER (*Delaware Sta. Rpt. 1898, pp. 39–46, fig. 1, dgms. 2*).—In continuation of the work begun 3 years previously, experiments were conducted for the prevention of apple scab in Winesap and Strawberry apples. Bordeaux mixture was applied to the trees, 2 applications being made before the time of blooming and one or two afterwards. To the last one or two sprayings, Paris green at the rate of 4 oz. per barrel was added to the fungicide. At harvest the apples were graded, and the yields tabulated. It appears that the attacks of scab were very disastrous to Strawberry apples, the entire yield from the unsprayed trees being unmarketable, while those trees which were sprayed 4 times gave about 65 per cent of marketable fruit. In the case of Winesaps the trees receiving 4 sprayings gave practically a full crop of perfect fruit, the unsprayed trees yielding 58.4 per cent of worthless apples.

In continuation of previous experiments, plat experiments were conducted on the use of sulphur for the prevention of scab of potatoes. There was reason to believe that the land used was infected with the scab fungus, and flowers of sulphur, at the rate of 300 lbs. per acre, was spread broadcast, just before planting, and harrowed in. At harvest the crop was graded, and as a result of the experiment it was found that the use of sulphur diminished the amount of scab from 26.8 per cent on the untreated plat to 12.4 per cent on the sulphured plat.

Report of the botanist, C. E. BESSEY (*Nebraska Bd. Agr. Rpt. 1898, pp. 139–161*).—A preliminary account of the diseases of the farm crops of Nebraska is given, in which the more important diseases are popularly described and remedies suggested.

Concerning the grain rusts in Austria during 1898, L. HECK (*Ztschr. Landw. Versuchsw. Oesterr., 2 (1899), No. 4, pp. 16, pl. 1*).

The rusts of our grain fields, O. LUGGER (*Farm Students' Rev., 4 (1899), No. 9, pp. 138–140, figs. 4*).—A compiled article treating of the life history of some rusts.

Investigations of some Swiss rusts, E. JACKY (*Ber. Schweiz. Bot. Gesell., 9 (1899), pp. 49–78; abs. in Hedwigia, 38 (1899), No. 5, Repert., pp. 215, 216*).—Notes are given on *Cæoma saxifragæ*, *Uromyces aconiti*, *Puccinia agrostidis*, *Melampsora æcidioides*, *M. populina*, *M. larici-capræarum*, *M. helioscopiæ*, *Puccinia dioicæ*, and *P. ægopodii*. The different host plants are mentioned and the æcidial forms of a number described.

Phoma betæ as the cause of leaf spot and a seed disease of beets, B. FRANK (*Ztschr. Ver. Deut. Zuckerind., 48 (1899), II, pp. 711–717*).

Observations on beet diseases which appeared in the Province of Saxony during 1898, M. HOLLRUNG (*Ztschr. Ver. Deut. Zuckerind., 1899, No. 518, I, pp. 256–262*).

Sugar-beet diseases in 1898, FRANK (*Ztschr. Ver. Deut. Zuckerind., 1899, No. 518, I, pp. 251–255*).

Bacterial rots of plants, L. BUSSARD (*Rev. Vit., 1899, Nos. 282, pp. 525–527; 285, pp. 613–616*).

The bacterial diseases of the potato, FRANK (*Centbl. Bakt. u. Par., 2. Abt., 5 (1899), Nos. 3, pp. 98–102; 4, pp. 134–139, figs. 3*).—Describes the effect of *Micrococcus* spp. on potato tubers.

Two sclerotia diseases of potatoes, E. J. MacWeeney (*Trans. British Mycol. Soc., 1897–98, p. 67*).

Two new diseases of cherries, L. Pynaert (*Tijdschr. Boomteelkunde, 1899, pp. 118–120*).

The black rot, G. Cruderic (*Bul. Soc. Cent. Agr., Hort., et Acclimation, 39 (1899), No. 8, pp. 141–144*).

Observations on the development of black rot, Guillon and Gouirand (*Rev. Vit., 1899, No. 280, pp. 453–455*).

The black rot in Gardillac during 1898, G. Cazeaux-Cazalet and J. Capus (*Rev. Vit., 1899, Nos. 276, pp. 341–348; 277, pp. 377–383; 278, pp. 403–405; 279, pp. 427–431*).

Combating Oidium tuckeri and Peronospora viticola, P. Held (*Württemburg Wchnbl. Landw., 1899, No. 22, p. 341*).

The diseases of coffee, D. Delacroix (*Rev. Cult. Coloniales, 5 (1899), No. 36, pp. 134–138*).

Gray and other tea blights (*Planting Opinion, 4 (1899), No. 37, pp. 732, 733, 738, 739*).—Popular notes are given on a number of blights that are said to threaten the Ceylon tea plantations. Suggestions are offered for their prevention, the principal of which are pruning, and collecting and burning diseased leaves.

Concerning a parasitic fungus causing a wart disease of the Japanese pine, M. Shirai (*Bot. Mag. [Tokyo], 13 (1899), pp. 153–158*).—This disease is described in Japanese.

Notes on the witches' broom of Pinus sylvestris, A. W. Borthwick (*Trans. and Proc. Bot. Soc. Edinburgh, 21 (1899), pt. 3, pp. 196, 197*).—Notes the occurrence of a well-developed hexenbesen on *Pinus sylvestris*. The growth was due to some fungus, but the species was not determined.

A fungus parasite on aloe, G. Massee (*Gard. Chron., 3. ser., 26 (1889), No. 668, p. 291, fig. 1*).—A disease due to *Montagnella maxima* n. sp. is figured and described. The fungus develops in the form of black convex, circular patches, varying from 1 to 1.5 in. in diameter. It is only known from aloe leaves, and the species attacked is not positively known.

Notes on Tuberculina sbrozzii, parasitic on leaves of Vinca major, F. Cavara and P. A. Saccardo (*Nuovo Gior. Bot. Ital., 6 (1899), pp. 322–329*).—*Tuberculina sbrozzii* is described as a new species.

The diseases and parasites of the chrysanthemum, G. Chifflot and Fatzer (*Maladies et parasites du chrysanthème. Paris: Doin, 1898, pp. 38, pl. 1*).

Treatment for the prevention of chrysanthemum diseases, H. Dauthenay (*Rev. Hort., 71 (1899), No. 16, pp. 377, 378*).—Spraying with Bordeaux mixture for the prevention of attacks of plant parasites, and sulphur or tobacco for insects are recommended.

Tree-root rot, G. Massee (*Jour. Bd. Agr. [London], 6 (1899), No. 2, pp. 166–168*).—Notes are given on *Agaricus melleus* together with suggestions of preventive measures.

Treatment of chlorosis by lime, F. Gos (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 21, pp. 142, 143*).—It is claimed that frequent application of lime to and around vines which have been attacked by chlorosis will prove beneficial. The lime on the vine and leaves will also destroy powdery mildew.

The treatment of chlorosis by lime, P. Paroissien (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 33, p. 188*).—A brief note is given of the successful use of slacked lime as a remedy for chlorosis.

Influence of wet weather upon parasitic fungi, B. D. Halsted (*Bul. Torrey Bot. Club, 26 (1899), No. 7, pp. 380–389*).—This paper was read before Section G of the American Association for the Advancement of Science August 23, 1898, and an abstract of it given in the proceedings of the association (E. S. R., 10, p. 858).

Sterilization with formalin, G. Gelm (*Staz. Sper. Agr. Ital., 32 (1899), No. 3, pp. 305–309*).—Gives details of experiments with formalin as affecting the germination of a number of fungi and growth of a dozen species of bacteria.

A lacto-cupric fungicide, E. CROUZET (*Messager Agr., 4. ser., 10 (1899), No. 8, pp. 306, 307*).—A fungicide composed of 2 kg. copper sulphate, 4 liters of milk, and water sufficient to make 100 liters. This mixture is said to remain in suspension for a very long time and is very adhesive to foliage.

Winter spraying, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope, 15 (1899), No. 4, pp. 267–270*).—Notes are given on the use of lime-sulphur-salt mixture for combating peach-leaf curl and scale insects. Where only the leaf curl is to be prevented Bordeaux mixture is recommended.

ENTOMOLOGY.

Insects injurious to beans and peas, F. H. CHITTENDEN (*U. S. Dept. Agr. Yearbook 1898, pp. 233–260, figs. 16*).—The article contains a general account of the more injurious insects of these two crops.

The pea weevil (*Bruchus pisorum*) is described and figured. A brief account is given of its habits and life history. As enemies of this insect the Baltimore oriole and crow blackbird are mentioned. As artificial remedies, the author suggests holding over the seed in a closed receptacle for a time, during which the beetles will emerge and die for want of food; late planting, fumigation of the seed with bisulphid of carbon, benzin, or gasolin; and dry heat at a temperature of 145° F. or one minute emersion in boiling water.

A description is given of the appearance, habits, and life history of the common bean weevil (*B. obtectus*). There are said to be about 6 generations annually of this insect in the latitude of the District of Columbia. It differs from the last-named species in the habit of depositing a large number of eggs in a single seed, 28 having been found in a single bean. Two species of parisitic Chalcidid flies (*Eupelmus cyaniceps* and *Bruchobius laticollis*) have been bred from this insect. As remedies the author suggests the application of bisulphid of carbon treatment and heat.

The cowpea weevil (*B. chinensis*) is now found in the District of Columbia, Maryland, Virginia, and westward and north to Iowa. It is said that in a warm indoor temperature there are 6 or 7 broods annually. This insect is preyed upon by *Pediculoides ventricosus*. The same remedies as those used for the last named species would be effective in this case. Economic and biological notes are given on the following species: *Bruchus 4-maculatus*, *B. rufimanus*, *B. lentis*, *Spermophagus pectoralis*. Against the attacks of *Macrobasis unicolor*, which often feeds upon the leaves, stems, and pods of legumes as well as other plants, the author recommends the use of Paris green in a spray, alone, or with Bordeaux mixture, or dry, mixed with from 10 to 20 parts of flour or air-slaked lime. The remedies which are recommended against *Cantharis muttalli* are driving the beetles into windrows of dry straw and burning them; sweeping them into a net; and beating them into pans of water on which is a thin film of kerosene.

The bean ladybird (*Epilachna corrupta*) is preyed upon in the egg condition by *Hippodamia convergens* and the *Coccinella transversoguttata*. Paris green as a spray may be used against this insect, but the leaves are apt to be scorched by the process. Kerosene emulsion applied as an underspray is more satisfactory.

The bean-leaf beetle (*Cerotoma trifurcata*) yields to a treatment with pyrethrum or an arsenical spray.

Brief notes are also given on the following insects: *Systena tæniata*, *S. blanda*, *Diabrotica 12-punctata*, *Heliothis armigera*, *Semasia nigricana*, *Feltia subgothica*, *Mamestra trifolii*, *Spilosoma virginica*, *Leucarctia acræa*, *Eudamus proteus*, and *Halticus uhleri*.

The principal insects affecting the tobacco plant, L. O. HOWARD (*U. S. Dept. Agr. Yearbook 1898, pp. 121–150, figs. 25*).—The tobacco flea-beetle (*Epitrix parvula*) feeds upon the tomato, potato, horse nettle, and jimson weed, besides being an important enemy of tobacco. A description is given of the appearance and damage caused by this insect. The author recommends the destruction of solanaceous weeds along the edges of the field, allowing a few clumps of these weeds to remain as trap crops which may be heavily sprayed with Paris green. When these preventive measures are not sufficient, it has been demonstrated that it is perfectly safe to spray the tobacco plants directly with Paris green. The Paris green may be used in the proportion of 1 lb. to 125 gal. of water, or it may be mixed with 20 parts of flour or dust.

The tobacco horn worms (*Protoparce carolina* and *P. celeus*) have similar habits and life histories, and are both injurious to tobacco, the former species being more abundant in the South and the latter in the North. The number of generations varies from 2 to 4 or perhaps more in different parts of the country. The caterpillars are often attacked by a bacterial disease. The remedies suggested are hand picking, spraying with Paris green, either dry or in liquid form; putting a poisonous bait in the flowers of the jimson weeds, which are visited by the moths of these two species; and the use of a sweetened preparation poisoned with arsenic and set in pans in the field.

Two species of bud worms (*Heliothis rhexia* and *H. armigera*) are well-known enemies of tobacco. The former species is more abundant toward the end of August, the caterpillars entering the ground and reappearing as moths toward the end of September. The caterpillars feed upon the rolled-up leaves or buds of the plants in August, and the next generation during September and October bore into the seed pod or flower stem. The caterpillars of the last generation enter the ground, and the insects hibernate in the pupal condition. *H. armigera* feeds mostly upon other plants and only attacks tobacco late in the season. The eggs are deposited in the buds. An arsenical spray is effective against both of the bud worms, but A. L. Quaintance recommends sprinkling poisoned corn meal in the bud of tobacco.

The new tobacco bug (*Dicyphus minimus*) has been reported as injurious in a number of States. Two generations in a year were observed in some specimens which were sent to the Division of Entomology. The entire life cycle, according to Quaintance, is about 15 days. According to the same author, a concentrated solution of nicotin diluted in 60 parts of water is an effective remedy for these bugs. Brief economic notes are added on *Pœcilocystus diffusus*, *Euschistus variolarius*, and *Corimelæna extensa.*

The tobacco-leaf miner (*Gelechia solanella*) bores between the surfaces of the leaf. There are two and perhaps more generations in the year. This insect feeds upon the potato, tobacco, horse nettle, tomato, and eggplant. From the fact that the larvæ come out of the leaf and reenter in a new place, they may be destroyed by an arsenical spray. The destruction of their native food plants about June 1 will also help materially to reduce their numbers.

A number of cutworms are known to feed upon tobacco. Three species are figured and the usual remedies recommended. Brief notes are given on *Plusia brassicæ*, *Mamestra legitima*, *Thrips tabaci*, *Aleyrodes tabaci*, *Œcanthus fasciatus*, *Dactilopius citri*, *Nectarophora tabaci*, *Diabrotica 12-punctata*, and *Limax campestris.* *Thrips tabaci* is known to be injurious in Russia and *Aleyrodes tabaci* is reported as damaging tobacco in Greece. These two species, however, have not thus far been known to attack tobacco in this country.

Economic and biological notes are given on the cigarette beetle (*Lasioderma serricorne*). The whole life cycle is said to require 47 days. The remedies recommended are fumigation with bisulphid of carbon, the use of steam and of benzin. In the bisulphid treatment, 1 oz. of the liquid should be evaporated for 62½ cubic feet of space.

Other insects reported as injuring dried tobacco are *Sitodrepa panicea*, *Calandra oryza*, and *Dermestes vulpinus.* The author believes that the use of solanaceous trap crops in the spring and thorough treatment of mutilated tobacco plants which are left standing in the fall will be found to be efficient remedies.

The chinch bug—experiments with insecticides, F. M. WEBSTER (*Ohio Sta. Bul. 106, pp. 237-256, figs. 6*).—The part of this bulletin which deals with the chinch bug is an abridged account of Bulletin 15 of the Division of Entomology of this Department (E. S. R., 10, pp. 1069-1071).

Some experiments were tried with kainit for the purpose of determining its insecticide value. Kainit was placed at the roots of grapevines in the amount of from ½ lb. to 8 lbs. to each vine. The larvæ of *Fidia viticida* were found at the end of the experiment to be not at all inconvenienced by the presence of the kainit. Experiments with kainit in a field of wheat at the rate of from 320 lbs. to 2,400 lbs. per acre gave entirely negative results; the wireworms, against which the kainit was used, being unaffected by it.

Tobacco dust to the amount of from ½ lb. to 4 lbs. was placed in shallow excavations about the stems of grapes in order to test its insecticide value against the grape-root worm. The tobacco appeared to have no effect upon the larvæ of this insect. The roots of some peach trees infested by the black peach aphis were treated with a mixture of 1 lb.

of whale-oil soap in tobacco water in the proportion of 2 lbs. of tobacco to 8 gal. of water. From 1 to 2 gal. of this mixture were poured about the peach trees. The lice were not destroyed by the application.

Bisulphid of carbon was tried as a remedy against the black peach aphis with the result that the trees were killed before the insects were destroyed. In some experiments made with bisulphid of carbon in a closed box for the purpose of testing its insecticide value upon the red spider and greenhouse aphides, it was found that these insects could be destroyed by this means without injuring the hardier plants such as chrysanthemums, pelargoniums, and cinerarias, but lettuce would not endure the treatment.

The San José scale, G. H. POWELL (*Delaware Sta. Rpt. 1898, pp. 234–246*).—An account is given of the work of the entomologist with the San José scale in Delaware. Thirty infestations are reported in the State. Experiments were tried with the following insecticides: Whale-oil soap, pure kerosene, diluted kerosene, resin wash, and the lime, salt, and sulphur wash. The last two were practically valueless, and the report is made only on the other insecticides. A number of trees, including the Bartlett, Manning, Duchess, Howell, and Lawrence varieties were treated in the spring with whale-oil soap in the proportion of 2½ lbs. per gallon of water. The first application was made February 15, and other applications a few days later with whale-oil soap at the rate of 2 lbs. per gallon of water. About 90 per cent of the scales were destroyed. About 95 per cent of fruit buds treated with 2½ lbs. of soap were injured, and those trees which were treated with the 2 lbs. mixture were damaged to the extent of about 50 per cent of their fruit buds. The amount of damage was not regular, but varied from row to row and indicated that a part of the difference was due to a difference in the soaps used.

Another experiment was tried upon trees of Bartlett, Duchess, Howell, and Kieffer pears, using 2 lbs. of potash fish-oil soap to the gallon of water. The buds were just beginning to swell when the spraying was done. The trees were sprayed twice at an interval of a few days. About 95 per cent of the scales were killed, and about 95 per cent of the buds were killed on all varieties except the Kieffer. In the fall of 1897 an experiment was made with fish-oil soap on Bartlett pear trees. Fish-oil soap was used in the proportion of 2 lbs. to the gallon of water. Potash soap, as used in the preceding experiment, was also tried for comparison with the fish-oil soap. The trees came into full bloom the next spring, although 5 per cent of the fruit buds were destroyed by each soap.

In September a large plum tree, a Duchess pear tree, a small apple tree, and a young peach tree were sprayed with 150° fire-test oil with a double Vermorel nozzle. The day on which the spraying was done was clear and windy. The plum and peach foliage was injured to some extent, but that of the apple and pear was uninjured. The peach tree was killed, the plum tree was nearly destroyed, and the apple and pear trees remained uninjured.

A number of experiments were made with various grades of oil, and the author attempted to determine the relative value for insecticide purposes of distillate oil and refined oil. He found that the distillate oil was fully as effective as the refined, and it can be had from the refineries at a much lower price than the refined oil. Trees sprayed with 150° fire distillate oil had 30 per cent of the fruit and leaf spurs injured, but there were still enough spurs left for a full crop. Trees sprayed with 150° fire refined oil suffered to about the same extent. Those trees which were sprayed with an oil called a pure distillate, 44 gravity, had nearly all the fruit spurs killed.

The scales were practically all killed by the kerosene washes. The kerosene method is, therefore, in the author's experience, much more effective in the destruction of the scale than the soap methods. The cost of the soap application is fully twice that of the kerosene. The author concludes as follows: "We feel quite certain that kerosene of 150° test, either a distillate or a refined oil, may be applied in a fine mist to dormant pear or apple trees on a clear day, and that every scale reached by the oil will be killed, but we do not feel safe in recommending its use, from our experience, on peach or plum trees."

Contribution to the study of the anatomy and biology of Phlœothrips oleæ and some new solutions of bisulphid of carbon and nicotin as insecticides, G. GUERCIO (*Atti R. Accad. Econ.-Agr. Georg. Firenze, 4. ser., 22 (1899), No. 1, pp. 50-76, figs. 6*).—The author gives an historical account of previous work on this insect, with bibliographical notices of the literature. Technical descriptions are given of the egg, the different stages of the larva, the pronymph, nymph, and adult. These descriptions are illustrated with figures. The number of eggs which are deposited by a single female varies from 10 to 30. The eggs which are laid in the spring hatch into larvæ within from 8 to 10 days. The larvæ are gregarious, whether upon the ground or upon the plant. Growth of the larvæ is slow, 30 to 35 days being required to attain the stage of pronymph. Up to this stage the insect remains on the green parts of the plant. In about a week the pronymph becomes a nymph. This usually happens about the middle of June, when the insects leave the foliage and collect together upon old scars upon the trees. Some injury to flowers and fruits is done from the middle to the latter part of August. There are 4 generations of the insect a year. The insects during all 4 generations are very active. The effect of the attacks of this insect upon the olive are figured and described. The first effect upon the leaves is noticed by discoloration in the form of a more or less regular spot; the leaf later becomes distorted to a greater or less extent, depending upon the severity of the attack. Finally the leaves show various forms of a gall like formation.

Among the other insect enemies of the olive the author mentions *Œcophora oleæella*, *Hylesinus oleiperda*, *H. fraxini*, and *Lecanium oleæ*, Different observers have thought to discover a preference of the phleothrips of the olive for certain kinds of soil, especially siliceous. The author considers this belief without foundation. The natural enemies of the insect are species of Chilocorus, Exocomus, Scymnus, Chrysopa, and a sporozoon, Coccidium.

As artificial means of checking the insect the author recommends trimming the trees so that the branches will not interlace and form an easy means for the insect to cross from one tree to another; the gathering and burning of all dry boughs and leaves; cutting away the callous growths upon the large branches of olives in winter; spraying with carbolized extract of tobacco, a 2 to 2½ per cent solution in water for the larvæ and adult stages, and a 2½ to 3 per cent solution for the nymphs. The author also recommends a simple mixture of water and petroleum, water and bisulphid of carbon, and an emulsion of bisulphid of carbon and heavy oil of wood tar rendered alkaline, the whole to be mixed with water. Simple solutions of soft soap, 2½ to 3 per cent in water, were found effective against the larvæ.

Report of investigations to determine the cause of unhealthy conditions of the spruce and pine from 1880 to 1893, A. D. HOPKINS (*West Virginia Sta. Bul. 56, pp. 197–461, figs. 99*).—This report contains an account of the author's investigations upon the destructive pine-bark beetle (*Dendroctonus frontalis*) as the chief enemy of spruce and pine in West Virginia, together with notes on a trip to Europe for the purpose of collecting living specimens of the European bark-beetle destroyer, *Clerus formicarius*, for introduction into America. About 6,000 of these insects were collected and imported to the United States, about 3,000 of them arriving in good condition. They were distributed in various badly infested localities. At the time of the distribution of these predaceous beetles it was found that the destructive pine-bark beetle had suddenly become extinct in all its stages. There was, therefore, no opportunity for testing the effectiveness of the imported beetle as a destroyer of the Dendroctonus. It was hoped that the imported Clerus would maintain itself in considerable numbers by feeding on other bark beetles, but no authentic evidence is given of their having been seen since they were released.

The bulletin contains a bibliography of titles by the author on spruce and pine insects, and an appendix in which is given a list of insects taken from spruce and pine during the years 1890 to 1898. This list includes 197 species.

Proceedings of the Imperial Russian Society for the Acclimatization of Animals and Plants. Division of Apiculture, I. A. KABLUKOV, editor (*Moscow, 1899, pp. 120; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, pp. 184, 185*).—Reports of the meetings of this division and an account of experiments made with reference to increasing honey production.

A history of the Royal Station of Agricultural Entomology, A. TARGIONI-TOZZETTI (*Nuove Relaz. R. Staz. Ent. Agr., 1. ser., 1899, No. 1, pp. 1–86*).—This article gives an account of the origin and work of the station with special reference to the most injurious insects with which the station has had to deal and the remedies which have been used with best success by the station.

The Hessian fly, F. M. WEBSTER (*Ohio Sta. Bul. 107, pp. 257-288, figs. 11*).—This bulletin is a revised account of the author's work upon the Hessian fly already published in Ohio Station Bulletin, Vol. IV, No. 7 (E. S. R., 3, p. 412); U. S. Dept. Agr., Division of Entomology Bulletin 23 (E. S. R., 3, p. 55); and Ohio Station Bulletin 51 (E. S. R., 6, p. 150). The list of enemies of the Hessian fly is taken from H. Osborn, U. S. Dept. Agr., Division of Entomology Bulletin 16 (E. S. R., 10, pp. 1074, 1075).

Life habits of the Hessian fly, W. PASPELOW (*Illus. Ztschr. Ent., 3 (1898), No. 7, p. 100*).—The spring brood injured wheat to the extent of 50 per cent and rye 20 per cent. Pupation took place in May, but the pupal stage was much prolonged by a dry summer. Hot weather is favorable to the development of the Pteromalinidæ, which destroy 50 to 70 per cent of the puparia of the Hessian fly.

On two new species of Phlœothrips, M. MATSUMURA (*Annot. Zool. Japonenses, 3 (1899), No. 1, pp. 1-4, pl. 1*).—Descriptions and biological notes are given of 2 species injurious to rice.

The animal enemies of the hop, E. GROSS (*Der Hopfen. Wien: H. H. Hitschmann, 1899, pp. 37-44*).—The author devotes this section to a discussion of the insect and snail enemies of the hop and to the parasitic and predaceous insects which assist the agriculturist by checking the undue multiplication of the injurious insects.

Pests of the hop crop, H. MYRICK (*The Hop. New York, Springfield, and Chicago: Orange Judd Co., 1899, pp. 113-158, figs. 25*).—Chapter X of the author's book on "The Hop" is devoted to a consideration of the common insect, fungus, and nematode enemies of this plant and a discussion of the remedies which have been found effective. The greater part of the discussion of insect enemies is written by L. O. Howard.

Some new notions about old insects, M. V. SLINGERLAND (*Trans. Massachusetts Hort. Soc. 1898, pt. 1, pp. 63-79*).—Contains a discussion of the many new facts recently discovered in the life history of the codling moth and the peach borer and on the changes in remedies which have followed these discoveries.

Comparative values of different methods of combating the codling moth, C. P. GILLETTE (*Colorado State Bd. Hort. Rpt. 1898, pp. 76-81*).

The scale problem, C. W. WOODSWORTH (*Oregon Bd. Hort. Rpt. 1898, pp. 371-374, pl. 1*).—A discussion of different methods for the extermination of the San José scale.

The Coccidæ of Ceylon, E. E. GREEN (*London: Dulau & Co., 1899, pt. 2, pp. 105-169+XIII-XLI, pls. 30*).—This part contains a continuation of a monograph of Chionaspis and Parlatoria. A supplementary chapter is devoted to the consideration of insecticides and insecticide machinery which are especially adapted for the control and destruction of the Coccidæ. This chapter. the author remarks, is largely a compilation of published methods, most of which are derived from the writings of American economic entomologists.

The woolly aphis attacking pear trees, F. PENEVEYRE (*Chron. Agr. Canton Vaud, 12 (1899), No. 17, pp. 383-387*).—This insect is reported as depredating on pear trees.

The louse-like insect enemies of plants in Brazil, H. VON IHERING (*Rev. Mus. Paulista, 2 (1897), pp. 385-420, fig. 1*).—The author describes species belonging to the families Aleurodidæ, Psyllidæ, Aphididæ, and Coccidæ. A brief bibliography of the subject is included.

The scale lice of sugar cane in Java, L. ZEHNTNER (*Verslag. Proefstat. Suikerriet, West Java, 1898, pp. 43-46*).—Notes on a few species of Chionaspis.

Notes on Capulinia jaboticabæ, A. HEMPEL (*Rev. Mus. Paulista, 3 (1898), pp. 51-61, pl. 1*).—This species of bark louse depredates upon a tree of the family Myrtaceæ, known as *Myrciaria cauliflora*. The author gives an account of the damage caused by the insect and a description of the adult and nymphal stages and of the eggs and larvæ. As remedies the author suggests the scraping of the old and loose bark from the trees and spraying with kerosene. Hydrocyanic-acid gas method, as described by Coquillet in *Insect Life* (*6, No. 2, pp. 176-180*), is quoted at length.

Outbreak of phylloxera in the Goulburn Valley, M. BLUNNO (*Agr. Gaz. New South Wales, 10 (1899), No. 7, pp. 677–680*).—Urges the exercise of precaution so as not to introduce the phylloxera on vines from that region.

The phylloxera problem in Italy, G. CUBONI (*Il Problema Fillosserico in Italia. Rome, 1899, pp. 14*).—This paper is a lecture which was delivered as an introduction to a course in vegetable pathology in the Royal University of Rome. It gives general outlines of the extent of infestation by the phylloxera in Italy and of the present studies on the phylloxera question.

The bark beetles of the ash (Hylesinus crenatus, H. fraxini, and H. oleiperda), A. C. FORBES (*Trans. Highland and Agr. Soc. Scotland, 5. ser., 11 (1899), pp. 245–262, figs. 12*).—The author gives careful descriptions of the 3 species of this genus, with detailed notes as to the life histories of each species and as to the differences in the tunnels made by each in the bark of the trees which they infest. Excellent illustrations are given of the different sorts of tunnels made by the 3 species.

As a preventive measure against *H. crenatus*, the author recommends the cutting down and destruction of infested trees. As a remedy for *H. fraxini*, the author recommends the cutting for lumber of the large trees during February and March, and allowing them to lie on the ground until June. The logs may then be removed and will have served as a trap in which the young larvæ will be found, and if the logs are removed a long distance from the woodland the beetles will not be able to reinfest the standing timber.

The periodical cicada, K. SAJO (*Prometheus, 10 (1899), Nos. 193, pp. 388–393, figs. 5; 194, pp. 401–406, figs. 6*).—This article contains an account of the habits and life history of the 17-year cicada, and is based largely on Bulletin 14 of the Division of Entomology of this Department.

Notes on the seventeen-year cicada, B. LANDER (*Jour. New York Ent. Soc., 7 (1899), No. 2, pp. 212–214*).—Notes on the cicada huts.

The migratory, or Asiatic, locusts; natural and artificial remedies, K. N. ROSENKOV (*St. Petersburg: Min. Agr. and Imperial Domains, Dept. Agr., pp. IV+37; abs. in Selsk. Khoz. i Lyesov., 193 (1899), May, pp. 469, 470*).—The author ascribes the migration of these locusts to the presence of their natural enemies, especially the Sarcophaginæ and the Acarina. These parasites attack the locusts after the latter have passed the second stage of larval growth. The author also recommends spraying with Paris green.

Visitation of spotted locusts, E. E. GREEN (*Roy. Bot. Gard. Ceylon Circ., ser. 1, 1898, No. 9, pp. 77–81*).—*Phymateus punctatus* is described together with an account of its injuries to areca and cocoanut palms and a discussion of its natural enemies and of the remedies to be applied against it.

The cochineal insect of Chili (Margarodes vitium), T. ALVAREZ (*Riv. Agron. Cien Apl., Paraguay, 1 (1898), No. 6–7, pp. 289–294*).—Contains notes on the habits and life history of the insect and a brief discussion of the remedies to be adopted in fighting it.

Ladybirds vs. bugs, C. FULLER (*Agr. Jour. Cape Good Hope, 15 (1899), No. 2, pp. 100–108, figs. 13*).—A popular article on the effectiveness of *Vedalia cardinalis* and *Rodolia iceryæ* in destroying *Icerya purchasi.*

The locust-leaf miner, E. D. SANDERSON (*Amer. Gard., 20 (1899), No. 249, p. 672*).—Brief notes on *Odontota dorsalis.*

Cetonia stictica in hotbeds, G. STAES (*Tijdschr. Plantenziekten, 4 (1898), No. 2, pp. 26–31*).—Reported as injuring narcissus. Its systematic position is discussed, and benzin was found to be a rather successful remedy.

Rose pests and how to exterminate them, E. M. WOOD (*Amer. Florist, 15 (1899), No. 590, pp. 222, 223*).—A popular account of the rose chafer, June beetle, green fly, rose-leaf hopper, thrips, and red spider, with suggestions of proper remedies.

Insects and fungi attacking ornamental trees and shrubs, S. T. MAYNARD (*Landscape Gardening. New York: J. Wiley & Sons, 1899, pp. 261–288, figs. 13*).—Popular notes on scales, leaf-eating beetles, and caterpillars, with directions for the use of insecticides and fungicides.

Paris green and certain other compounds vs. insect enemies of fruit gardens, S. A. Mokrzhetzky (*Simferopol, 1899, 3. ed., pp. 15; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, p. 180*).—An outline of methods for making insecticides adhere to the leaves and for combating field insects such as cicadas and locusts.

The preparation of sprays; spray calander (*Oregon Bd. Hort. Rpt. 1898, pp. 183–203, figs. 6*).—Formulas for making insecticides and fungicides with reference to special insect and fungus diseases.

The hot-water cure, G. B. Mallett (*Gard. Chron., 3. ser., 26 (1899), No. 661, pp. 166, 167*).—The different temperatures to which water should be heated in order to make an effective insecticide or fungicide are given for a number of fruits, vegetables, and greenhouse plants.

FOODS—ANIMAL PRODUCTION.

The use of milk in the manufacture of bread and confectionery, W. Smith (*Jour. British Dairy Farmers' Assoc., 14 (1899), pt. 2, pp. 93–97*).—The food value of skim milk is discussed, as well as methods for extending its use. According to the author, skim milk improves the appearance and increases the food value of bread and the amount which may be made from a given quantity of flour. Its use will more than repay the extra expenditure and care required. It is stated that 280 lbs. of flour will take up 175 lbs. of water to make a good dough for loaf bread. When baked this will yield 96 four-pound loaves, there being a loss of 71 lbs. in baking. The same amount of flour will take up 210 lbs. of skim milk and the dough will yield 110 four-pound loaves, or 14 more than is obtained when water is used. In this case there is a loss of 50 lbs. during baking. The water bread is valued at 10 cts. per four-pound loaf, and milk bread at 11 cts. Deducting the cost of the skim milk, which is estimated as $1.64, the milk bread gives 86 cts. greater profit than the water bread. Analyses of water bread and bread made with skim milk (containing 0.03 per cent fat and 9 per cent solids) are reported. Two of these follow:

Composition of bread made with water and with skim milk.

	Water.	Protein.	Fat.	Nitrogen free extract.	Crude fiber.	Ash.
	Per cent.	*Per cent*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Bread made with water	39.36	7.31	0.12	52.59	0.33	*a*0.29
Bread made with skim milk	38.64	9.19	.51	51.07	.31	*a*.28

a Including 0.15 phosphates.

The superior food value of skim milk bread is discussed and the use of skim milk for bakers' goods other than bread is treated of at some length.

Bread made from wheat by the so-called "antispire" system of Desgoffe and Avedyk, L. Pagliani and C. Mazza (*Riv. Ig. e San. Pubb., 9 (1898), No. 4, pp. 118–140, pl. 1*).—The process of making whole-wheat bread by the "antispire" system of Desgoffe and Avedyk is described. By this method the grain is rubbed into a fine powder and does not become heated. Experiments with healthy young men are reported, in which this bread was compared with army bread (black bread) and with ordinary white bread. In the following table the coefficients of digestibility obtained and the daily income and outgo of nitrogen are shown:

Experiments with bread of different sorts.

Food per day.	Time.	Coefficients of digestibility.					Nitrogen.			
		Dry matter.	Nitrogen.	Fat.	Carbohydrates.	Ash.	In food.	In urine.	In feces.	Gain.
MAN, C. P.										
	Days.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Grams.*	*Grams.*	*Grams.*	*Grams.*
200 gm. milk, 200 gm. meat, 500 gm. army bread	5	87.3	81.3	79.1	89.8	71.5	13.4	9.2	2.5	1.7
200 gm. milk, 200 gm. meat, 520 gm. "antispire" bread (made in Berlin)	5	83.8	70.3	80.6	85.6	67.3	14.3	9.5	2.8	2.0
200 gm. milk, 200 gm. meat, 565 gm. white bread	5	92.5	80.6	87.4	96.6	75.1	13.6	9.7	2.6	1.3
MAN, F. G.										
200 gm. meat, 917 gm. army bread	5	93.6	85.8	44.7	96.3	66.6	16.5	12.8	2.3	1.4
200 gm meal, 799.2 gm "antispire" bread (made in Berlin)	5	87.4	80.4	32.9	92.9	74.5	16.1	10.1	3.2	2.8
MAN.										
350 gm. milk, 150 gm. cheese, 590 gm. "antispire" bread (made in Rome)	5	88.6	73.8	82.8	81.2	73.4	14.2	9.1	3.7	1.4
350 gm. milk, 150 gm. cheese, 61.7 gm. army bread	5	92.3	80.8	93.1	92.6	75.3	13.5	10.0	2.6	.9

The principal conclusions are: The "antispire" whole-wheat bread contains a little larger percentage of albuminoids than other breads commonly in use. This bread has a nutritive value somewhat greater than army bread and somewhat less than common white bread. Since this bread may also be prepared more cheaply, its use is more economical than bread prepared from flour ground in the ordinary way.

Further investigations on the effect of fermentation on the value of hay, HOLDEFLEISS (*Mitt. Landw. Inst. Breslau, 1899, No. 1, pp. 59–74*).—In continuation of previous work,[1] the author reports experiments on the effect of fermentation which takes place in the curing of hay. From all his investigations the following conclusions are drawn: The curing of hay is not simply a drying process. In addition to drying, the hay undergoes fermentation which has a marked effect upon it. To obtain good hay it must be treated in such a way as to secure proper fermentation. The best hay is obtained if the green crop is raked into heaps or placed on drying racks after it has wilted slightly. The heaps should be from ½ to a meter high at first. After the grass or other material is more wilted, they may be 2 meters high. Drying on racks is especially desirable with leguminous crops.

---

[1] Deut. Landw. Presse, 24 (1897), p. 433.

In addition to the production of aromatic bodies, fermentation improves the hay by diminishing the quantity of crude fiber and by increasing the relative amount of other nutrients, especially nitrogen-free extract. The greater the fermentation the more the crude fiber is diminished, and this is especially marked when hay is dried on racks. Hay which has undergone proper fermentation has a better flavor and agrees with animals better and is apparently more digestible than hay which has dried quickly in the sun without fermentation. Fermentation apparently diminishes the amount of pentosans in hay, especially that made from grass. It also seems that the amount of true protein is increased.

Feeding experiments (*Agr. Students' Gaz., 9 (1899), No. 4, pp. 116, 117*).—A brief account is given of a feeding experiment with steers at the farm of the Royal Agricultural College of Cirencester. Two Aberdeen-Angus steers fed during the winter a daily ration of 4 lbs. decorticated cotton-seed cake, 6 lbs. maize meal, 18 lbs. hay and chaff, and 15 lbs. roots, gained 14 lbs. per head per week. The cost of a pound of gain was 10.5 cts. Two similar steers fed a daily ration of 7 lbs. linseed cake and 3 lbs. oatmeal, with the same amount of hay, chaff, and roots as the others gained 12 lbs. per head per week, the cost of a pound of gain being 15 cts. The dressed carcass in the first lot constituted 60.6 per cent of the live weight and in the second 59.3 per cent. The flesh of the first lot was regarded as superior, showing more lean in proportion to fat. The composition of the concentrated feeds used is reported.

Poultry experiments, J. DRYDEN (*Utah Sta. Bul. 60, pp. 119–137, figs. 10*).—The experiments, which are a continuation of previous work (E. S. R., 10, p. 77), have to do with the relative value of year-old hens and pullets, early and late hatched pullets, and the effect of exercise on egg production, as well as a comparison of different breeds. Ten lots were used in the tests. Lots 1 to 5 each contained 5 Rose-comb Brown Leghorns, lots 1 and 2 being early-hatched pullets; lots 3 and 4, early-hatched year-old hens, and lot 5 late-hatched pullets. Lot 6 contained 3 Black Leghorn pullets; lot 7, 5 late-hatched Barred Plymouth Rock pullets; lot 8, 4 year-old Light Brahma hens; lot 9, 5 late Brahma pullets, and lot 10 Barred Plymouth Rock pullets. Three of the lots (Nos. 3, 4, and 8) were used in the test of the previous year. All the chickens were given in the morning a warm mash of bran, ground oats, and ground corn (2:1:1), seasoned with salt and a little cayenne pepper. During the forenoon a little whole grain (oats and wheat on alternating days) was fed, and late in the afternoon all the wheat they would eat up clean. Three times a week all the lots were given cut green bone or meat scraps. A suitable amount of green food was also supplied. The lots were kept in pens, as in the previous test. Lots 2 and

3 were fed from boxes and had no exercise. All the other lots had exercise. This consisted in scratching for the grain ration, which was scattered in straw litter. With the exception of 3 lots the test covered 1 year, beginning November 9, 1897. With lot 6 it began about 1 month later; with lot 7, about 4 months later, and with lot 10 about 2 months later. Records were kept of the temperature of the poultry house. The following table summarizes the principal results of the test:

Results of feeding test with chickens.

Lot.		Cost of food per fowl.	Average number of eggs laid per fowl.	Value of eggs.	Cost of food per dozen eggs.	Profit on food.
	WITHOUT EXERCISE.	*Cents.*			*Cents.*	*Per cent.*
2	Pullets	64.4	157	$1.81	4.9	185
3	Year-old hens	62.1	150.8	1.68	4.9	170
	WITH EXERCISE.					
1	Pullets	67	160.2	1.91	5	182
4	Year-old hens	66.5	114.2	1.11	7	67
5	Late-hatched pullets	60.5	164.6	1.78	4.4	194
6	Black Leghorn pullets	74.6	130	1.33	6.9	77
7	Late-hatched barred Plymouth Rock pullets	[a]56.7	105	1.11	6.5	97
8	Year-old light Brahmas	90.2	97	.96	11.1	8
9	Light Brahma pullets	82.9	129	1.33	7.7	37
10	Barred Plymouth Rock pullets	[b]72.2	127	1.28	6.9	77

[a] For 8 months.

[b] For 10 months.

The results of this trial and those of the previous year are discussed at length. Some of the principal conclusions follow:

"The best egg record during the second year was made by a pen of Brown Leghorn pullets, hatched June 10. . . .

"As to the effect of exercise [on the amount of food required to produce a dozen eggs], contradictory results were secured. . . . Exercise had little apparent effect on the weight of the fowl, that little being a slight increase in weight. The eggs from the 2 lots without exercise averaged 4 per cent heavier than those from the 2 exercised lots. This confirms results of the previous year. The eggs from lots 3 and 4 weighed 3½ per cent more during their second year than during their first. The exercised lots consumed a trifle more food than those without exercise.

"The eggs from the 2 lots of Light Brahmas weighed an average of 1.64 lbs. per dozen; those from the 5 lots of Brown Leghorns averaged 1.46 lbs. per dozen, or about 12 per cent in favor of the former."

Maize as a popular article of diet in Servia, A. Zega and R. Majstorović (*Chem. Ztg., 23 (1899), No. 51, pp. 544, 545*).—The authors describe the ways of preparing and serving ground and ripe maize in Servia. The unripe ears are roasted or boiled, a variety of maize is popped, and several sorts of bread and similar articles and a fermented beverage are made from maize meal. The composition of yellow and white maize meals is reported as well as that of the boiled maize, popped corn, and a number of sorts of maize bread, etc.

Sugar as food, F. Strohmer (*Chem. Ztg., 23 (1899), No. 44, p. 467*).—An abstract of an address before the meeting of the "Central-Vereins für Rubenzucker-Industrie" of Austria-Hungary at Bozen in May, 1899.

Chemical analysis of bread made by the "antispire" system of Desgoffe and Avedyk, P. Griacosa (*Riv. Ig. e San. Pubb., Roma, 9 (1898), No. 4, pp. 140–147*).

Macaroni wheats (*Agr. Gaz. New South Wales, 10 (1899), No. 9, pp. 980, 981*).—Notes on macaroni making and on growing macaroni wheats in Australia.

Edible flowers (*Jour. Hyg., 24 (1899), No. 1183, pp. 168, 169*).—A popular article taken from *Bul. Soc. Hort., Orleans et Loiret.*

Cold storage for eggs (*Agr. Gaz. New South Wales, 10 (1899), No. 9, pp. 889, 890*).—The value of cold storage for preserving eggs is pointed out. Notes are given on the application of this method in New South Wales.

Practical introduction to the chemistry of nutrition, H. THOMS (*Einführung in die praktische Nahrungsmittelchemie. Leipzig: S. Hirzel, 1899, pp. VIII + 415, figs. 115*).—This contains a botanical and microscopical section by E. Gigl.

Simple methods of examining food materials, beverages, air, water, illuminating materials, etc., P. O. SMOLENSKI (*Prostyeĭshie Sposobuĭ Īzslyedovaniya Ī Otzyenki Dobrokachestvennosti. St. Petersburg, 1899, 3. ed., pp. 526*).—This volume includes chapters on nutrition, meat and meat products, fish and fish products, milk, cream, butter, cheese, fats and oils, eggs, honey, flour, meal, bread and confectionery, leguminous seeds, vegetables, beverages, including tea, coffee, wine, beer, etc.; condiments, spices, preservatives, coloring matters injurious to health, kitchen utensils, air, water, water supplies, soil, dwellings, illumination and illuminants, and clothing. Many references are given to works in Russian and other languages.

The adulteration of flours with rye, buckwheat, rice, barley, maize, beans, and potato starch, BALLAND (*Jour. Pharm. et Chim., 6. ser., 8 (1898), Nos. 5, pp. 239–243; 6, pp. 286–290*).

The examination of flour, J. HOCKAUF (*Oesterr. Chem. Ztg., 2 (1899), No. 15, pp. 409–412*).—Some of the recent work on the examination of flour for the detection of adulterants is reviewed.

Microscopic examination of wheat flour, E. COLLIN (*Jour. Pharm. et Chim., 6. ser., 8 (1898), Nos. 3, pp. 97–105; 4, pp 150–156, fig. 1; 5, pp. 200–211, figs. 2*).—Histology of the wheat kernel and comparison of wheat flour with like materials used as adulterants.

Some results of dietary studies in the United States, A. P. BRYANT (*U. S. Dept. Agr. Yearbook 1898, pp. 439–452*).—The principal results of the dietary studies made among people of different incomes and occupations in the United States are cited, and ways are pointed out in which the information obtained may be used.

Inspections of milk tests and feeding stuffs, J. L. HILLS (*Vermont Sta. Bul. 68, pp. 33–38*).—Some of the reasons for legislation to protect dairymen and purchasers of feeding stuffs are given, as well as the text of the Vermont laws on these subjects. . The essentials of the laws are discussed.

Utilization of residues from beet-sugar manufacture in cattle feed, G. L. SPENCER (*U. S. Dept. Agr. Yearbook 1898, pp. 213–220*).—The author discusses the feeding value of beet tops, pulp, and molasses. In his opinion the tops, which contain a comparatively large percentage of various salts, should be left on the soil for their fertilizing value unless the manure of the animals fed is returned to the land. Foreign experiments on the feeding value of beet pulp for farm animals are cited from a previous publication of the Department (E. S. R., 9, p. 344), and the successful feeding of the pulp and molasses in the United States is briefly treated of.

Food value of guinea grass (*Queensland Agr. Jour., 5 (1899), No. 3, pp. 302–304*).—The work of the Botanical Garden of Trinidad (E. S. R., 10, p. 1089) on guinea grass (*Pancium maximum*) is cited and discussed.

Treatise on the oil-bearing seeds and vegetable oils, GABAIN BROS. (*Traité sur la question des graines oleagineuses et des huiles végétales. Havre, 1899, pp. 32*).

The influence of fermentation on the value of hay (*Deut. Landw. Presse, 26 (1899), No. 56, pp. 643, 644*).—A brief account of Holdefleiss' experiments (see p. 479).

Problems and progress of animal physiology in relation to agriculture, N. ZUNTZ (*Leistungen und Aufgaben der Tierphysiologie im Dienste der Landwirtschaft. Berlin: P. Parey, 1899, pp. 16*).

Animal heat. Chemical principles of the production of heat by living animals, BERTHELOT (*Chaleur animale. Principes chimiques de la production de la chaleur chez les etres vivants. Paris: Gauthier-Villars, 1899, vol. 1, pp. XVI + 171; vol. 2, pp. 151*).—Volume 1 contains the text and volume 2 the tables.

The formation of fat from protein in a cat, M. CREMER (*Ztschr. Biol., 38 (1899), No. 2, pp. 309–314*).—A controversial article in which a metabolism experiment with a cat is reported which is believed to establish the formation of fat from protein.

Metabolism experiments with proteid bodies containing phosphorus and free from phosphorus, H. ZADIK (*Arch. Physiol. [Pflüger], 77 (1899), No. 1–2, pp. 1–21*).—Experiments with a dog are reported in which the balance of income and outgo of nitrogen was determined.

The effect of sugar, J. VON KÓSSA (*Arch. Physiol. [Pflüger], 75 (1899), No. 6–7, pp. 310–331*).—A number of experiments with birds and mammals are reported in which sugar solutions (usually saccharose) were injected subcutaneously. The author concludes that large doses thus injected or small doses when continued for a long time produce serious pathological changes.

The effect of sodium chlorid on the cleavage of protein, W. STRAUB (*Ztschr. Biol., 37 (1899), No. 4, pp. 527–549, dgms. 5*).—The balance of income and outgo of nitrogen was determined in a number of experiments with a dog. The conclusion was reached that sodium chlorid diminished the cleavage of protein, although the effect was slight.

The excretion of phosphoric acid after castration, N. SCHULZ and O. FALK (*Ztschr. Physiol. Chem., 27 (1899), No. 3, pp. 250–254*).—In view of experiments with female dogs the authors conclude that Curàtulo and Tarulli's[1] opinion that the increased excretion of phosphoric acid in the urine after castration is due to retention of phosphorus in the body is not substantiated. Their own experiments do not enable them to explain the cause of this increase.

The value of accurate determinations of the sulphur in urine in judging of changes which take place in metabolism, E. HARNACK and F. K. KLEINE (*Ztschr. Biol., 37 (1899), No. 4, pp. 417–442*).—A number of experiments are reported. The general conclusion was drawn that determinining the sulphur in urine is not of great value in judging of disease, since this factor is greatly influenced by the food.

Rational stock feeding, F. E. EMERY and J. M. JOHNSON (*North Carolina Sta. Bul. 163, pp. 261–286*).—This is a general discussion of the subject, the topics treated of being definition of terms, composition and digestibility of feeding stuffs, feeding standards, and the method of calculating rations. The bulletin includes a table showing the coefficients of digestibility of a large number of feeding stuffs and mixed rations. In every case the source of the figures given is indicated.

Handbook of the rational culture of fields and meadows and the utilization of crops based on the modern theories of feeding, R. BRAUNGART (*Handbuch der rationellen Wiesen- und weiden-Kultur und Futterverwendung, entwickelt und ausgestaltet auf den Grundlagen der modernen Fütterungslehre. München: T. Ackerman, 1899, pp. VII + 664*).

The maintenance ration of cattle, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1897–98, pp. 65–71*).—A brief summary of some of the principal results and deductions reported in Bulletin 42 of the station (E. S. R., 10, p. 1079).

Keeping goats for profit, A. BARNES (*U. S. Dept. Agr. Yearbook 1898, pp. 421–438, pls. 2*).—Statistics of the number of goatskins used annually in the United States and of the number of goats raised here and abroad are given, as well as of the uncultivated land suitable for goat raising available in this country. Since so few of the goatskins needed are produced here, the author believes goat keeping may be made a profitable industry, since the milk, hair, flesh, etc., may also be made to yield considerable returns.

Feeding and slaughter experiments with pigs fed animal meal and the residue from the manufacture of tropon, O. HAGEMANN and E. RAMM (*Deut. Landw. Presse, 26 (1899), Nos. 70, pp. 790, 791, figs. 12; 71, pp. 805, 806, fig. 1*).—Feeding and slaughter experiments are reported with 3 lots of 2 pigs each: One lot was fed animal meal and one the residue from the manufacture of tropon, while the third lot served as a control.

---

[1] La secrezione interna delle ovaie. Rome: Fratelli Centenari, 1896.

Stations for raising poultry, KNAUP (*Ztschr. Landw. Ver. Hessen, 1899, No. 34, pp. 428–431*).—A plan for cooperation in raising poultry is described and instances cited to show that the plan may be successfully carried out.

Russian poultry and egg industry (*Jour. Bd. Agr.* [*London*], 6 (*1899*), *No. 1, pp. 28–33*).—A somewhat extended account is given of egg production and marketing in Russia.

Five hundred years of pisciculture at Wittingau, J. SUSTA (*Fünf Jahrhunderte der Teichwirthschaft zu Wittingau. Stettin: Herrcke & Lebeling, 1899, pp. XI+232*).

DAIRY FARMING—DAIRYING.

Contributions on the rational nutrition of cows, O. HAGEMANN (*Landw. Jahrb., 28* (*1899*), *No. 3–4, pp. 485–534*).—The principal object of this investigation was to determine whether rations rich in fat produce milk with high fat content, as claimed by Soxhlet (E. S. R., 8, p. 1016). Two cows were used, and feeding and metabolism experiments were made with different rations in 6 periods. The basal ration consisted of hay, straw, dried beet diffusion residue, and salt. To this was added in the first period malt sprouts, in the second period peanut-cake meal and a mixture of 50 parts by weight of cocoa shells and 40 parts of molasses, in the third period linseed meal, and in the fourth period "maize-cake meal." In the fifth and sixth periods the rations were the same as in the first, except that 500 gm. of sesame oil, emulsified in the drinking water, was added in the fifth period, and sesame oil in a weak alkaline emulsion in the sixth period. These rations furnished quite widely varying amounts of fat. The experiment began December 13, 1897, and continued until May 27, 1898. The metabolism experiment covered 10 days in each period except the last, which was only 7 days, as the cows would not drink the alkaline emulsion longer. The individual record for the production of milk and fat and for the metabolism experiment is given for each period.

All the calculations of the results of the experiment are based upon the amounts of nutrients digested, as shown by the digestion experiments In considering the results account is taken of the natural shrinkage with advancing lactation. On the supposition that except for the difference in rations the shrinkage would have been regular from month to month, a table is presented which shows the actual yields of milk and fat, and the calculated yields allowing for a regular shrinkage between the first and fifth periods, during which practically the same rations were fed. The difference between the actual yields and the calculated yields in any period is assumed to be due to the ration. The actual milk yield in the intervening periods is shown to be higher than the calculated yield, allowing for natural shrinkage. Although a larger amount of total digestible nutrients was eaten in these periods it is thought that this alone could not have accounted for the increase, for in period 3, when the largest increase in yield was apparent, the smallest amount of nutrients was digested. The largest amount of digestible protein was consumed in this third period, however, which is thought to bear out the theory that milch cows require rations rich in protein.

In regard to the fat, the results furnish no indication that the fat of the food affects the production of fat in the milk. The largest amount of fat was digested in the fourth period, but the milk in that period was poorest in fat. The ration in the third period contained considerably less fat but the milk was richer in fat and contained a larger total amount. The largest total yield of fat and the largest percentage of fat in the milk occurred in the second period, when the ration contained approximately the right amount of fat for a cow (218 gm. for a cow weighing 560 kg.), the smallest amount contained in any of the rations rich in fat.

The author concludes that neither the percentage nor the absolute amount of milk fat is dependent upon the fat digested from the food. He believes that some feeding stuffs contain certain materials, the nature of which is at present unknown, which stimulate the lacteal glands to greater general activity in some cases, and in other cases so modify the cell activity of the glands that a milk richer in fat is produced. This is held to explain why the fat content increased so materially under the mixture of cocoa shells and molasses, and why in the fourth period on maize-cake meal the milk yield was maintained in spite of the natural shrinkage, although the fat content of the milk diminished. The author cites numerous experiments in support of this hypothesis, among others some conducted by Ramm and himself (E. S. R., 9, pp. 788, 879) on 10 concentrated feeding stuffs of widely different fat content. In these experiments the 2 feeding stuffs poorest and richest in fat both gave milk with the same fat content, while the poppy cake, very rich in fat, gave milk with the lowest fat content, and the mixture of molasses and palm-nut cake, which was very poor in fat, gave much the highest fat content.

During the time the emulsified sesame oil was fed the milk yield decreased and the fat content increased slightly, but this is believed to have been due to the advanced stage of lactation rather than to the effect of the oil. At that time the cows were giving less than 3 qts. of milk per day. They refused to take the emulsion after the seventh day. The substance giving the characteristic sesame-oil reaction was not transmitted from the food to the milk.

Herd testing, C. L. PENNY (*Delaware Sta. Rpt. 1898, pp. 159–197, dgms. 2*).—The author discusses the utility of herd testing; fluctuations in quantity and quality of milk from morning to evening, from one day to the next, from the beginning of lactation to the end, and from year to year; basis of herd selection; balancing a herd; determining the efficiency of dairy cows, and the ratio of butter fat to total solids. The discussion is based on results of tests of a large private herd, covering a number of years, a large part of the data for which are given in tabular form.

The results bearing on fluctuations in milk from morning to evening are summarized as follows:

> "In comparison between morning and evening of the same day, out of 109 distinct observations, 46 showed more milk in the morning, 57 more in the evening, and 6 equal quantities. Out of 104 distinct observations, 72 showed a higher percentage of fat in the morning, 27 in the evening, and 5 an equality in percentage."

A table gives the detailed data for a test of 5 cows for 3 periods of one week each, with averages for each cow for the different periods. The differences in yield of milk from one morning to the next and from one evening to the next are reported separately as the daily fluctuations. The average of each series of daily fluctuations is expressed in actual weight and as a percentage of the average yield for the period.

> "It appears from the table that the least mean fluctuation in weight of milk from one morning to the next, or from one evening to the next, is 0.26 lb., equivalent to 2¼ per cent, and that the greatest mean fluctuation within any one period is 1.58 lbs., equivalent to nearly 12 per cent.[1] . . . The average of the 5 cows for the 3 periods is a mean daily fluctuation in percentage of fat of 0.29 per cent, while the average of the extreme fluctuations within each several period is 0.56 per cent."

Computed for semi-weekly periods, the average fluctuation in butter fat was 0.08 per cent, in contrast to the daily fluctuations of 0.29 per cent. "This shows how much nearer the truth is a three-day sample than a sample from a single milking."

With regard to compensation in yield, the results of several tests are noted as showing that within short intervals of time "it is not the general rule that an increase of quantity means a decrease in solids, but rather the independence of the two, with a slight inclination in the opposite direction, *i. e.*, with a slight inclination to show the heavier yield of milk to be richer in quality than the poorer."

Eleven cows were each tested 3 times at equal intervals during the period of lactation. The average results showed a uniform decline in yield of butter fat. The individual cows, however, showed great irregularities, indicating that tests at repeated intervals during the period are necessary to determine the productiveness in the case of individual cows. Annual fluctuations in yield are not considered sufficiently great from a practical standpoint to warrant the testing of a cow beyond the first period of lactation, or, if the indications are unfavorable, beyond the second period.

Under basis of herd selection, the author discusses different bases depending upon the use to be made of the milk. The municipal ordinance of Philadelphia prescribing for milk a minimum content of 12 per cent solids and 8.5 per cent solids-not-fat is not considered a good basis as it makes no requirement for fat. Balancing a herd consists in combining cows of high yield in solids so that the mixed milk will, with maximum weight, clear the legal standard as to quality. The efficiency of a cow may be determined by computing the arithmetical mean of the tests made at equal intervals during one period of lactation. In this way the relative order of merit of 46 cows as regards production of milk, total solids, and butter fat was determined. Of the whole number, 19 gave over half of the weight of milk, 20 over half of the solids, and 21 over half of the butter fat. The ratio of butter fat to total solids in one herd was found to vary from 0.238 to 0.427, with an average of 0.312.

---

[1] A communication from the author states that the greatest mean fluctuation should have been given as 2.53 lbs., equivalent to 21.3 per cent.

Investigations on the varying composition of butter, J. J. L. VAN RIJN (*Chem. Ztg., 23* (*1899*), *No. 43, pp. 453, 454*).—The investigation relates to the volatile fatty acids of butter. During the months of September, October, November, and December weekly samples of butter were taken from 24 different places in various parts of Holland. In this way about 700 samples of butter were examined. In these samples the volatile fatty acids were found to range between 17 and 32, being for the larger number of samples between 23 and 26, although the figures 20, 21, and 22 were quite frequent. Half of the samples showed less than 25 volatile fatty acids and thus were below what is usually considered the normal for butter fat.

About half the butter examined was made from mixed milk of 500 to 1,000 cows, so that no individual influence could have been exercised. Nearly all of the cows had calved between the previous February and April. It was found that there was a decrease in the volatile fatty acids with advancing lactation up to some time in October, when there was an increase; and there was a noticeable connection between the increase in volatile fatty acids and the time the cows were taken off of fall pasturage and fed in the barn. The author concludes that stall feeding has a marked influence on the composition of butter, and that this affords a means of preventing the volatile fatty acids of the butter from falling so low in the autumn as to be suspected of being adulterated with margarin, under present laws.

Keeping milk in summer, H. M. COTTRELL, F. C. BURTIS, and D. H. OTIS (*Kansas Sta. Bul. 88, pp. 7, figs. 7*).—An account is given of a method employed at the station during the summer for keeping milk in good condition for 40 to 52 hours without the use of ice and at a very small cost. The building used for this purpose was made of old fence boards and covered with building paper. The total cost was about $5. The milk was cooled immediately after milking to about 60° F. by passing over a milk cooler. The cans containing the milk were placed in half barrels and surrounded with well water, which was changed morning and night. Care was taken to avoid contaminations in milking and handling. The results are considered as showing that "any farmer in the State can deliver milk in good condition to the creamery in the hottest weather, and deliver Sunday's milk as well as that of other days."

Bacteria in cheese, J. WEINZIRL (*Bul. Sci. Labs. Denison Univ., 11* (*1899*), *Art. 7, pp. 149–163*).—The author reviews the work of others on this subject and reports some investigations made by himself in collaboration with H. L. Russell of the Wisconsin Station. The examination of 6 experimental cheeses showed "the overwhelming preponderance of the class of germs we have designated as the lactic-acid bacteria, while the casein digesters are relatively few in number and soon disappear from the cheese entirely."

To study the distribution of these classes of bacteria in cheese, 36 samples of cheese procured from 9 of the principal cheese-producing States were examined. The lactic acid producing germs were found in all of the samples, being the most numerous class in three-fourths of the samples. Gas-producing germs were present in all samples but one and were the most numerous class in approximately one-fourth of the cheeses.

> "The presence in relatively small numbers or the entire absence of the digesting and neutral classes confirms our conclusion that these play no important function in the cheese and are present in it only because they were present in the milk, perhaps by accident or carelessness in handling the product, but never really flourish in the cheese medium. . . . There can scarcely be any question that [the lactic-acid bacteria] are directly beneficial, although playing no important rôle in changing the casein into soluble products. . . . They probably furnish much of the flavor peculiar to our best cheese."

Investigations on the ripening of Edam cheese, F. W. J. BOEKHOUT and J. J. O. DE VRIES (*Landbouw. Tijdschr., 7 (1899), pp. 65–81; Centbl. Bakt. u. Par., 2. Abt., 5 (1899), No. 9, pp. 304–307*).—Culture tests were made to discover what sort of bacteria were found in the cheese, using whey gelatin as culture medium. Both aerobic and anaerobic cultures were made, although it is assumed that cheese contains no free oxygen. Edam cheese made with milk colored blue by means of indigo sulphanid of soda was colorless at the end of 2 days, the indigo being reduced to white indigo. Sections exposed to the air turned blue again on account of the absorption of oxygen by the white indigo, indicating that the cheese was free from oxygen. Like Freudenreich, only lactic-acid micro-organisms were found in the cheese. Subsequent cultures with milk gelatin as medium led to the same results, indicating lactic-acid organisms to be the cause of the ripening process. Accordingly, cheese was made from milk pasteurized at 70° C. and inoculated with lactic acid bacteria isolated from Edam cheese. This cheese did not ripen. The experiment was repeated with other lactic-acid bacteria likewise isolated from Edam cheese, but with no better success. Inoculation of pasteurized milk (70° C.) with a mixture of lactic bacteria was likewise unsuccessful.

On the theory that the ripening might be due to bacteria which are not susceptible to culture, milk pasteurized at 70° C. was inoculated with a piece of Edam cheese 14 days old. This, however, did not ripen. The theory of Weigmann that the ripening process is the result of different micro-organisms working consecutively, and soon dying, was tested with milk pasteurized at 70° C. to which 1 liter of market milk was added, with negative result.

The preceding tests were repeated with milk pasteurized at 55° C., but while there was a more decided ripening, it was not normal. Milk was then used which was drawn from 4 cows under as nearly aseptic conditions as possible. Separate portions were inoculated with young cheese (14 days old), with a lactic-acid ferment isolated from Edam cheese, and with ordinary commercial milk. The results were now quite different. Cheese from milk inoculated with young cheese and with commercial milk ripened well, but that from the use of lactic organisms did not ripen. The three control portions not inoculated gave no ripened cheese.

The authors conclude that: (1) The casein of milk which has been heated is so changed that it is not susceptible to ripening processes. (2) Although the ripening is due to lactic organisms, not every lactic-acid ferment can produce ripening. (3) The theory of Babcock and Russell is incorrect, otherwise the control cheeses should have ripened. (4) The theory of Weigmann, if correct, must be modified as to the dying of the micro-organisms, since the cheese used for inoculating the milk was 14 days old.

Dairy cows, G. HENRY (*Quebec Dept. Agr. Bul. 1, pp. 63, figs. 4*).—A popular discussion on the feeding and care of dairy cows and the improvement of herds.

Jersey cattle, their feeding and management (*London: Vinton & Co., 1898, pp. 57*).—This is a popular work prepared by the English Jersey Cattle Society.

Building, remodeling, and ventilating barns, F. H. KING (*Wisconsin Dairymen's Assoc. Rpt. 1899, pp. 151–163, figs. 4*).—A discussion of stables for dairy cows.

Dairying in Denmark, A. MONVOISIN (*Jour. Agr. Prat., 1899, II, Nos. 36, pp. 349–352; 37, pp. 388–391, figs. 8*).

Cooperative dairying in Belgium, M. BEAU and M. BOUGUERET (*Jour. Agr. Prat., 1899, II, No. 40, pp. 482–486*).

Milk: Its nature and composition. A handbook on the chemistry and bacteriology of milk, butter, and cheese, C. M. AIKMAN (*London: A. & C. Black, 1899, 2. ed., pp. XX+180*).

Contribution to the study of cow's milk, A. VAN ENGELEN and P. WAUTERS (*Bul. Agr. [Brussels], 15 (1899), No. 4, pp. 298–312*).—Determinations were made of the yield and composition of milk of 9 cows for one year. The results are given in tabular form and conclusions drawn. "Food has scarcely any influence on the composition of milk. . . . Richness depends primarily on individual aptitude, and has no relation to the quantity of milk produced."

Contributions on the spontaneous curdling of milk, Y. KOZANI (*Ztschr. Hyg. u. Infectionskrank., 31 (1899), p. 337; abs. in Chem. Ztg., 23 (1899), No. 52, Repert., p. 193*).—The kind of lactic acid present in spontaneously curdled milk is considered.

Report on sanitary and bacteriological work for the Department of Agriculture, A. L. HAINES (*Rpt. New York State Dept. Agr., 5 (1897), I, pp. 528–548, pls. 2*).—The author gives a summary account of his work in the State in the inspection of creameries, cheese factories, milk-shipping stations, dairy apparatus, dairy products, and the surroundings and food supplies of dairy animals, and describes a number of bacteria found in milk.

On the presence of tubercle bacilli in the commercial milk and butter in Turin, A. RONDELLI (*Riv. Ig. e San. Pubb., Roma, 9 (1898), No. 24, pp. 873, 874*).—The investigations were confined to milk. Endoperitoneal inoculations in 40 guinea pigs were made with commercial milk from 15 different sources. A number of the animals died suddenly, about 24 to 48 hours after the inoculation, with symptoms of intoxication from bacterial products or of acute infection by *Bacterium coli*. Of the 40 guinea pigs inoculated, only 2 died with generalized tuberculosis. The remainder were killed 6 months after the inoculation, and were found, on examination, to be in sound condition. The author concludes that the presence of the tubercle bacillus in the commercial milk of Turin is not of frequent occurrence, and that the milk is in quite satisfactory condition in this respect.

The development of the mechanical skimming method and its influence on Swedish dairying, K. F. LUNDIN (*K. Landt. Akad. Handl., 38 (1899), No. 3, pp. 127–153*).

A B C in butter making, J. H. MONRAD (*Winnetka, Ill., 1899, pp. 108, figs. 79*).—This is a quite elementary treatise designed, as the subtitle states, "for young creamery butter makers, creamery managers, and private dairymen."

Tests of a new butter ferment, F. D. CHESTER (*Delaware Sta. Rpt. 1898, pp. 47–49*).—Butter was made from cream ripened with *Micrococcus butyri-aromafaciens* and compared with creamery butter. As regards both flavor and keeping quality, the evidence of experts was slightly in favor of the ferment butter. The advantages in the use of a good butter ferment as compared with the fortuitous ripening of cream are noted.

The trials of cream separators at Maidstone, R. M. GREAVES and J. A. VOELCKER (*Jour. Roy. Agr. Soc. England, 3. ser., 10 (1899), pt. 3, pp. 525–545, figs. 6*).—Detailed results of tests of 6 power and 9 hand separators.

Seventh annual report of Wisconsin Cheese Makers' Association, 1899 (*Wisconsin Cheese Makers' Assoc. Rpt. 1899, pp. 210, figs. 39*).—Among the papers contained in the report are the following: The foreign cheese business in Wisconsin, J. W. Decker; Cost of milk and butter production, T. L. Haecker; Modern improved methods of cheese making, D. M. MacPherson; The construction of curing rooms from a practical standpoint, F. H. King.

Stilton cheese, J. M. DUGDALE (*Jour. Roy. Agr. Soc. England, 3. ser., 10 (1899), pt. 2, pp. 351–370, figs. 5*).—The author reviews the history of Stilton cheese and describes the method of manufacture as observed by him in Leicestershire and elsewhere, and points out certain causes of failure.

Influence of temperature on the ripening of cheese, E. CASTEL (*Jour. Agr. and Hort., 3 (1899), Nos. 6, pp. 142–144; 7, p. 163*).

How to construct a subearth duct, J. W. DECKER (*Wisconsin Dairymen's Assoc. Rpt. 1899, pp. 127–134*).—Notes on the construction, advantages, and cost of subearth ducts.

Dairy products of Canada, J. L. BITTINGER (*U. S. Consular Rpts., 1899, No. 224, pp. 17–32*).—A statistical review of the production of butter and cheese in Canada, with a summary of dairy legislation.

The value of skim milk, W. A. HENRY (*Wisconsin Dairymen's Assoc. Rpt. 1899, pp. 97–102*).—Discusses the value of skim milk for feeding calves and pigs.

VETERINARY SCIENCE AND PRACTICE.

The preparation and use of tuberculin, E. A. DE SCHWEINITZ (*U. S. Dept. Agr. Yearbook 1898, pp. 111–120, pl. 1*).—The author gives a detailed description of the method used in the laboratory of the Bureau of Animal Industry in the preparation of tuberculin, and general directions for its use.

The culture medium is made in the following manner: One pound of meat and 1 liter of water, to which is added 1 per cent of peptone, 0.25 per cent of salt, and 7 per cent of glycerin. The solution is boiled, filtered, and placed in sterilized flasks. The solution in the flask is then inoculated. The tubercle germs introduced must be deposited carefully upon the surface, where they are allowed to increase until the surface of the medium is covered. The flasks are then shaken gently, so that all but a small patch of the germs fall to the bottom. The remaining germs are allowed to multiply until the surface is again covered, and this process is repeated until the medium is thoroughly filled with the germs. The flask is then sterilized by heating at a temperature of 125° C. The contents of the flask are filtered and the filtrate concentrated to about one-fifth of its original value.

The tuberculin sent out from the laboratory for immediate use is diluted to such a degree that 2 cc. of the diluted tuberculin is a proper dose for an animal of 1,000 lbs. weight.

The author gives a general table of directions for guiding State veterinarians and other persons who are using the tuberculin test in the taking of the temperatures before and after injection of the tuberculin.

The question of the diagnostic value of tuberculin is discussed, and the author maintains that from general results thus far obtained tuberculin is for all practical purposes an infallible test, there having been reported but very few cases of doubtful or misleading results from its use.

Cattle dipping, experimental and practical, V. A. NÖRGAARD (*U. S. Dept. Agr. Yearbook 1898, pp. 453–472, figs. 2*).—This paper contains a detailed account of the experiments which led to the discovery of an effective cattle dip for destroying the cattle tick (*Boophilus bovis*).

The first remedies which were tried, carbolic acid and corrosive sublimate, were not at all satisfactory for the reason that they were too strongly irritant upon the skin of cattle and not effective in destroying the ticks.

Cotton-seed oil, the next remedy to be applied, was floated on the surface of the water in the dipping vat, the oil forming a layer of about 2 to 3 in. in depth. It was found that many of the ticks survived this treatment and at the same time that the oil had a decided heating effect upon the cattle. Paraffin oils of less and less specific gravity were used in succession, and finally sulphur was added to the oil, but still without perfectly satisfactory results. Some ticks always survived the treatment, and the cattle suffered to a greater or less extent.

The dipping solution which proved most satisfactory was a so-called dynamo oil of very light specific gravity, free from acid, and containing less paraffin and more of the volatile substances than the other oils which had been used. To this oil sulphur was added, and from a series of experiments it was found that all ticks were destroyed by a single dipping.

The author gives the history of the experiments by means of which it was shown that cattle taken from below the quarantine line and dipped in the solution just described could be safely transferred immediately after dipping to States north of the quarantine line and allowed to mingle freely with cattle which had never had Texas fever, without danger of communicating the disease. During these experiments it was noticed that some cattle which appeared free from the disease suffered an acute attack of Texas fever in consequence of dipping. The disease is apt to undergo a recrudescence from severe exposure.

Remarks on anthrax and rabies with special reference to outbreaks recently investigated, V. A. MOORE (*Rpt. New York State Dept. Agr., 5 (1897), I, pp. 549–566, pls. 3*).—An outbreak of anthrax, during which several cows died at Elmira, was investigated. The origin of the infection was not learned. The preventive treatment adopted was the method recommended by Touissant. Defibrinated blood was drawn from an animal immediately after death, thoroughly heated in an autoclave, strained, and filtered. Four cubic centimeters of this sterilized blood preparation was injected into each of the well animals and into 3 cows which already showed signs of the disease. None of the well animals showed any elevation of temperature, and the 3 sick ones subsequently recovered. This method is considered under certain circumstances even superior to that of Pasteur.

The bacillus of anthrax (*Bacillus anthracis*) is described, with various biological notes, and is distinguished from the bacillus of symptomatic anthrax and from *B. subtilis*.

A report is made on an investigation of two outbreaks of rabies, during which several dogs, cows, horses, and one man died. Attention is called to the importance of careful examination and diagnosis of the disease in case of the death of a dog with symptoms of rabies. This is necessary in order that proper treatment may be given other animals and human beings which may have been bitten by the dog.

A report concerning the nature of infectious swine diseases in the State of New York, with practical suggestions for their prevention and treatment, V. A. MOORE (*Rpt. New York State Dept. Agr., 5 (1897), I, pp. 567–619, pls. 5*).—The author gives a historical sketch of the early literature of swine diseases in this country, and the synonymy of names which are used for the same diseases in European countries.

The symptoms, morbid anatomy, and appearance of the diseased organs are described at some length. The usual remedies and preventive measures, including the serum treatment, are described and urged upon the farmers for use.

The two diseases swine plague and hog cholera are separately described and distinguished one from another. The section of the report dealing with serum therapy in swine diseases is practically the same as the article by the author which is abstracted in E. S. R., 10, p. 693.

Accounts are given of investigations of outbreaks of swine diseases in New York, one of which was not well determined; the second was due to filthiness of the food among some swill-fed hogs, and a few outbreaks were due to a combination of hog cholera and swine plague.

Detailed descriptions are added of the morphology, biochemic properties, thermal reactions, and pathogenesis of the bacillus of hog cholera and of the bacillus of swine plague, and for convenience of comparison, the characteristic properties of these two bacteria are arranged in parallel columns.

Nenta, D. Hutcheon (*Agr. Jour. Cape Good Hope, 14 (1899), No. 13, pp. 862–873, figs. 3*).—Nenta is a disease of goats which has been called by other names, such as cerebro-spinal meningitis and Krimpziekte. It has been attributed to various plants of the earlier Leguminosæ and other families. A number of observers have suspected *Lessertia annularis* as being the cause of the disease. The author made experiments in feeding dogs with portions of the body of goats affected with the disease. It was found that dogs, when fed with an extract of the stomach contents of the goat, contracted the disease within a few hours. The disease could also be transmitted from one goat to another in the same manner. No specific germ of the disease was discovered, although it was strongly suspected that such a germ would be found. The cause of the disease is believed to be the plant *Cotyledon ventricosa.* Various experiments made in feeding goats portions of the plant and extracts from the plant were attended with constant and positive results. All goats so fed acquired the disease.

The symptoms of the disease are difficulty in traveling, staggering gait, shivering, and difficult breathing. When lying down, the goats throw the head back upon the side of the body. When large quantities of the plant are eaten a severe tympanitis is apt to follow besides the other symptoms. No specific antidote for the poison has been found and no treatment has been devised which may be considered curative. The author found, however, that full doses of epsom salts, followed by chloral hydrate, repeated 3 or 4 times a day, had good effects in the milder cases. On farms where this plant has been exterminated the disease has completely disappeared.

The International Veterinary Congress in Baden-Baden, Peter and Jess (*Berlin. Tierärztl. Wchnschr., 1899, Nos. 32, pp. 383–385; 33, pp. 395–401*).—A general account of this meeting and of the subjects discussed.

Aphthous fever, Weber (*Rec. Méd. Vét., Paris, 8. ser., 6 (1899), No. 16, pp. 303–313*).—A study of the disease and particularly of the milk during the progress of the dis-

Aphthous fever, A. Simoes (*Arch. Rural, Portugal, 4 (1899), Nos. 3, pp. 41–43; 6, pp. 91–93*).—Contains a description of the disease and recommends disinfection by corrosive sublimate.

A bacillus resembling anthrax from a suspected case of anthrax, F. D. Chester (*Delaware Sta. Rpt. 1898, pp. 52–55*).—Cultures were made of bacillus from an animal which died apparently from anthrax. The bacillus closely resembles that of anthrax, but differs from it in its behavior on different culture media, and is therefore considered a new species—*Bacillus anthracis similis.* The bacillus did not produce any pathological results when injected into mice.

On the presence of specific agglutinins in bacterial cultures, E. Malvoz (*Ann. Inst. Pasteur, 13 (1899), No. 8, pp. 630–636*).—Specific agglutinating substances are supposed by authors generally to be developed by the reactions of the organism. These reactions are usually attributed to the influence of some microbe or to a normal physiological activity of the host organism. The author's investigations led him to believe that it is unnecessary to assume the existence of normal or pathological secretions in order to explain the agglutinating power of serums. In making cultures of anthrax bacillus the author found specific agglutinating substances in the cultures themselves and believes this may be true in the case of other bacteria.

Study of the relationship between agglutinins and lysins in anthrax, O. GENGOU (*Ann. Inst. Pasteur, 13 (1899), No. 8, pp. 642–656*).—In this paper the author discusses the agglutinating power of normal serum and of the serum of immunized animals. The agglutinating power is specific and is not transmitted to offspring. The agglutinins can pass through the walls of blood vessels, but are not dialyzed through a collodion sack when placed in the peritoneal cavity of an immunized animal. There is no relationship between the germicidal power of a serum and its agglutinating power. The specific agglutinating serum is not more strongly germicide than normal blood. The author believes that there is no direct relationship between the agglutinating property of serums and leucocytosis. It was impossible to show that any organ of the body was directly concerned in the production of agglutinating substances.

Tuberculosis and the tubercle bacillus, I. STRAUSS (*La tuberculose et son bacille. Paris: Rueff & Co., 1895, pp. 884, figs. 72*).—This work discusses in a thorough manner all of the topics connected with the study of tuberculosis, including the morphology, culture, and biology of the tubercle bacillus, the tuberculosis of different animals, the methods of contagion, attempts at immunization, tuberculin, and a clinical study of its effects.

Tuberculosis in dairy cattle, and how shall we get rid of it, N. E. REINHART (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 7, pp. 413, 414*).—Recommends the tuberculin test for all dairy herds.

Tuberculosis problems before the Seventh International Veterinary Congress, G. REGNER (*Landtmannen, 10 (1899), No. 36, pp. 579–581*).—An account of the discussion concerning methods of transmission of tuberculosis, and of means for combating it.

A case of tuberculosis, W. SOMERVILLE and A. MEEK (*Veterinarian, 72 (1899), No. 861, pp. 635–637*).—Animals suffering from acute tuberculosis may be closely associated with other animals without communicating the disease.

Investigations on the milk of cows which react to the tuberculin test but show no clinical symptoms of tuberculosis, OSTERTAG (*Ztschr. Fleisch u. Milchhyg., 9 (1899), No. 12, pp. 221–232*).—A large series of experiments failed to show any tubercle bacilli in the milk of such cows.

Artificial tuberculin, GÖRIG (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 37, pp. 325, 326*).—Two injecting fluids claimed by Sirot to be good substitutes for tuberculin were tried on 12 animals with entirely negative results.

Vaccination against blackleg, N. NOTARNICOLA (*Giorn. R. Soc., Accad. Vet. Ital., 48 (1899), No. 29, pp. 679–682*).—A description of the technique and an account of the effectiveness of the operation.

Blackleg vaccine, E. P. NILES (*Virginia Sta. Bul. 90, pp. 67–77, figs. 2*).—The bulletin contains directions for the guidance of stockmen in the preparation of vaccine from the dried material and for the care and use of the hypodermic syringe, the choice of a place for giving the inoculation, the dose, and methods of securing the animal to prevent accidents.

Rinderpest, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 14 (1899), No. 12, pp. 773–781*).—Inoculation with the bile of infected animals is recommended for giving immunity, and directions are given for preparing the bile and making the inoculations.

Texas fever problems—V, D. E. SALMON (*Breeders' Gaz., 35 (1899), No. 1, pp. 5, 6*).—Urges farmers to look forward to the extermination of the cattle tick. By keeping all cattle out of infested pastures for about 2 years the pastures are rendered safe and free from ticks.

The actinomyces group and the bacteria related to it, E. LEVY (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 1, pp. 1–11*).—This paper discusses the morphological relationships of actinomyces and the bacteria which are usually classified with it to bacteria which have similar microscopic and physiological characters. Actinomyces is considered to be closely related to the bacillus of glanders and tuberculosis.

Investigations in the control of foot and mouth disease, HECKER (*Berlin. Tierärztl. Wchnschr., 1899, No. 34, pp. 407–411*).—This paper contains a discussion of the method of contagion and the technique of the preparation of immunizing serum. According to the author the healthy skin is not affected by the contagium.

Preventive inoculation against foot and mouth disease, F. LÖFFLER (*Deut. Tierärztl. Wchnschr., 7 (1899), No. 36, pp. 317–320*).—The technique of the serum preparation is given. Good results were obtained. Experiments were made to determine the duration of the immunity.

Report on the outbreak of foot and mouth disease which occurred in Sweden during 1897 and 1898, J. LUNDGREN (*Meddel. K. Med. Styr., 1898, No. 31, pp. 1–24*).—In this pamphlet an account is given of the supposed origin of this outbreak of the disease, together with detailed directions for disinfecting the stables and the clothes of the attendants.

Contagious abortion in cows, J. LAW (*Rpt. New York State Dept. Agr., 5 (1897), I, pp. 620–636*).—This paper contains a discussion of the different forms of abortion, such as those caused by ergot, smut, etc., and the contagious forms of the United States and Europe. The author considers the various means of transmission of the disease, and discusses the evidence in favor of the disease being contagious. A scheme of prevention and treatment is outlined.

Serum inoculation, O. SCHREIBER (*Berlin. Tierärztl. Wchnschr., 1899, No. 37, p. 449*).—The serum of animals which are immunized against hog cholera was found to give immunity against chicken cholera also.

Acute glanders in the stables of the street railway companies of Utrecht, J. VAN ZIJVERDEN (*Tijdschr. Veeartsenijk. en Veeteelt, 26 (1899), No. 5, pp. 363–372*).—A discussion of outbreaks of glanders with tables showing the temperature records of horses which were tested with mallein.

Report of the glanders committee appointed by the Board of Agriculture, J. A. W. DOLLAR (*Veterinarian, 72 (1899), No. 861, pp. 657–669*).—A discussion of the mallein tests and recommendations as to the slaughter of glanderous horses.

On the use of the silver preparation of Credé as a means for diagnosing glanders, A. BALDONI (*Clin. Vet., 22 (1899), No. 32, pp. 373–380*).—A discussion of the method of applying this diagnostic agent, and statement of results obtained.

Equine distemper, C. MCCULLOCH (*Virginia Sta. Bul. 89, pp. 57–65*).—This bulletin gives a brief account of the disease known as horse distemper, including its history, etiology, symptoms, course, pathological anatomy, and treatment.

Bacteriological investigations on a chicken epizootic of recent occurrence, C. MAZZA (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 6, pp. 181–185*).—By experimental cultures and inoculations the author was able to determine that the micro-organism which caused this disease differed in several particulars from the bacillus of chicken cholera.

The parasitic diseases of poultry, F. V. THEOBALD (*Offic. Rpt. National Poultry Conference, Reading, July, 1899. London: E. Arnold, pp. 28–40*).—This article contains a general description of the diseases of poultry caused by bird lice, mites, the gapeworm, and plant parasites.

On a recent epizootic of chickens in Lombardy, S. BELFANTI and C. ZENONI (*Clin. Vet., 22 (1899), No. 34, pp 397–402*).

The hydrotherapy of domestic animals, STIETENROTH (*Berlin. Tierärztl. Wchnschr., 1899, No. 17, pp. 205–206*).—A general account is given of the value of a cold-water treatment for local fever conditions, especially in the case of the horse. The various uses of hot and cold water irrigation for digestive disorders are discussed as well as the value and effects of hot and cold baths for animals.

Deadly nightshade, or belladonna, G. C. KESLER (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 8, pp. 491, 492*).—Gives symptoms and treatment in case of poisoning of sheep by this plant.

The antiseptic power of iodoform, A. FONSECA (*Compt. Rend. Soc. Biol. Paris, 11. ser., 1 (1899), No. 23, pp. 590, 591*).—Records the germicide power of iodoform as shown in experiments with a number of bacteria.

Chinosol as a disinfectant, E. TURKIN (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 5, pp. 265–281*).—The article contains a discussion of the physical characters of chinosol, its toxic activity, checking influence of chinosol upon the growth of bacteria, its disinfectant and germicidal character, its clinical application, and a record of a large number of experiments in which different bacteria were exposed to its action.

Protargol, H. GIESECKE (*Berlin. Tierärztl. Wchnschr., 1899, No. 26, pp. 311, 312*).—A silver preparation which it is claimed contains silver in organic union with a proteid molecule. In 0.25 per cent to 2 per cent solutions it is useful for treating conjunctivitis and fistula.

Russian waters (blister fluid), VOIGT (*Berlin. Tierärztl. Wchnschr., 1899, No. 26, pp. 312–314*).—A new skin irritant useful in treatment of contusions, œdematous swellings, and blood extravasations.

Contributions to the toxicology of ricin, F. MÜLLER (*Arch. Exper. Path. u. Pharmakol., 42 (1899), No. 2–4, pp. 302–322*).—The poisonous principle of ricin is said not to be affected by the action of the digestive juices, and is therefore not considered a nitrogenous substance. The action which ricin has of causing red blood corpuscles to fuse together is destroyed if the ricin is acted upon by the digestive juices. Its poisonous action is therefore not directly upon the red corpuscles.

STATISTICS—MISCELLANEOUS.

Tenth Annual Report of Delaware Station, 1898 (*Delaware Sta. Rpt. 1898, pp. 268*).—Financial statement for the fiscal year ended June 30, 1898; organization list of the station; a brief review of station work by the director; and reports of the mycologist, chemist, horticulturist, entomologist, and meteorologist, containing articles noted elsewhere. The report also includes reprints of Bulletins 38, 39, 41, and 43 of the station on the following subjects: Some principles in Delaware apple culture (E. S. R., 10, p. 354); sorghum, its development as a commercial source of sugar (E. S. R., 10, p. 345); the European and Japanese chestnuts in the eastern United States (E. S. R., 10, p. 962); veterinary studies; State and municipal milk legislation; the use of basic slag as a fertilizer in hay farming (E. S. R., 11, pp. 141, 185, 189).

Annual Report of Pennsylvania Station, 1897–98 (*Pennsylvania Sta. Rpt. 1897–98, pp. 346*).—The report covers the 18 months ended June 30, 1898, and contains the organization list of the station; financial statements for the fiscal years ended June 30, 1897 and 1898; a report of the director reviewing the work of the station in soils and fertilizers, horticulture, and stock feeding and dairy husbandry; a general discussion on the computation of rations for farm animals reprinted from the Annual Report of the Station for 1896 (E. S. R., 9, p. 873); several articles noted elsewhere; exchanges, and a subject list of station publications. Reprints are also included of Bulletins 39–43 of the station on the following subjects: Variety tests of wheat, oats, and potatoes (E. S. R., 10, p. 41); the sugar beet in Pennsylvania (E. S. R., 10, p. 40); the comparative value of buckwheat middlings, dried brewers' grains, and Cerealine for milk and butter production (E. S. R., 10, p. 589); the maintenance ration of cattle (E. S. R., 10, p. 1079), and apples in Pennsylvania (E. S. R., 10, p. 1042).

Ninth Annual Report of Utah Station, 1898 (*Utah Sta. Rpt. 1898, pp. XLII*).—This contains a report of the director on the work, publications, staff, and equipment of the station; reports of the different departments, parts of which are noted elsewhere; a financial statement for the fiscal year ended June 30, 1898; a list of periodicals received, and a subject list of the bulletins issued by the station, An index to the annual report and bulletins issued during the year accompanies the report.

Yearbook of the Department of Agriculture, 1898 (*U. S. Dept. Agr. Yearbook 1898, pp. 768, pls. 41, figs. 136*).—This consists of a general report by the Secretary on the operations of the Department during the year; 36 miscellaneous articles noted elsewhere; and a summary of useful information published in the form of an appendix. In addition to the usual statistical matter the appendix of the present Yearbook contains a more extended agricultural directory and an account of Cuba and the Philippine Islands.

Report of the State experiment station at Gembloux for 1898, A. PETERMANN (*Bul. Agr. [Brussels], 15 (1899), No. 4, pp. 221–237*).—A report on the work of the station with a summary of the results obtained.

Farming in North Carolina, W. F. MASSEY (*North Carolina Sta. Bul. 162, pp. 227–257*).—This is a popular bulletin designed to give suggestions as to the more profitable uses of the soil and crops of the State, and includes a discussion of the use of commercial fertilizers, home-mixing of fertilizers, care of home-made manures, Piedmont red clay and its improvement, the treatment of the sandy lands of the coast region, culture of cotton and corn, the cowpea and its value in the acquisition of nitrogen, curing the cowpea for hay, the importance of stock feeding, the capacity of the black-pea soils of eastern North Carolina for stock feeding, making and care of pastures, hog raising, curing hams and bacon, trucking as an adjunct to general farming, and other topics.

Agricultural experiments in Alaska, C. C. GEORGESON (*U. S. Dept. Agr. Yearbook 1898, pp. 515–524, pls. 2, map 1*).—This is a popular account of experimental work in Alaska reported in greater detail in Office of Experiment Stations Bulletin 62 (E. S. R., 11, p. 42).

The Hawaiian Islands, W. MAXWELL (*U. S. Dept. Agr. Yearbook 1898, pp. 563–582*).—The agricultural conditions and possibilities of the islands are discussed under the following headings: Area and population, climatic conditions, soils, products, new cultures and industries, forests, ranches, dairying, and labor conditions.

Agriculture in Puerto Rico, R. STONE (*U. S. Dept. Agr. Yearbook 1898, pp. 505–514, map 1*).—A popular description of the conditions and methods of agriculture in the island.

Puerto Rico, its conditions and possibilities, W. DINWIDDIE (*New York: Harper Bros., 1899, pp. 293, ill.*).

Notes on the plant products of the Philippine Islands, F. H. HITCHCOCK (*U. S. Dept. Agr., Division of Botany Circ. 17, pp. 8*).—In order to supply a demand for popular information relative to the plant products of the Philippines, the author has translated a consular report by M. de Bérard published in *Bul. Consulaire Français, 22 (1891), pt. 6.* The data relating to exports are drawn from U. S. Dept. Agr., Section of Foreign Markets Bulletin 14.

The public domain of the United States, M. WEST (*U. S. Dept. Agr. Yearbook 1898, pp. 325–354*).—The public domain of the United States is described by States and Territories and a summary given of the various acts of Congress under which vacant public lands are open to settlement. Exclusive of Alaska and the new island possessions, the total area of vacant Government lands is placed at 573,995,000 acres, and of Government reservations at 145,122,000 acres. Estimates are given on the area of public lands reclaimable by irrigation. Tables show the areas of vacant, reserved, and appropriated lands and the classification of lands reserved from settlement in each State.

Notes on some English farms and farmers, G. W. HILL (*U. S. Dept. Agr. Yearbook 1898, pp. 583–589*).—A brief description of general farm conditions in the counties of Leicester and Rutland, England, and of a number of individual farms in the same counties.

L'Armagnac; its soils, vineyards, brandies, and lands, F. BERTHAULT (*Ann. Agron., 25 (1899), No. 9, pp. 421–447*).—Data on the agricultural conditions of this region are reported and discussed.

Press Bulletins Nos. 1 to 34 (*Kansas Sta. Bul. 86, pp. 62*).—This is made up of reprints of weekly press bulletins issued by the station from August 2, 1898, to April 7, 1899. The articles are based largely on the results of experiments at the station. Following are the subjects treated: Wheat experiments, keeping milk in hot weather, the fringed-wing apple-bud moth, soil moisture and soil stirring, blackleg, the sand plum, Kafir corn for fattening pigs, some reasons why fruit does not set, the peach twig-borer, fall preparation for alfalfa seeding, celery, the balanced ration, seed breeding, the fruit-tree bark-beetle, Kansas sugar beets for 1898, actinomycosis, hardy ornamental shrubs, notes on weeds, the potato-stalk weevil, possibilities in corn improvement, winter protection of peach buds, grazing grasses of western Kansas, the spring cankerworm, a new crop for Kansas farmers, alfalfa hay for fattening hogs, *Tænia fimbriata* (fringed tapeworm), sugar-beet experiments for 1899, treatment of winter-injured trees, milking scrub cows, lice on animals, potato scab, get ready for the drought.

Agricultural articles in the Russian press during 1898 and 1899. I, The present condition of agriculture, S. KIZENKOV (*Selsk. Khoz. i Lyesov., 193 (1899), June, pp. 663–708*).

Outline of instruction given at the agricultural institute at Gembloux (*Bul. Agr. [Brussels], 15 (1899), No. 4, pp. 164–171*).

Some types of American agricultural colleges, A. C. TRUE (*U. S. Dept. Agr. Yearbook 1898, pp. 63–80, pls. 7*).—The institutions in the United States in which agricultural instruction of college grade is provided are divided into 3 classes: (1) Colleges having only courses in agriculture; (2) colleges having courses in agriculture along with those in a variety of subjects, including especially mechanic arts; and (3) colleges (or schools or departments) of agriculture forming a part of universities. The chief characteristics of the different classes are brought out by descriptions of a number of institutions. The Massachusetts Agricultural College is described as the only exclusively agricultural college in the United States. The Michigan State Agricultural College, Mississippi Agricultural and Mechanical College, Kansas State Agricultural College, Iowa State College of Agriculture and Mechanic Arts, Pennsylvania State College, and the Alabama Polytechnic Institute are taken as types of the agricultural and mechanical colleges. Of the State universities having courses in agriculture Cornell University, Ohio State University, University of Wisconsin, and the University of California serve as typical institutions. Some features of student life in the colleges and State universities are noted.

Construction of good country roads, M. O. ELDRIDGE (*U. S. Dept. Agr. Yearbook 1898, pp. 317–324, pls. 2*).—The general principles of road construction and maintenance are discussed, the following topics being treated: Location, grades, drainage, surfacing, earth roads, gravel roads, stone roads, macadam and telford roads, and road maintenance.

Steel-track wagon roads, M. DODGE (*U. S. Dept. Agr. Yearbook 1898, pp. 291–296, pls. 3, fig. 1*).—The merits of this kind of road are discussed, directions for construction are given, and tests of the road at the Trans-Mississippi Exposition at Omaha are reported.

NOTES.

Alabama College Station.—R. W. Clark and Moses Craig have been appointed assistants in agriculture and horticulture, respectively.

Nebraska Station.—The terms of office of Thomas Rawlings and Charles Weston as regents of the university have expired. Their successors, chosen at the November election, are Edson C. Rich, 1537 Park avenue, Omaha, and John L. Teeters, 139 North Ninth street, Lincoln. Vergil C. Barber, assistant animal pathologist of the station, has resigned to accept a position with a business firm of Chicago.

New Mexico Station.—The programme of work for the coming year consists more largely than ever before of work upon the various problems connected with the use of water in New Mexico agriculture. At a recent meeting of the board, the director of the station was authorized to take up the matter of adding an irrigation engineer to the station staff. T. D. A. Cockerell has been invited by the director of the Arizona Station to spend a month in Arizona working up certain insect problems in the southern part of that Territory. A farmers' institute has been held in the San Juan Valley, in the northwestern part of the Territory, under the management of C. E. Mead, superintendent of the substation at Aztec. This substation and the two others in the Territory now receive a special appropriation of $1,000 each per annum from the Territorial funds.

Ohio Station.—Chas. W. Mally, assistant entomologist, has been appointed assistant to the government entomologist of Cape Colony, South Africa, and Wilmon Newell. assistant entomologist at the Iowa Experiment Station, has been appointed in his place.

Tennessee Station.—Weston M. Fulton, United States weather observer at Knoxville, has recently been appointed meteorologist to the station. The station staff is cooperating with the State bureau of agriculture in holding farmers' institutes over the State. Much enthusiasm is manifested in the work of the station.

Texas College and Station.—The title of the horticultural department in the college and station has been changed to that of horticulture and mycology. Assistant H. Ness has been made professor of botany, and A. M. Ferguson has been elected assistant in the department of horticulture and mycology. The foundation for the new agricultural and horticultural building has been laid. The building will be two stories, 72 by 172 ft., with a meteorological observatory 60 ft. above ground. Provision is made for the teaching and investigation of the agricultural and horticultural departments of the college and station, and the general offices of the station will also be located in this building.

Wyoming University and Station.—At the semiannual meeting of the board of trustees of the university, held December 4, plans were adopted for a new science hall, which will be erected the coming season. The building will cost $35,000 and be so constructed that wings can be added as more money is available. The part to be built next season will accommodate the museum and the biological and chemical departments. This will provide much needed room for the station laboratories and relieve the present crowded condition in the main university building.

Alaska Stations.—Prof. C. C. Georgeson, in charge of the Alaska experiment stations, has returned to Washington to present his report of the past season's operations, and for consultation as to plans for future work. The first year has been quite largely occupied in the preliminary work of clearing land, erecting buildings, and getting some cooperative work started in different places. Several acres of land have been cleared on the reservations at Sitka and at Kenai. A two-story frame building to serve as headquarters for all the stations has been erected and partially completed at Sitka, and log barns, implement sheds, and silos for preserving the native grass have been built at both Sitka and Kenai. Further experiments in growing grains and vegetables have been made at Sitka. Kenai, and Kadiak The results of these experiments were even more encouraging than those of the preceding year. Some half dozen varieties of spring wheat, a dozen varieties each of barley and oats, and also flax and Siberian buckwheat all matured at Sitka. At the Kenai station the experiments were equally successful, although carried out on a smaller scale. There was no old ground available at that place; a piece had therefore to be cleared and broken before any seeding could be done, but, in spite of late seeding, Mr. H. P. Nielsen, who was in charge of the work there, succeeded in maturing samples of wheat, barley, oats, buckwheat, and flax. At both places most of the hardy vegetables were also grown successfully. Some heads of cauliflower grown at Kenai measured more than 12 in. across, and ruta-bagas attained a weight of 10 lbs. It is planned to make some reservations of land in the interior the coming summer, and to institute similar tests there. At the coast stations several lines of experiments will be inaugurated. Chief among them will be the problems incident to the bringing of raw land into condition for culture in that region, also the selection and development of varieties of cereals suited to Alaska conditions.

MISCELLANEOUS.—Dr. M. Hollrung, director of the experiment station for plant protection at Halle, Germany, has begun the publication of a yearly review of the literature relating to plant diseases and their prevention. He is desirous of obtaining all publications relating to the subject. Reprints, excerpts, etc., may be sent to him at Halle a. S., Germany. The first volume of this annual, which reviews the literature of 1898, contains 184 pages and gives quite full abstracts of much of the literature which appeared during the year. A brief review of the legislation and decrees of various countries to prevent the introduction and spread of various insect and fungus pests is given. The distribution of some diseases and injurious insects is noted, and publications relating to a number of insects, fungi, weeds, etc., are reviewed without reference to host plants. The principal part of the work is taken up with reviews of literature relating to various fungus diseases and destructive insects, together with suggested means for their suppression. The principal groupings are: Injuries to cereals, fodder grasses, root crops, garden crops, large and small fruits, grapes, and forest trees. The means described for protection are classed as natural and artificial, the latter being divided into mechanical and chemical methods. An index of literature completes the volume.

According to the Bulletin of Miscellaneous Information of the Botanical Department of Trinidad, for October, 1899, the government has decided to establish a course of elementary agriculture in the rural schools. In order to prepare the necessary teachers, it was decided to institute a three weeks' course, the time to be equally divided between the experiment station at St. Clair and the government laboratory. This course was held during August and was remarkably successful. Twenty teachers attended classes, seventeen of whom reported for examination. The course was conducted by Director Hart, assisted by Mr. William Leslie, and consisted of lectures and practical demonstrations of the chief points of agricultural theory and practice.

Dr. L. Hiltner, formerly connected with the experiment station at Tharand, Saxony, entered upon his duties in the bacteriological laboratory of the Imperial Health Department, at Berlin, on November 1, 1899.

Dr. J. M. Jause, formerly of Buitenzorg, has been called to the chair of botany in the University of Leyden.

EXPERIMENT STATION RECORD.

VOL. XI. No. 6.

For nearly a century some form of apparatus for measuring and analyzing the products of respiration has been recognized as desirable in studying the fundamental laws of nutrition, and for the past 40 or 50 years it has been regarded as of prime importance. From the imperfect and crude forms of apparatus at first devised for this purpose the respiration apparatus has been developed until it may be said to be an instrument of precision, complicated in its construction, but so perfect and reliable in the performance of its work as to make its measurement and determination of the respiratory products comparable in accuracy with those ordinarily made in laboratory analysis.

In the course of its development this apparatus has passed through various stages, which it may be of interest to trace briefly. It is not known definitely who first conceived and constructed a respiration apparatus, but Lavoisier, who first explained the nature of respiration, used simple forms of apparatus for measuring and determining the respiratory products and the heat given off by the body in short intervals. His results were published in 1789.

In 1809 Allen and Pepys constructed a simple form of the ventilated-chamber apparatus, for experiments with guinea pigs, in which fresh air was constantly supplied. This consisted of a bell jar through which air was drawn with an aspirator, the carbon dioxid and water being determined in the outgoing air. A similar apparatus was employed by Boussingault in his experiments, published in 1844. The first apparatus of this type for experiments on human subjects was that used by Scharling (1843). The air current was very slow, however, and on account of the accumulation of carbon dioxid in the chamber experiments could not be continued for more than an hour.

An apparatus of a different type was employed by Regnault and Reiset, who published the results of a large number of experiments with small animals in 1849. In their apparatus, which has sometimes been called a closed-circuit apparatus, the same air was passed through the respiration chamber again and again, the carbon dioxid being absorbed and an equal volume of pure oxygen added to the air. Subsequently (about 1863) they enlarged their apparatus so as to make it applicable to experiments with swine, sheep, and calves.

The ventilated-chamber apparatus received its greatest development at the hands of Pettenkofer, who constructed a large apparatus for experiments on man. This apparatus was described in 1862. Pettenkofer, instead of passing the whole air current through the absorption apparatus, extracted aliquot samples for analysis. This enabled him to use a ventilating current of sufficient volume to maintain an atmosphere of normal composition in the respiration chamber. The substitution of baryta water for caustic potash as absorbing agent enabled him to obtain much more accurate estimations of carbon dioxid than any of his predecessors.

The Pettenkofer apparatus was adapted to experiments with large animals and used by a number of German investigators, notably Henneberg and Stohmann, Grouven, and Kühn. It was adapted to experiments with dogs and other small animals by Voit. Considerably later Tigerstedt constructed a very large respiration apparatus of this type, in which, in addition to the carbon dioxid, he attempted to determine the moisture of the air by means of hydrometer, psychrometer, and dew-point apparatus. The error in the measurement of water was about 7 per cent.

The ratio between the oxygen consumed and the carbon dioxid excreted (respiratory quotient), which has been found to be a delicate index of the changes going on in the body, has been arrived at with another form of respiration apparatus, in which the respiration chamber is practically eliminated. In place of the latter a sort of mask is worn in experiments with man, the mask being provided with valves and connected with suitable devices for measuring and analyzing the incoming and outgoing air. In experiments with animals a tube is often inserted in the trachea, through which the subject must breathe, and this tube is connected with a device for measuring and analyzing the inspired and respired air. Zuntz has used apparatus of this form quite extensively in experiments with both man and animals. In his apparatus for the investigation of human respiration the analytical apparatus is attached to the shoulders of the subject and carried about by him, so that experiments can be made under a great variety of conditions.

None of the forms of apparatus mentioned above take account of the heat given off from the body of the subject, but this has been found an important factor in studying the economy of food in the body. A number of different forms of calorimeters for use with small and large animals and with man have been devised from time to time. The earliest was probably that of Crawford (1779), followed later by those of Despretz and Dulong. All three of these were water calorimeters, the chamber being surrounded by a water jacket of known volume, which absorbed the heat radiated by the animal's body. Other forms were devised of the so-called emission type, of which the air calorimeter is a variety; the vaporization calorimeter, in which such liquids as aldehyde and ether were used and the amount volatilized measured; and the form in which the heat given off was measured by the amount of ice melted. An elaborate water calorimeter, suitable for experiments with animals, was devised by Pashutin, of St. Petersburg, and this was adapted to experiments with man by Likhachev. Both calorimeters were so arranged that the respiratory quotient of the subject could be studied for short periods—and, in fact, most of the calorimetric experiments on animals have been accompanied by respiration experiments of some sort. These were sometimes made separately, were often quite crude, and frequently covered only short periods, so that the total respiratory products were not determined. In most cases the object, primarily, was the study of the heat rather than the respiratory products.

An instrument which combined the respiration apparatus and the calorimeter—that is, a respiration calorimeter—was devised by Rubner about 1890. It permitted the determination of the respiratory products and the heat simultaneously in the same chamber, and was suitable for experiments with small animals. The respiration apparatus was of the Pettenkofer and Voit type. The calorimeter was composed of jackets of air and of water surrounding the respiration chamber, the heat given off being measured by the expansion of the air in this jacket (as in an air thermometer) and by the rise in temperature of the water jacket.

In 1893 Rosenthal described a respiration calorimeter, also for small animals, in which the principle of the Regnault and Reiset respiration apparatus was employed.

The highest development in this direction which has yet been reached is the respiration calorimeter elaborated by Professors Atwater and Rosa in this country, which is adapted to experiments with man. This is a modification of the Pettenkofer respiration apparatus, with original devices for the accurate determination of the water and the heat eliminated by the subject. The measurement of water is facilitated by passing the air through a freezing mixture as it enters and leaves the respiration chamber, which freezes the most of the water out of it. This water is collected in copper cylinders, which can be removed and weighed, and the residual moisture in the air current is absorbed in tubes of sulphuric acid.

The respiration chamber, which is likewise the calorimeter chamber, is provided with double metal walls, surrounded by a wooden jacket with air spaces. Advantage is taken of the fact that if the two metal walls are kept at the same temperature there will be no radiation of heat through the walls, and there is a delicate arrangement for maintaining this condition. The current of air is kept at the same temperature as it enters and leaves the respiration chamber. All the heat generated in the chamber is taken up in so-called absorbers by a current of cold water passing through them.

Many of the mechanical devices which contribute materially to the success of the apparatus are due to the ingenuity of the mechanician, Mr. O. S. Blakeslee. This is true of the meter pump—a marked improvement over the aspirators formerly used—which performs the threefold office of drawing the air current through the respiration chamber, measuring and recording its amount automatically, and delivering an aliquot portion for analysis.

Considered as an instrument of precision, this respiration calorimeter is very satisfactory. It is possible to measure with it the large amounts of water and carbon dioxid given off by a subject during long periods as accurately as these factors are ordinarily determined in the laboratory analysis of organic compounds. The measurement of heat is equally accurate, showing 99 per cent or more of the theoretical amount.

The Atwater-Rosa apparatus is to be adapted to use with animals, which will necessitate some devices for supplying food and collecting the urine and feces. The first step in this direction has been taken by the Pennsylvania Experiment Station in cooperation with the Bureau of Animal Industry of this Department. An apparatus suitable for experiments with cattle is being constructed, under the direction of Prof. H. P. Armsby, which will involve some minor modifications of the Atwater-Rosa apparatus.

It is interesting to note also that funds for the construction of respiration calorimeters of the Atwater-Rosa type have recently been appropriated by the Prussian and the Austro-Hungarian governments. Both will be adapted to experiments with cattle or other large animals. The Prussian Government has appropriated $6,000 for such an apparatus, to be built under the direction of Prof. Oscar Hagemann at the Physiological Institute of Poppelsdorf, near Bonn. The apparatus provided for by the Austro-Hungarian Government will be located in the new Physiological Institute at Budapest, under the direction of Professor Tangl. Both of these gentlemen are planning to come to this country soon for the purpose of studying the apparatus and its operation, and will have parts of the apparatus made here.

Naturally, an apparatus so expensive in construction and operation can be maintained by only a few of our experiment stations. It is a matter for congratulation that the apparatus has been brought up to so high a state of perfection, and that its use is not to be confined to experiments with man. Already it has been employed to demonstrate experimentally the application of the law of conservation of energy in the body. It is adapted to the study of a wide range of problems connected with the principles of nutrition, in a much more thorough and conclusive manner than has hitherto been possible. In experiments with animals, for example, such problems as the comparative value of different foods and rations for maintenance and the production of energy, the value of different rations for the production of body fat and milk fat, and the possibility of inducing gains in nitrogenous tissue in the body by any system of feeding may be investigated. Further, it will, it is believed, be possible to measure the amount of energy required to chew and digest different kinds of foods, and thus to learn their real nutritive values.

RECENT WORK IN AGRICULTURAL SCIENCE.

CHEMISTRY.

Proceedings of the twelfth and thirteenth conventions of the Association of Agricultural Experiment Stations in the German Empire (*Landw. Vers. Stat., 52 (1899), No. 1–2, pp. 1–136, pls. 3*).—The twelfth convention was held at Münster September 17, 1898, the thirteenth (extra) at Berlin October 30, 1898. The subjects considered included the determination of the citrate solubility of phosphoric acid in Thomas slag, the sifting of Thomas slag for analysis, the various forms of phosphoric acid in soils and their determination, the permissible amount of perchlorate in nitrate of soda, the determination of the "freshness" of feeding stuffs, the valuation of molasses feed, means of encouraging more accurate cooperative experiments with fertilizers, the participation of the German stations in the international exposition at Paris in 1900, and miscellaneous topics.

The direct precipitation method of determining citrate-soluble phosphoric acid in Thomas slag (E. S. R., 9, p. 1022) was adopted as official. The recommendation of the section on fertilizers, that ground Thomas slag be sifted through a 2 mm. mesh sieve and the fine meal analyzed, the results being calculated to the original meal, was accepted.

Numerous comparative tests of P. Wagner's new method for determining assimilable phosphoric acid in slag (treatment with 2 per cent instead of 1.4 per cent citric acid) were reported. There was very satisfactory agreement between the results of different analysts, the average being slightly higher than that obtained by the old method. Wagner claims, on the basis of pot experiments, that the new method gives results more nearly identical with actual availability to plants than the old method. The method was adopted, to go into effect November 1, 1898.

A paper containing a general discussion of the forms of phosphoric acid in the soil and their determination was read by O. Emmerling, and the subject was discussed by others.

The association adopted the proposition to determine perchlorates and chlorates together in nitrate of soda, using the Gilbert oven and omitting the use of manganese peroxid. M. Maercker called attention to the fact that 1½ per cent of perchlorate may prove injurious in case of rye, and suggested further study of the allowable amount of perchlorate in nitrate.

The question of the determination of the "freshness" of feeding stuffs was presented by O. Emmerling and discussed by others. The matter was referred back for further study. The same action was taken regarding the question of valuation of molasses feed. It was agreed that in stating the analysis of molasses feeds the total nitrogen multiplied by 6.25 should be designated "nitrogenous matter derived from molasses and similar food materials."

Certain minor changes and corrections were made in the rules for seed testing.

The discussion of means of securing more accurate cooperative experiments with fertilizers was led by T. Pfeiffer, who recommended a system of prizes. No action was taken on this proposition.

The utilization of the space granted the association at the Paris Exhibition was discussed and 10 groups of exhibits were decided upon as follows: (1) Animal physiology (Möckern and Poppelsdorf stations), (2) dairying (Kiel, Kleinhof-Tapiau, Hameln), (3) fermentation industries and starch manufacture (Berlin), (4) soil investigations (Rostock, Kiel), (5) moor culture (Bremen), (6) fertilizer control (Halle, Bonn, Münster), (7) feeding stuffs control (Bonn, Kiel), (8) seed control (Tharand, Hamburg), (9) plant protection (Halle), and (10) vegetation experiments (Bernburg).

Various tests for calcareous fertilizing materials proposed by B. Tacke were accepted by the association.

It was agreed to determine ammonia in fertilizers guaranteed to contain nitrogen in this form by distilling an aliquot of a solution obtained by shaking 20 gm. of the substance in 1 liter of water with magnesia.

J. König presented a report on the conditions and needs of the stations, in which he asserted that the work of the German stations suffers from an excessive amount of control work, from lack of efficient assistants and of cooperation of the various agencies having the same or similar aims, and from the practice of publishing the results of investigations only in annual reports, thus causing much delay in the publication of important investigations.

A new apparatus for preparing ash of plants for analysis, G. M. TUCKER (*Ber. Deut. Chem. Gesell., 32 (1899), No. 14, pp. 2583–2585, figs. 2; abs. in Chem. Ztg., 23 (1899), No. 92, Repert., p. 329, fig. 1*).—This apparatus is similar in principle to that of Shuttleworth (E. S. R., 11, p. 304), but air is drawn instead of forced through the apparatus, the gases evolved being passed through a wash bottle to prevent loss. The apparatus is of platinum, and rather simpler in construction than Shuttleworth's. It is small at the bottom, with sloping sides, and has a tight-fitting cover with two openings, the air tube in the center extending to the bottom and carrying the stirrer, and the outlet at one side carrying a platinum tube. The outlet has a trap to prevent particles being carried over mechanically. The platinum tube connects by a glass tube with a wash bottle, an aspirator being connected with the other opening of the bottle.

The crucible is first heated in a conical sand bath and later over the naked flame, being placed in a ring cut from asbestos for the latter heating.

Determination of the total phosphoric acid in Thomas slag, C. ASCHMAN (*Chem. Ztg., 23 (1899), No. 41, pp. 435, 436*).—In the method proposed 5 gm. of the slag is placed in a 500 cc. flask, which is filled to the mark with nitro-sulphuric acid (420 gm. of pure nitric acid, 1.2 sp. gr., and 50 gm. of concentrated sulphuric acid in 10 liters of water). The flask is rotated for ½ hour in an apparatus making 40 to 45 revolutions per minute. The solution is filtered and allowed to stand 12 hours, or overnight, thus getting rid of the greater part of the calcium sulphate. To 50 cc. of the solution 10 cc. of citric acid solution (500 gm. of citric acid per liter of water) is added. The solution is then made slightly alkaline with ammonia, and 50 cc. of water added. When the solution has cooled and become perfectly clear the phosphoric acid is precipitated with 20 cc. of magnesia mixture (Wagner's), stirring for ½ hour. The precipitation is considered complete at the end of from 1 to 2 hours. Longer standing does no harm.

Estimation of the lime, potash, and phosphoric acid in Hawaiian soils probably available for the immediate crop, W. MAXWELL (*Jour. Amer. Chem. Soc., 21 (1899), No. 5, pp. 415–417*).—In investigations on Hawaiian soils (E. S. R., 10, p. 527) it was found that "aspartic acid dissolves phosphoric acid, lime, potash, and other bases (iron and alumina) out of the soil in almost the exact proportions that these elements have been found in the 'waters of discharge,' and in which they are being removed by 'cropping.'" The method of procedure recommended is as follows:

"Two hundred grams of whole soil (not fine earth), air-dried, is put into a glass-stoppered Winchester quart bottle; to this soil is added 1,000 cc. of distilled water containing 10 gm. of pure aspartic acid, thus making a 1 per cent solution. The bottle is gently shaken every 15 minutes during the day portion of 24 hours (from 8 o'clock a. m. to 5 o'clock p. m.). By 'gently shaken' is meant that the bottle is taken up, and shaken in circular movement until the soil at the bottom is totally and thoroughly moved, but without ever rising above the surface of the solution, thus avoiding a remnant of the soil attaching to the sides of the bottle above the solution surface. . . . At the end of 24 hours the contents of the bottle are emptied upon a filter, when 750 cc. of the clear filtrate is taken for analysis. The 750 cc. of filtrate is evaporated to dryness, and the residue gently ignited to remove all organic matter. The mineral residue is moistened with hydrochloric acid, evaporated and dried; then again softened with the same acid, warmed, and taken up with water, and filtered. After removal of iron and alumina from the filtrate with ammonia, the lime and potash are estimated in the usual way. The ammonia precipitate, containing also the iron and alumina, is dissolved in a little hydrochloric acid, neutralized with ammonia, the solution cleared with a little nitric acid, after which the phosphoric acid is precipitated and estimated by the common practice. . . .

"As a 1 per cent solution of aspartic acid takes out of Hawaiian soils in 24 hours the same amounts of lime, potash, and phosphoric acid that are removed during the production of 10 crops of cane, therefore one-tenth of these amounts may be taken as a nearest approach to the proportions of lime, potash, and phosphoric acid that are available for the immediate crop."

Contribution to the determination of the available phosphoric acid in soils under cultivation, C. A. GOESSMANN, H. D. HASKINS, and C. I. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 127–134*).—Samples of soil from plats which had been used for a number of years for comparative tests of phosphates (E. S. R., 9, p. 337) were examined by 3 different methods for available phosphoric acid: (1) The official fifth-normal hydrochloric-acid method, (2) Dyer's 1 per cent citric acid method, and (3) a neutral ammonium-citrate method, which is thus described:

Digest 10 gm. of the soil for ½ hour at 65° C., with 500 cc. of strictly neutral solution of citrate of ammonia, specific gravity 1.09, in a rubber-stoppered flask, shaking thoroughly every 5 minutes. At the expiration of 30 minutes remove flask from bath and filter as rapidly as possible. Wash thoroughly with water at 65° C. Evaporate the solution to dryness, char, and abstract with dilute nitric acid. Filter and wash thoroughly with water. Burn the residue to a white ash, add it to the solution and bring to complete dryness on sand bath. Take up with hot water and a few cc. of nitric acid. Digest for ½ hour. Filter and wash thoroughly and determine the phosphoric acid in the solution in the usual way.

The results obtained were as follows:

Available phosphoric acid in soils by different methods.

No. of sample.	Moisture.	Total phosphoric acid.	Available phosphoric acid. By fifth-normal hydrochloric acid.	Available phosphoric acid. By 1 per cent citric acid.	Available phosphoric acid. By neutral ammonium citrate.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
1	0.77	0.255	0.0285	0.01825	0 0735
2	.87	.290	.0338	.01650	.0945
3	.95	.210	.0407	.01420	.0865
4	1.07	.220	.0330	.01920	.0925
5	1.02	.180	.0345	.01430	.1070

The results varied with the different methods and did not correspond with the yields obtained on the plats.

Method of analysis of citric acid extracts of soils, J. EGOROV (*Izv. Moscow Selsk. Khoz. Inst., 5 (1899), No. 1, pp. 88–90; abs. in Bul. Soc. Chim. Paris, 3. ser., 22 (1899), No. 13, p. 687*).—For analysis of these extracts the author proposes the following method: Add fuming nitric acid and not more than 0.2 gm. of manganic oxid (Mn_3O_4) to the extract and heat gently over the naked flame until oxidation is complete.

Two simple and rapid methods of determining carbon dioxid in caustic lime, limestone, etc., and especially in soils, V. SCHENKE (*Chem. Ztg., 23 (1899), No. 59, pp. 612–614, fig. 1.*)—The author employs, with slight modifications and in an apparatus of modified form, the well-known method of decomposing the carbonates by an acid and determining the carbon dioxid by the loss of weight. He uses hydrochloric instead of sulphuric acid, and calcium chlorid for drying instead of sulphuric acid.

The author claims to have worked out a simple and effective method of determining the lime and magnesia in soils by the amount of carbon dioxid they are capable of taking up. These bases in the soil are combined in the main with carbon dioxid or with humus acids, and when the soil is ignited these compounds are decomposed, the caustic bases being left behind. Five grams of the soil is ignited over a blast lamp for about 10 minutes in a platinum dish, cooled in a desiccator, and weighed quickly. The residue is then treated with a saturated solution of ammonium carbonate, dried and heated again to about 150° to drive off the excess of ammonium carbonate, again cooled and rapidly weighed. The increase in weight is due to the carbon dioxid which has combined with the lime and magnesia, and from this the amount of these constituents in the soil can readily be calculated. It is claimed that other bases in the soil are not affected by this treatment in a way that will vitiate the results.—J. T. ANDERSON.

Determination of reducing sugars in musts and wines, PELLET (*Rev. Chim. Analyt. et Appl., 4* (*1899*), *No. 8, pp. 253–256*).—A study of the influences of neutral and subacetate of lead upon the polarization process, and the action of Fehling's solution. Among the results presented are the following: (1) Direct polarization of must at 22 to 23°, —37.8°; (2) with 10 parts per 100 of neutral lead acetate, (30 per cent), —37.4°; (3) with 10 parts per 100 of subacetate of lead, 30 Baumé, in neutralized must, —38.4°; (4) with 10 parts per 100 of neutral lead acetate, —37.4°; (5) with 10 parts per 100 of subacetate of lead, —39.4°. After inversion according to Clerget No. 2 showed —42.35° and No. 3 —42.35°. By the use of Fehling's solution the following results were obtained: No. 1, must, direct, 18.7 per cent; No. 4, with the neutral acetate, 18.5; No. 5, with subacetate of lead, 18.4; and No 2, after inversion, 18.5. Ten cubic centimeters of Fehling's solution was found to correspond to 0.052 gm. levulose and to 0.048 gm. dextrose; for ordinary determinations the Fehling solution may be considered as corresponding to equal parts of levulose and dextrose, but when the sugar percentages amount to 60 to 70 per cent a sensible error is introduced.—H. SNYDER.

Report of the chemist, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 105–141*).—This includes a brief review of the work of inspection of fertilizers in 1898 (see p. 528), miscellaneous chemical analyses, notes on wood ashes (see p. 527) and on fertilizers for pot and greenhouse plants (see p. 528), an account of tests of the availability of the nitrogen in dried blood and leather refuse in the presence of acid and alkaline phosphates (see p. 526), investigations on the availability of the phosphoric acid in cultivated soils (see p. 508), and analyses of drainage waters (see p. 525).

Laboratory work in physiological chemistry, F. G. NOVY (*Ann Arbor: G. W., 1898, pp. 326, pl. 1, figs. 24*).—A laboratory manual.

Methods of analysis adopted by the Association of Official Agricultural Chemists, November 11, 12, and 14, 1898, H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Bul. 46, rev. ed., pp. 86, figs. 4*).—The methods of the association are given in full, revised to include changes adopted at the Washington meeting in 1898.

Micro-chemical analysis, M. E. POZZI-ESCOTT (*Rev. Chim. Analyt. et Appl., 4* (*1899*), *No. 9, pp. 303–306*).—A short discussion of the importance of micro-chemistry, and a brief mention of the contributions of some of the investigators who have worked along this line. The accuracy of the methods employed, and their application to the study of precipitates, and to the study of complex chemical reactions are considered.—H. SNYDER.

Electrolytic determinations and separations, L. G. KOLLOCK (*Jour. Amer. Chem. Soc., 21 (1899), No. 10, pp. 911–928*).—Some of the earlier methods are reviewed, and the conditions of current density, amperage, voltage, and other factors fully worked out.—L. H. MERRILL.

Preservation of Hubl's reagent, R. BOLLING (*Amer. Chem. Jour., 22 (1899), No. 3, pp. 213, 214*).—An investigation as to the loss of strength under varying conditions demonstrated the fact that the loss was very rapid and was but little retarded by the use of absolute alcohol or by the exclusion of light and air.—E. B. HOLLAND.

The analysis of golden sirup, R. BODMAN, N. LEONARD, and H. M. SMITH (*Analyst, 24 (1899), No. 283, pp. 253–257*).—A report on the examination of 26 samples of sirup by optical and gravimetric methods and the interpretation of the results.—E. B. HOLLAND.

The determination of the fat content of milk, R. WINDISCH (*Landw. Vers. Stat., 52 (1899), No. 3, pp. 209–211*).—The author describes the method of Liebermann and Székely (E. S. R., 4, p. 776), and gives the results of a comparison between it and the Gerber rapid method on 14 samples of milk. The results by the 2 methods compared well, rarely showing over 0.05 per cent difference.

Determining the amount of boracic acid [in butter], VADAM (*Jour. Pharm. et Chim., 6. ser., 8 (1899), No. 3, pp. 109–111*).

Progress in the examination of spices and their adulterations, T. F. HANAUSEK (*Chem. Ztg., 23 (1899), No. 44, pp. 463–466*).—A review of recent literature.

Analytical methods for distinguishing between nitrogen of proteids and nitrogen of simpler amids or amido acids, J. W. MALLET (*Chem. News, 80 (1899), Nos. 2080, pp. 168–171; 2081, pp. 179–182*).—See E. S. R., 10, p. 819.

The coagulation of albumin, C. HALPHEN (*Jour. Pharm. et Chim., 6. ser., 8 (1899), No. 4, pp. 173–175*).—The use of citrate of ammonia in estimating albumin is pointed out.

The color reactions of sesame oil, and three new characteristic reactions, M. J. BELLIER (*Rev. Chim. Analyt. et Appl., 4 (1899), No. 7, pp. 217–220*).—The following reactions are discussed: (1) Behrens' (equal parts of sulphuric and nitric acid), (2) Bishop's (hydrochloric acid), (3) Baudouin (hydrochloric acid 1.18 sp. gr.), (4) Villavecchia and Fabris' (hydrochloric acid, containing a small quantity of furfurol), (5) Tocher's (hydrochloric acid 14 cc., pyrogallic acid 1 gm.), and (6) Cavalli's (60 per cent hydrochloric acid, 40 per cent nitric acid). Tocher's reaction is considered as worthy of the most confidence. The new reactions reported are with (1) ammonium vanadate, (2) formaldehyde, and (3) resorcin.—H. SNYDER.

A characteristic color reaction of tartaric acid, M. J. WOLFF (*Rev. Chim. Analyt. et Appl., 4 (1899), No. 8, p. 263*).—Sulphuric acid and resorcin produce an intense coloration, which disappears upon dilution with water. Neither oxalic nor citric acid gives this reaction under similar conditions.—H. SNYDER.

Water and sewage examination results (*Chem. News, 80 (1899), No. 2080, pp. 161, 162*).—This is the report of the committee appointed to establish a uniform system of recording the results of the chemical and bacteriological examination of water and sewage, read before the British Association for the Advancement of Science at its Dover meeting in 1899.

Fractional precipitation of peptic digestion products by means of zinc sulphate, E. ZUNZ (*Ztschr. Physiol. Chem., 27 (1899), No. 3, pp. 219–249*).

The preparation of lecithin and other myelin bodies from egg yolk and brain extracts, G. ZUELZER (*Ztschr. Physiol. Chem., 27 (1899), No. 3, pp. 255–266*).

Gossypol, a constituent of cotton seed, L. MARCHLEWSKI (*Jour. Prakt. Chem., 60 (1899), pp. 84–90; abs. in Chem. Ztg., 23 (1899), No. 64, Repert., p. 232*).—This name is applied to a phenol-like body extracted from raw cotton seed by sodium hydrate and precipitated in an impure state by acids. The properties of the purified substance are described.

On isomaltose, Pottevin (*Ann. Inst. Pasteur, 13 (1899), No. 10, pp. 796–800*).

Protein compounds of arginin, U. Susuki (*Chem. Ztg., 23 (1899), No. 64, p. 658*).

Action of formaldehyde on enzyms and on certain proteids, C. L. Bliss and F. G. Novy (*Jour. Expt. Med., 4 (1899), pp. 47–80; abs. in Tech. Quart., 12 (1899), No. 2, Rev. Chem., pp. 55, 56*).

Cause of blackening of bean pods, Bourquelot and Hérissey (*Jour. Pharm. et Chem., 6. ser., 7 (1898), p. 385; abs. in Amer. Jour. Pharm., 71 (1899), No. 6, p. 281*).—A chemical study.

The index of refraction of a number of species of starch, Emma Ott (*Oesterr. Bot. Ztschr., 49 (1899), No. 9, pp. 313–317, fig. 1*).

A new method for measuring temperatures, D. Berthelot (*Bul. Mus. Hist. Nat. [Paris], 1898, No. 6, pp. 301–304*).

Liquid air and the liquefaction of gases—theory, history, biography, practical applications, manufacture, T. O'C. Sloane (*New York: Norman W. Henley & Co., 1899, pp. 365, pls. 9, figs. 71*).

Continuous extractors for volatile solvents, E. Van Melckebeke (*Bul. Assoc. Belge Chim., 13 (1899), No. 5, pp. 242–245; abs. in Jour. Soc. Chem. Ind., 18 (1899), No. 9, p. 863, figs. 3*).

A new automatic burette, E. Lallemant (*Bul. Assoc. Chim., 17 (1899), No. 2, pp. 149, 150, fig. 1*).

Platinum apparatus for ash determination (*German Patent No. 105058; Chem. Ztg., 23 (1899), No. 87, p. 943, fig. 1*).—A description of Shuttleworth's apparatus which has been patented by the maker, W. C. Heraeus.

Relative efficiency and usefulness of various forms of still heads for fractional distillation, with a description of some new forms possessing special advantages, S. Young (*Trans. Chem. Soc. [London], 1899, pp. 679–710; abs. in Jour. Soc. Chem. Ind., 18 (1899), No. 9, pp. 859–863, figs. 5*).

BOTANY.

The resumption of root growth in spring, E. S. Goff (*Wisconsin Sta. Rpt. 1898, pp. 220–228, figs. 6*).—To ascertain the bearing of early spring root growth of perennial plants upon the operations of transplanting and early cultivation, the author conducted a series of observations upon the root growth of several species of trees and other plants in the spring of 1898. The observations were made by excavating a short ditch near the point where the main roots were supposed to terminate, and washing out by means of a gentle stream of water the roots and root branches to their tips. The experiment developed some rather important points which, if not new to science, have been but little applied in plant culture.

As a result of numerous observations, the conclusion was reached that in many plants root growth starts before stem growth. This was found true in the case of Norway, white, Douglas, and Colorado blue spruce, American arbor vitæ, Scotch pine, hemlock, spruce, tamarisk, sugar maple, apple, pear, morello cherry, chokecherry, white birch, Russian mulberry, Russian olive, red currant, white currant, and gooseberry. In the case of the red currant the root development was found to be far in advance of bud development. Some herbaceous plants were noted as starting root growth extremely early in the spring. On March 22 roots of strawberry and quack grass appeared to have made considerable growth, but there was at this time no visible growth of plants above ground. On a few plants the root growth apparently did not begin earlier than bud growth. This was found true in the case of a vine of Worden grape and possibly others.

Observations made on plants representing a number of botanical species, showed that root growth was most vigorous at the apex of the main roots, next to this it is most vigorous at the apex of the principal branches, and the earliness and vigor of starting diminishes as we recede from the growing points of the principal roots. This gradational growth was well shown in measurements from a root of a seedling of the Early Richmond cherry washed out on April 28. This root terminated in two very thick shoots, each of which at this time had made 2 in. of new growth. At the base of these two shoots were five smaller shoots, the combined length of which was 2¾ in. Thus the total new growth at and just behind the apex amounted to 6¾ in. The next branch of any considerable size had grown 1¼ in., the next a little less than 1 in., the next ½ in., and the next two but ¼ in. each. Farther back than this very little growth had taken place. The vigorous resumption of growth in the apical portion of the root apparently starves many of the older branchlets, for the number of these rapidly diminishes as we follow back the main roots toward the trunk. The early and vigorous terminal growth of roots would seem to have an important bearing upon the time that trees and other perennial plants should be lifted for transplanting. The most favorable time for lifting such plants is probably in autumn or very early in spring. If replanting can not be performed at once, the roots may be temporarily planted or heeled in in soil, sand, sawdust, or other well aerated and moist medium. In this way the root growth which starts will have a better chance of being saved than if the tree be lifted immediately before planting.

As the surface of the soil is first warmed in the spring, naturally root growth would be most active in this layer of soil, and the parts of the soil from which roots are in a measure excluded during the dry weather of summer may serve as a feeding ground in early spring. This was strikingly shown in the case of the currant when an inch of the surface soil from an area of about 4 sq. ft. having been washed away, revealed a multitude of delicate rootlets. This very shallow depth of early root growth would seem to offer an objection to the early cultivation of currants and gooseberries and other plants that commence growth especially early.

It has been repeatedly stated in horticultural publications that the fibrous roots of perennial plants die in autumn and are renewed on the resumption of growth in the spring. The author investigated this subject on the plants already named above and in addition about 15 other species, and failed to find any evidence of the general death of finer roots. On the contrary the new growth generally starts from the identical tips where it ceased in autumn. The erroneous idea of general death of root tips may probably have come from superficial observation, since in many plants examined the rootlets appeared dead to the naked eye, but on closer examination it was evident that only the outer bark layer was really dead, and beneath this the tissues were usually plump and in good condition.

In conclusion the author states that "no evidence was brought out to warrant the conclusion that the finer roots of plants may be wisely ignored in transplanting. It is undoubtedly true that these roots are usually short-lived under adverse treatment, but this fact should emphasize the importance of so handling the plant as to preserve the finer roots rather than to be construed as a license for their wholesale destruction. . . . The nearer we can approach in transplanting to the methods practiced in shifting plants, the more highly will the transplanting art have been developed."

The relation between the green coloration of leaves and their chlorophyll assimilation, E. Griffon (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 4, pp. 253–256*).—The author has sought to ascertain whether any relationship exists between the intensity of the color of leaves and the degree with which they decompose carbon dioxid, and whether it would be possible in all cases to explain the differences in assimilation by difference in structure of leaves and the quantity of chlorophyll.

Experiments were conducted with varieties or nearly related species of cereals, lettuce, fuchsias, begonias, grapes, roses, privets, cannas, chrysanthemums, spirea, peaches, and plums whose foliage exhibited marked variations. With a number of these the intensity of assimilation semed to be in almost direct proportion to the intensity of their green color, while in others almost diametrically opposed results were obtained. In some cases the thickness and structure of the mesophyll, development of palisade tissue, and the number, size, and color of the chromoleucites in each cell seemed to be influencing factors in the variation of carbon assimilation, but there are evidently other causes for the variation in carbon dioxid assimilation, such perhaps as the specific activity of the chromoleucites or differences in the nature of the chlorophyll.

The rôle of sodium in plants, Stahl-Schröder (*Ann. Agron., 25 (1899), No. 6, pp. 294–297*).—Experiments are reported with oats, carrots, and buckwheat, from which it appears that these plants can absorb relatively large amounts of sodium without inconvenience to growth. The phosphate, and especially the nitrate of sodium, are absorbed directly by the plant. When the soil is rich in potash, sodium is not taken up by the plant in any considerable quantity except as the acid is needed by the plant. The decomposition of sodium salts takes place principally in the roots, although a small quantity is decomposed in the stem and leaves and still less in the seed.

Investigations were conducted to ascertain whether sodium can replace potassium in the economy of the plant, and the author concludes that it can not, the yield in every case being proportional to the amount of potassium in the soil or added as a fertilizer. He attributes to sodium an indirect action in influencing a larger assimilation of potassium.

Soils for artificial cultures, R. WARINGTON (*Nature, 59 (1899), No. 1527, p. 324*).—The author states that it is often assumed in artificial cultures that a pure quartz sand watered with solutions supplying phosphates, sulphates, and chlorids of potassium, magnesium, and iron is a fit and proper soil, and that any deficiency of luxuriance in plants grown in such a medium is due to some special circumstance unconnected with the general conditions of the experiment. He claims that such a soil is in several respects a very unnatural medium for plant growth and is generally unsuited for the purposes of investigation. The salts in question if applied to an ordinary arable soil would undoubtedly supply the ash constituents required by the plant, but in this case they would reach the plant in an entirely different form from that which occurs in the case of an artificial soil of quartz sand. In natural soils containing calcium carbonate, hydrate silicates, and hydrate ferric oxid, all the alkali salts are decomposed, their acids combined with the lime of the soil and their bases held in feeble combination on the surface of moist silicates and ferric oxid, from which they are easily extracted by the acid sap of the root hairs. In a naturally fertile soil the alkalis are supplied to the plants as bases and the soil water itself always contains a quantity of calcium carbonate dissolved in carbonic acid. That a plant requires a supply of bases is shown by the character of the plant ash. The ashes of leaves and stems are always of an alkaline character.

The immense improvement in the luxuriance of an artificial culture in sand has been observed when nitrates are added to the nutritive salts employed, but it is not to be entirely attributed to the supply of nitrogen given. The nitrate in this case is the only salt which can supply the plant with a base and its addition to the soil greatly improves the general conditions of growth. The nitrate acts in this manner because the nitric acid is employed in the plant for the production of nitrogenous organic matter and its base at once becomes available for combination with organic acids.

The author states that for most purposes any fertile sandy soil may be employed for artificial cultures, and it can be as thoroughly sterilized if sufficient care be taken, but if its special chemical properties are to be retained it should not be dried or burned. If an artificial soil is needed, quartz sand should in every case be mixed with from 2 to 5 per cent of calcium carbonate. Powdered feldspar is an excellent addition to an artificial soil. In the case of an artificial soil the sand should be fine in order to have a sufficient power of holding water, and if the conditions of the experiment do not forbid it, some humic material should be supplied. The addition of 1 per cent of moss litter to this soil is said to be more advantageous. Since the water of natural soils always contains carbonic acid, this point should not be forgotten, especially when no addition of humic material is made.

The effect of Nitragin and inoculation soil on yellow lupines, ADLER (*Ber. Landw. Versstat. Jena, 1898, pp. 19, 20*).—Zinc pots were filled with sandy soil, poor in lime and well fertilized with potash and phosphatic acid fertilizers. Yellow lupines were sown in all the pots. Five pots received no further treatment, 5 were inoculated with Nitragin, and 5 were inoculated with soil on which lupines had grown. All pots were cared for in like manner. The grain yield was increased 34.44 per cent by the use of Nitragin and 106.51 per cent by the use of inoculated soil, and the hay yield 12.17 per cent by the use of Nitragin and 42.86 per cent by the use of the inoculated soil.

North American slime molds, T. H. MACBRIDE (*New York: The Macmillan Co., 1899, pp. XVII + 233, pls. 18*).—In this work, which is an outgrowth of the author's monograph on the Myxomycetes of eastern Iowa, all the species are for the first time brought together in English.

The arrangement of the larger divisions is essentially that of Rostafinski, modified by the author to include some recent ideas relative to the sequence of species.

In the introduction the author discusses the much-contested position of the slime molds, and suggests that they are possibly independent, with a somewhat nearer kinship to plants than to the animal kingdom. There are said to be 44 genera and about 212 species. Of this number 19 genera are monotypic. All species except 4 or 5 are said to be saprophytic, and of the parasitic ones the only one of economic importance is that causing the club root of crucifers, *Plasmodiophora brassicæ*.

The influence of atmospheric and soil constituents on the anatomical structure of plants, W. MEYER (*Bot. Centbl., 79 (1899), No. 11-12, pp. 337-350*).—A study is given of a large number of alpine plants to show the effect of weather and soils on their structure.

Influence of temperature on respiration, W. PALLADIN (*Warsaw, 1899; abs. in Bot. Centbl., 80 (1899), No. 1, pp. 18, 19*).

Caoutchouc, or India rubber (*Roy. Bot. Gard. Ceylon Circ. 1899, No. 12-14, pp. 105-168, figs. 4*).—Gives notes on the origin and methods of collection, preparation for market, etc.

The diameter increment of the wood of coniferous trees in relation to climatic conditions, R. TURNBULL (*Trans. and Proc. Bot. Soc. Edinburgh, 21 (1898), pt. 2, pp. 94-104, pl. 1*).—An attempt is made to find some relationship between the annual diameter increment and the climatic and meteorological conditions. The observations were on larch, Scotch pine, and Norway spruce.

Frost formations in trees, R. KOPEZKY (*Centbl. Gesam. Forstw. Wien, 25 (1899), No. 10, pp. 426-431, figs. 3*).—The character of frost injuries to trees is discussed.

On the poisonous quality of Boletus luridus, G. ARCANGELI (*Atti Soc. Toscana Sci. Nat, 11 (1899), pp. 139-142*).

A new species of Oöspora which causes efflorescence on cigars and in fermenting tobacco, A. SPLENDORE (*Riv. Tec. e Amministr. Rome, 1899, pp. 27, pl. 1; abs. in Hedwigia, 38 (1899), No. 5, Repert., p. 221*).—A description is given of *Oöspora nicotianæ* which causes an efflorescence on fermented tobacco. Notes are given on the effect of temperature on the development of the fungus and means are suggested for preventing its appearance.

On the biology of some wood-frequenting fungi, F. CZAPEK (*Ber. Deut. Bot. Gesell., 17 (1899), No. 5, pp. 166–170.*)

Studies on the parasitism of Agaricus melleus, G. WAGNER (*Ztschr. Pflanzenkrank., 9 (1899), No. 2, pp. 80–88*).—The author reports 32 host plants for this fungus and gives results of a number of experiments to infest other trees with it. Additional host plants for *Agaricus ostreatus* and notes on *Plasmopara viticola* and *A. mucidus* are given.

Conidia formation in certain fungi, C. WERNER (*Inaug. Diss., Frankfurt, 1898, pp. 48, figs. 55; abs. in Bot. Centbl., 80 (1899), No. 4, pp. 129, 130*).—The conditions under which conidia are formed by *Nectria cinnabarina* and *Volutella ciliata* are discussed and the different forms of conidia described.

The effect of removing the flowers on the assimilation of nitrogen by leguminous plants, M. SOAVE (*Staz. Sper. Agr. Ital., 32 (1899), No. 5, pp. 499–516*).—Experiments are quoted with *Vicia faba, Phaseolus multiflorus, Pisum sativum*, and *Lupinus albus*, in which duplicate lots of plants were grown under similar conditions except one lot flowered and the other had the flowers constantly removed. In the case of the Vicia there was a decided gain in dry weight and nitrogen content where the flowers were removed. In the other examples there was either a loss in dry weight or nitrogen content or both. Root tubercle development was good in every case.

Nitragin, a germ fertilizer, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1898, pp. 63–65*).—A brief description is given of this material and a plan of experiments in which it was tested is outlined. In these tests with the field pea and alfalfa a slightly better crop was given where the Nitragin was used in combination with mineral fertilizers than where the fertilizers were used without. The experiments thus far conducted seem to indicate some slight benefit following the use of this germ fertilizer.

The fixation of nitrogen by algæ (*Pharm. Jour., 4. ser., 1899, No. 1498, p. 241*).—A brief note on Bouilhac's work.

Sugar as an agent in nitrogen fixation and an aid to the growth of plants, J. GOLDING (*Jour. Soc. Chem. Ind., 18 (1899), pp. 564–566; abs. in Jour. Chem. Soc. [London], 76 (1899), No. 444, II, p. 689*).—In case of alfalfa and beans grown in sterilized sand inoculated with nodule bacteria the addition of sugar increased the yield, a fact attributed to the increased activity of the nitrogen-fixing bacteria due to the sugar.

Experiments on the staining of cell walls, J. CHALON (*Bul. Roy. Soc. Bot. Belg., 37 (1898), No. 2, pp. 59–90*).

METEOROLOGY—CLIMATOLOGY.

Investigations on periodicity in the weather, H. H. CLAYTON (*Proc. Amer. Acad. Arts and Sci., 34 (1899), No. 22, pp. 599–618, charts 13*).—This is an account of a continuation of previous studies by the author along the same line (E. S. R., 6, p. 698; 7, p. 930), and includes a summary of studies by the author and by European meteorologists (Van Bebber, Ekholm, Arrhenius, Howard, and others), on the influence of the moon on atmospheric pressure, temperature, rainfall, thunderstorms, atmospheric electricity, etc.

The curve plotted from 13 years' (1886–1898) observations on temperature at Blue Hill, Mass., though somewhat irregular, agrees with curves based on similar observations at Greenwich and Oxford, England, and Oust Silosk, Siberia, "in showing a generally higher temperature between new moon and full than between full moon and new." The curve for the normal temperatures at Blue Hill from October, 1898, to February, 1899, shows that the minimum temperatures for

October, December, January, and February occurred very near the times of new moon, the interval between the minima approximating the length of a synodic period of the moon. The curve for frequency of thunderstorms in the United States shows that while the range is small it follows that based upon observations in Sweden in showing a maximum a few days preceding the greatest northern declination of the moon.

The author's general conclusions regarding the periodicity of the weather are thus stated:

"(1) That every weather period is rendered complex by the existence of periods which bear the relation of harmonics to the primary; that is, their lengths are twice, one-half, one-third, one-fourth, etc., the length of the primary. (2) The periods in different parts of the world have different phases, as, for example, in the annual period it is cold in the northern hemisphere when it is warm in the southern, and in the sun-spot period it is dry in Russia when it is wet in India. (3) At any given place on the earth's surface the harmonics, and in some cases the primaries, reverse in phase. In the case of some of the longer periods this has been traced to a movement of the center of oscillation from place to place. (4) At any given place the periods and their harmonics do not vary synchronously. Sometimes the primary period is weak, while one or more of the harmonics are strong, and the reverse."

Climatology of the Isthmus of Panama, H. L. ABBOT (*U. S. Dept. Agr., Weather Bureau Doc. 201, pp. 19, figs. 5*).—This article, reprinted from Monthly Weather Review, 27 (1899), No. 5 (E. S. R., 11, p. 430), includes data and discussion on temperature, winds, barometric pressure, and precipitation.

Report of meteorology of Scotland for the year ending September 30, 1898, R. C. MOSSMAN (*Trans. Roy. Scottish Arbor. Soc, 15 (1898), pt. 3, pp. 301-307*).

Temperature variations in the free atmosphere as measured by balloon observations, L. T. DEBORT (*Compt. Rend. Acad. Sci. Paris, 129 (1899), No. 8, pp. 417-420, fig. 1*).—The variations at different heights are charted and discussed.

Results of rain, river, and evaporation observations made in New South Wales during 1897, H. C. RUSSELL (*Rpt. Govt. Astronomer New South Wales, Sidney, 1898, pp. 220, map 1, dgms. 8*).

Notes on frost, E. B. GARRIOTT (*U. S. Dept. Agr., Farmers' Bul. 104, pp. 23*).—In this bulletin the formation of frost and various means of protection from its injuries are treated in a popular way, and so far as the nature of the subject will permit the information is made applicable to all localities rather than to restricted districts.

WATER—SOILS.

Principles and conditions of the movements of ground water, F. H. KING (*Nineteenth Ann. Rpt. U. S. Geol. Survey, 1897-98, pt. 2, pp. 59-294, pls. 11, figs. 52*).—The introductory chapter of this article contains a general discussion of the following topics: The amount of water stored in the ground (sandstone, soil, and other rocks); depth to which ground water penetrates; general movements of ground water due to gravitation, temperature changes, and capillarity; percentage of precipitation which penetrates the soil; how seepage waters find their way into drainage channels; configuration of the ground water surface; and elevation of ground water surface due to precipitation and percolation. This discussion is based largely upon results of investigations reported elsewhere.[1] The other chapters report the results of investigations by the author and others on the flow of fluids through porous media, including the study of the flow of water and air through rigid porous media, such as wire gauze, perforated sheet brass, and sandstone; through sand; and through capillary tubes. One of the main objects of the author's investigations was to test the accuracy of the Poiseuille-Meyer law, which states that "the flow is directly proportional to the pressure and inversely proportional to the depth or thickness of the stratum." The results of the investigations are reported and discussed in detail. They are briefly summarized as follows:

> "With all the observations of all of the observers, whether with sands, rock, or capillary tubes, whether with high or low pressures, and whether with long or short tubes or columns, the departures from the Poiseuille-Meyer law have been systematically either plus or minus instead of first one side and then the other, as should be expected if the departures were due to errors of observation, unless indeed some peculiarity in the many forms of apparatus is responsible for the systematic departures which have been so persistently found by nearly every observer."

It is shown that the form, diameter, and arrangement of soil and sand grains are factors of fundamental importance in determining the rate of flow. The apparatus and methods used and the results obtained in observations on these points are described in detail.

> "The general conclusion which appears to be indicated by this series is that with the smaller sizes, where the grains give a minimum pore having diameters of 0.0117 mm., 0.01361 mm., 0.01619 mm., and 0.01809 mm. and under pressures not exceeding a gradient of about 3 to 5, the flow increases faster than the pressure; but when the diameters of the pores are 0.02756 mm., 0.0248 mm., 0.03249 mm., 0.04094 mm., and 0.05821 mm. the flow does not increase so rapidly as the pressures, even when the gradient is no steeper than 1 to 5 in the three coarsest.
>
> "In other words, the flow becomes so turbulent in the larger pores that considerable amounts of energy are absorbed even under very low pressures.
>
> "Since the length of the sand columns in these cases was 12 in. (30.48 cm.), the ratio of diameter to length of tube is as 1 to 5,236 in the coarsest and as 1 to 26,000 in the finest grained sand, whereas in Poiseuille's tube the ratio of diameter to length was 1 to 361; yet a very close agreement with the law was found under a pressure of 58 times the highest pressure used here.
>
> "It would appear, therefore, that Poiseuille's law for sands and other porous media holds only within very much narrower limits than has been found true for capillary tubes."

The general applications of the facts thus observed to the movement of soil water, seepage in case of canals and rivers, the flow of wells (driven and open), and the determination of the diameter of soil particles (see p. 523) are discussed. The conclusion is reached that mathematical treatment of the problems of the movement of ground water is "inapplicable to natural conditions except those of small areas" since "the movements of ground water across long distances must take place in considerable measure through passageways larger than those which depend upon the pore space fixed by the diameters of the grains which constitute the beds themselves."

---

[1] Wisconsin Sta. Rpts. 1892, p. 129; 1898. U. S. Dept. Agr., Weather Bureau Bul. 5 (E. S. R., 4, p. 670; 5, p. 486).

In experiments with driven-well points 18 in. long and 1¼ in. in diameter, connected with an ordinary suction pump, it was found that the point did not deliver water to the pump as rapidly as required by the pump worked at ordinary speed, and the labor of pumping was greater than in case of open wells, "due to the fact that the water came in too slowly to fill the cylinder behind the piston as rapidly as the piston was raised and as a vacuum was formed behind it."

"The drive-well point, with pumps to be worked by hand, is only adapted to circumstances where small amounts of water are required. . . . The best method of increasing the capacity of the point is to increase its length.

"Where an open well can be dug to the water and then one or two 10 ft. lengths of 6 in. points sunk below this into the water-bearing beds, so that a large suction pipe can be lowered well down toward the bottom of the casing, large quantities of water may be secured if the water-bearing sands are reasonably coarse.

"It is never desirable to make the well point a part of the suction pipe if considerable quantities of water are to be raised, for the reason that a heavy shock comes upon the pump with every stroke, owing to the necessity of filling the point with new water from the ground as rapidly as the piston is raised. When the point is larger and open, the water can fall outside to relieve the shock which otherwise would come and there is less chance for a shock on the back stroke in rapid pumping."

Theoretical investigation of the motion of ground waters, C. S. SLICHTER (*Nineteenth Ann. Rpt. U. S. Geol. Survey, 1897–98, pt. 2, pp. 295–384, pl. 1, figs. 36*).—In this article an attempt is made to derive, from purely theoretical considerations, an expression for the flow of water or other fluid through a column of soil made up of grains of nearly uniform size and of approximately spherical form.

"For the purpose of constructing this formula, a study was made of the pores of the ideal spherical-grained soil, and the relation of porosity to the average arrangement of the grains was shown and made a factor in the resulting formula. The author derived as the formula for the quantity of water per second transmitted by a column of soil the following expression:

$$q = [1.0094]\frac{p\,d^2 s}{\mu\,h\,K} \text{ cubic centimeters per second,}$$

in which—

q is the quantity in cubic centimeters;

p is the difference in pressure at the ends of the cylinder in centimeters of water at 4° C.;

d is the mean diameter of soil grains in centimeters;

s is the area of cross section of the cylinder in square centimeters;

h is the height of the column of sand in centimeters;

μ is the coefficient of viscosity of the fluid;

K is a constant [for the porosity of the soil (ideal)—a table of such constants is given];

[1.0094] is the logarithm of a factor.

"Measuring q in cubic feet, p in feet, h in feet, s in square feet, and d in millimeters, this formula becomes:

$$q = [9.3036-10]\frac{p\,d^2 s}{\mu\,h\,K} \text{ cubic feet per minute,}$$

and for water at 10° C. this becomes

$$q=[1.1846]\frac{p\,d^2\,s}{h\,K}\text{ cubic feet per minute,}$$

in all of which the brackets inclose the logarithm of a factor."

The author attempts to derive a formula for determining the effective size of the soil particles by measuring the rate of flow of air through the soil. This work has been noted elsewhere (see p. 523).

The general problem of the movement of water in soils and rock was investigated and it was shown "that there exists in the case of ground-water movements what is known as a potential function, from which we may derive, in any determinate problem, the velocity and direction of flow, and the pressure at every point of the soil or rock." In the study of the vertical motion of ground water "the fact appears that a change of pressure may be brought about throughout a water-bearing medium without changing the level of the water table, and the conclusion is forced upon us that an interference with wells and underground water supply may take place without much general disturbance of the water table in the immediate neighborhood of the disturbed wells and shortened underground supply."

The problem of the flow of wells is also discussed.

"The formula found for the capacity of an artesian well which completely penetrates the water-bearing strata is as follows:

$$f=\frac{2\pi h\,(k_1a_1+k_2a_2+\ .\ .\ .\ .)}{\log_e(1+600/r)}\text{ cubic feet per minute,}$$

in which h is the amount in feet that the water is lowered by pumping, r is the radius of the well in feet, and a_1, a_2, . . . are the thicknesses in feet of the various strata, and k_1, k_2, . . . are the constants depending upon the transmission capacity of the various strata. The symbol $\log_e$ calls for the natural or hyperbolic logarithm. It is also shown that the capacity of a well is not largely influenced by the size of the bore, except as the flow is controlled by pipe friction.

"The flow from a well which does not completely pass through the water-bearing strata is found to be given by a formula similar to the above, but containing the additional term—

$$2.5\pi\,k_n\,hr,$$

in which k_n is the transmission constant for the bottom stratum.

"The interference of two, three, and several wells with one another was investigated, and results are given in tabular form, illustrating the conclusions reached. Diagrams of lines of flow are given for several cases, and a method is explained by which the lines of flow into any number of interfering wells, however placed, may be constructed upon the drafting board."

The influence of early spring tillage on soil moisture as compared with later spring tillage, F. H. KING and J. A. JEFFERY (*Wisconsin Sta. Rpt. 1898, pp. 115, 116, fig. 1*).—On two parallel fields, one clover sod and the other potato land, alternate plats were plowed (1) 6 in. deep and smoothed April 12 and disked April 29 and May 7; (2) 7 in. deep May 12 and 14. A marked contrast in the moisture content of the different plats was soon visible to the eye, the later plowed plats being drier and lighter colored than the others. Moisture determinations made May 16 showed that the earlier plowed plats on clover sod contained 3.49 lbs. per square foot and on the potato ground 2.45 lbs. per square foot more water than the later plowed plats.

A laboratory study of the effectiveness of soil mulches, F. H. KING and J. A. JEFFERY (*Wisconsin Sta. Rpt. 1898, pp. 134–148, figs. 2*).—Experiments on this subject in the laboratory and greenhouse are reported. In the laboratory experiments 3 soils "(1) a black marsh soil of a very fine, close texture and devoid of peat, which had been under cultivation but 2 years; (2) a sandy loam cultivated many years, and (3) a medium virgin clay loam from a second growth black-oak grove," were uniformly packed into cylinders 22 in. deep with a cross-section area of 0.1 sq. ft. The cylinders used were of galvanized iron painted on the inside with an acid and waterproof paint. Each cylinder had a water reservoir at the bottom, with which it was connected by a series of notches cut in the lower edge of the cylinder. The reservoir had a supply pipe and a vent tube. A layer of sand was placed in the bottom of the cylinders. The height of the soil column above the level of the water in the reservoirs was 19 in.

The object of the experiment was to determine the relative effectiveness of soil mulches 1, 2, 3, and 4 in. deep, as compared with no mulch. Each experiment was conducted in duplicate, there being 10 cylinders in each set. The mulches in each case were produced by removing the soil to the desired depth and working this into the crumbled condition, when so much was at once returned as was required to fill the cylinder level full. Water was added until the soils were nearly saturated, the marsh soil containing 56.37 per cent, the virgin clay soil 35.57, and the sandy loam 19.71 per cent. During the first two periods of the experiment (63 and 80 days) the cylinders were placed in a case through which air was drawn at an estimated rate of 3,386 ft. per hour during the first period, and 2,476 ft. per hour during the second period. During the third period (37 days) the cylinders were placed out of doors and exposed to the air and sun. The mean rates of loss of water per 100 days were as follows:

The mean loss of water in tons per acre in 100 days.

Kind of soil.	No mulch.	Mulch 1 in. deep.	Mulch 2 in. deep.	Mulch 3 in. deep.	Mulch 4 in. deep.
	Tons.	*Tons.*	*Tons.*	*Tons*	*Tons*
Black marsh soil	620.9	367.0	274.3	248.9	213.8
Sandy loam	724.1	397.1	288.8	269.2	251.8
Virgin clay loam	1,779.6	1,249.6	1,029.2	974.6	881.6

"This table shows clearly that the effectiveness of the mulches increases rapidly with the depth of each of the 3 types of soil, and that the loss of water has been much more rapid both from unmulched and from each of the mulched surfaces of the virgin clay loam than from either of the other soils.

"The rate of evaporation under the field conditions was greater than during the 80-day period in the laboratory with the 3 soils, and it was greater during the first period in the laboratory than it was during the second period. These relations should be expected because in the first and third periods the experiments started with wet mulches while at the beginning of the 80-day period the mulches were comparatively dry. Under the out-of-door conditions there was both a stronger wind movement and direct sunshine upon the soil."

Experiments were made in the plant house with the black marsh soil in cylinders 52 in. deep and 3 ft. in diameter; and with the virgin clay soil in cylinders of the same depth, but 1½ ft. in diameter. The cylinders were divided into 4 groups, 1 set not being cultivated at all, and the 3 others cultivated 1 in., 2 in., and 3 in. deep, respectively, and at intervals of 2 weeks, 1 week, and one-half week, respectively, in different cases. All soils were saturated and allowed to stand 10 days before the mulches were made. The experiments then proceeded as follows:

"In the case of the black marsh soils the surfaces were smoothed and then tamped with a 5 lb. weight and left in this condition where no mulches were developed. In the other cases the soil was stirred to the desired depth with a four-tined potato fork upon whose tines a gauge was fixed so as to slide upon 2 pieces of gas pipe resting on the rim of the cylinder, thus securing the desired depth of mulch.

"In the case of the small cylinders enough soil was removed to secure a level undisturbed surface 1¼ in. below the rim of the cylinder plus the depth of the desired thickness of mulch. Enough of the soil removed was then returned at once in a finely crumbled condition to the several cylinders to bring their surfaces to 1¼ in. below the rim.

"The cylinders were all weighed and the experiment proper begun on November 24, 1897, and continued without the addition of water to any of the soils during the first period of 30 days.

"At this time, December 24, after weighing, water was added to the surface soil of all cylinders to the amount of a rainfall of ¼ in. and 4 days later all of the mulched surfaces were stirred, using the four-tined potato fork in the manner described in preparing the mulches. All cultivations of these soils have been made in this way.

"In starting the second period of the experiment the soils stood 4 days after wetting before cultivation. Thirty-two days from the first wetting and 28 days after the first cultivation of this period all cylinders were again given the equivalent of a rainfall of ¼ in.; but following this wetting 4 days only cylinders cultivated once per week and twice per week had the soil stirred and the experiment was closed February 1, after a period of 39 days."

The losses of moisture from the 2 soils were as follows:

Losses of moisture from soils with mulches of different depths.

	Virgin clay loam.			Black marsh soil.		
	Loss of water per acre in 100 days.		Water saved by mulching.	Loss of water per acre in 100 days.		Water saved by mulching.
	Tons.	*Inches.*	*Per cent.*	*Tons.*	*Inches.*	*Per cent.*
Not cultivated	724.1	6.394	....	319.0	2.816	....
Cultivated 1 in. deep:						
Once in 2 weeks	551.2	4.867	23.88	248.4	2.194	22.13
Once a week	545.0	4.812	24.73	255.9	2.260	19.78
Twice a week	527.8	4.662	27.10	262.6	2.319	17.65
Cultivated 2 in. deep:						
Once in 2 weeks	609.2	5.380	15.88	249.1	2.200	21.93
Once a week	552.1	4.875	23.76	249.8	2.206	21.70
Twice a week	515.4	4.552	28.81	268.9	2.374	15.72
Cultivated 3 in. deep:						
Once in 2 weeks	612.0	5.280	15.49	266.2	2.351	16.53
Once a week	531.5	4.694	26.60	282.6	2.495	11.41
Twice a week	495.0	4.371	31.64	274.5	2.424	13.94

"It will be seen from the table of evaporations from the clay loam, that with each of the three depths of cultivation the percentage of moisture saved, over that which was lost from the not cultivated ground, increased with the frequency of cultivation; that is to say, if one is cultivating ground of this character 1 in. deep, then the largest saving of moisture results from stirring the soil twice per week; and when this saving over the cultivation once in 2 weeks is expressed in tons per acre the amount is 23.29 tons per 100 days, or 0.23 ton per day, and 1.6 tons per week per acre.

"If he is cultivating 3 in. deep twice per week, as against 3 in. deep once in 2 weeks, then the saving of moisture is 116.9 tons per 100 days; 1.17 tons per day, and 8.18 tons per week per acre. Or, if the comparison is made between cultivation 3 in. deep twice per week and no cultivation, then the saving of moisture is 229.1 tons per 100 days; 2.29 tons per day, and 16.03 tons per acre per week.

"If we refer to the table for the losses of moisture which have occurred under the cultivation once in 2 weeks for each depth, it will be seen that the greatest saving appears to have resulted from the cultivation 1 in. deep, and the least saving when the cultivation was 3 in. deep. These relations may possibly be an expression of a principle in tillage, but further observations will be required to establish it. . . .

"When the results from the black marsh soil are considered, they appear to stand in contradiction to those of the same soil in the first series of experiments, and from those of the virgin soil in both series. This difference, however, is much more apparent than real, and is due (1) to the fact the black soil has so very high a water capacity, and (2) to determining the losses by weighing, making no distinction between the losses from the mulches themselves and from the body of the soil."

A record is given of a series of observations with the Piche evaporometer in connection with these experiments. The rate of evaporation as thus observed is compared with the losses determined, by weighing, in the following table:

The comparative rates of evaporation from a Piche evaporometer and soil surfaces of different characters.

	Mean evaporation per acre per 100 days.	
	Tons.	*Inches.*
Piche evaporometer	1711.0	15.105
Saturated sand surface	690.1	6.094
Unstirred virgin clay loam	724.1	6.394
Virgin clay loam cultivated 1 in. deep once in 2 weeks	551.2	4.867
Virgin clay loam cultivated 2 in. deep once in 2 weeks	609.2	5.380
Virgin clay loam cultivated 3 in. deep once in 2 weeks	612.0	5.280
Black marsh soil not cultivated	319.0	2.816
Black marsh soil cultivated 1 in. deep once in 2 weeks	248.4	2.194
Black marsh soil cultivated 2 in. deep once in 2 weeks	249.0	2.199
Black marsh soil cultivated 3 in. deep once in 2 weeks	266.2	2 351

The temperature of the air under which these observations were made is also recorded.

A new method of mechanical analysis of soils, F. H. KING (*Wisconsin Sta. Rpt. 1898, pp. 123–133, figs. 4*).—It is shown in this article that the methods of soil examination in general use do not give "a very close measure of the aggregate amount of surface possessed by a unit volume of a given soil. . . . It has been the custom of different investigators to get the diameter of soil grains, either by direct measurements with a micrometer or by counting and weighing a certain number of grains and then computing the diameter of the mean grain from the specific gravity, number, and weight. But in order to

get results which are even approximately accurate a large number of measurements in three dimensions of the grains must be made, and a large number of the grains must be counted and weighed." Even when the soil is separated into a large number of sizes "it is not possible to arrive at a very exact knowledge of the real surface which the soil may possess, per unit, volume or weight." With the assistance of Prof. C. S. Slichter of the University of Wisconsin, the author has devised a method for studying the pore space in soils, based upon the laws of the flow of air through capillary tubes. The apparatus and method are described as follows:

"*Apparatus.*—The apparatus for determining the effective size of soil grains consists of a water receptacle A, fig. 2; an aspirator bell B; an air tube 1, 1, 1, leading from the bell to the air chamber D; a soil tube C, C, provided with a tight cap 4 at one end and a cap with wire gauze at 3.

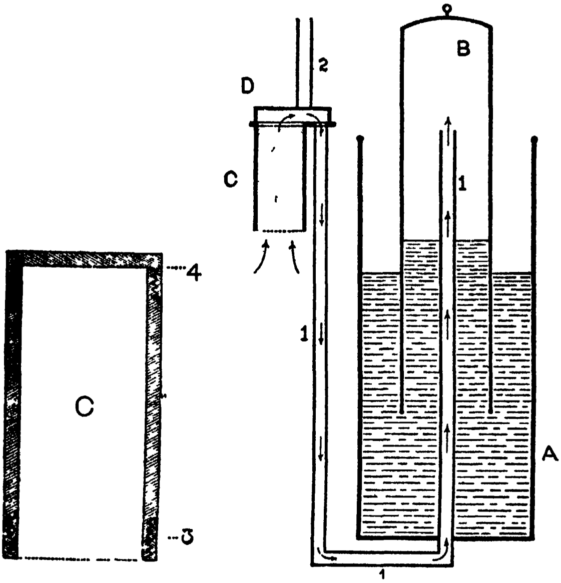

FIG. 2.—Apparatus for determining the effective diameter of soil grains.

"The air meter is a clock gear . . . and the bell is calibrated to read seconds of dial in cc. The pressure gauge connects at 2, and . . . consists of a pressure tube rising 1 in 10, and connected with a large water receptacle used to avoid reading the gauge at both ends. Pressures can be read to tenths of a mm. The pressure is developed by a weight. The soil tube C is given a capacity of 100, 200, or 300 cc., according as the soil used is fine or coarse, the area of cross section being 11.3903 sq. cm., in our case. Two bells are also used, one in which 1,000 cc. and the other 3,000 cc. may be measured, to be used with the fine and coarse soils.

"*Method of using the apparatus.*—To fill the soil tube C, the cap 4 is screwed down close and the cap 3 removed. The sample is then introduced in small lots at a time, 3 to 5 cc., and gently tamped with a flat-faced pestle until level full, then it is held rigidly between the thumb and fingers and, resting on the table, jarred by repeated light blows from a light stick, turning the tube around as the jarring progresses. This is repeated as long as any settling can be produced, and more soil is added and finally 'struck off' and made even full with a piece of plate glass.

"The object is to secure the closest possible packing. If violent jarring is resorted to, or if the tube is not pressed firmly on the table while jarring, the soil will be loosened up.

"Soils may be sorted by means of screens and the effective size of the separates determined, or the whole soil may be used as desired. Where the aim is to get a measure of the finest grains, the air-dry sample is rubbed down in a mortar with a rubber-tipped pestle to remove lumps. If it is desired to investigate the soil as to its normal crumb structure then the destruction of these would be avoided.

"*Formula for determining the effective diameter*—Prof. Slichter's formula for determining the effective diameter of the grain is as follows:

$$d^2 = k \frac{h}{spt} \; [8.9434 - 10] \text{ where}$$

d = diameter of grain in cm.
h = length of sand column in cm.
s = area of cross section of sand column in sq. cm.
p = pressure in cm. of water at 20° C.
t = time in sec. for 5,000 cc. of air to flow through at a temperature of 20° C.
[8.9434 — 10] is a logarithm of a constant.
k is a constant taken from the following table:

Pore space.	Log. k.	d.	Pore space.	Log. k.	d.
Per cent.			*Per cent.*		
26	1.9258	563	37	1.4173	377
27	1.8695	500	38	1.3816	371

1	.5824	.6006	94.8	80.6	75.7
0	.4891	.5169	72.3	66.8	59.8

"When it is observed that the flow of air was not measured with the identical sample of sand through which the flow of water was measured, and that it was in a different piece of apparatus, and further, that the flow of fluids through soils varies, theoretically, as the squares of the diameters, it will be conceded that, while there is not as close an agreement between the observed and the computed results as could be wished, the agreements are so close as to show that for such materials there is much more than a chance agreement. It will be seen further that, in general, there is a closer agreement between the observed flows and those computed from the aspirator diameters than with those computed from the count and weight diameters."

Analysis of drainage waters, C. A. Goessmann, H. D. Haskins, and R. H. Smith (*Massachusetts Hatch Sta. Rpt. 1898, pp. 134–141*).—Analyses of the drainage water from 11 plats which have been used in fertilizer experiments for a number of years are reported. It was found that wherever muriate of potash had been used "exceptional quantities of the chlorids of calcium and magnesium" were present in the drainage water. "The belief that a liberal use of muriate of potash had resulted in wasting in an exceptional degree in particular the lime resources of the soil and thereby reducing the yield of the crops has since been confirmed. The annual yield of the crops has been restored to its former satisfactory condition after a liberal addition of air-slaked lime to the manures used for years upon the field in question."

A comparative study of rapid processes of purifying water, F. MALMÉJAC (*Jour. Pharm. et Chim., 6. ser., 10 (1899), No. 8, pp. 344-347*).—Comparative tests of the alum methods of Babes and Werner and the ferric chlorid methods of Almen and Manget are reported.

Congo soils, MASSON (*Bul. Agr. [Brussels], 15 (1899), No. 4, pp. 265, 266*).—Chemical analyses (water, organic matter, phosphoric acid, lime, potash, and nitrogen) of 34 samples are reported.

The aeration of the soil, E. WOLLNY (*Fühling's Landw. Ztg., 48 (1899), Nos. 10, pp. 377-382; 11, pp. 401-405; 12, pp. 441-445*).

Subsoilers, M. RINGELMANN (*Jour. Agr. Prat., 1899, II, No. 44, pp. 630-633, figs. 8*).—Various subsoil plows of French manufacture are described.

FERTILIZERS.

Analysis of kraal manure, J. LEWIS (*Agr. Jour. Cape Good Hope, 15 (1899), No. 8, pp. 517-521*).—Analyses of 11 samples of manure accumulating in sheep corrals and 3 samples of the ash of such manure are reported. The averages of these analyses are as follows:

Composition of sheep-corral manure and manure ash.

	Water.	Ash.	Nitrogen.	Lime.	Potash.	Phosphoric acid.	Chlorin.
	Per cent	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Manure (average of 11 analyses)	13.52	41.28	1.31	7.08	2.84	1.26	1.25
Manure ash (average of 3 analyses)	2.23	*a* 87.12	....	16.97	7.60	2.59	1.57

a Pure ash.

The phosphoric acid was all citrate-soluble.

Observations with dried blood and two kinds of leather refuse as the sources of nitrogen for growing rye in presence of acid and alkaline phosphates, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 123-127*).—This is a continuation of experiments in boxes briefly described in the report of the State Station for 1894 (E. S. R., 7, p. 297). The method followed was the same as in the earlier experiments, except that the phosphates used were dissolved boneblack and Thomas slag, and potash was added in the form of the sulphate. The 2 kinds of leather refuse were the Philadelphia Tankage (steamed leather waste) used in the previous experiments and raw ground sole-leather waste. Rye was again grown. The moisture content of the soil was maintained at 15 to 18 per cent. Data relating to the weight and composition of the crop are reported. The following conclusions are drawn from the results:

> "The alkaline phosphate (phosphatic slag meal) has under fairly corresponding conditions increased the availability of the nitrogen contained in steamed leather, in leather scraps, and in dried blood in a higher degree than the acid phosphate. The influence is apparent alike in the general character of the entire plant and in the composition of the kernels. The difference in the relative agricultural value of both articles as nitrogen sources remains, however, the same; for leather in any form, without a previous destruction of the tanning principle, tannin, is worthless for manurial purposes."

Is the phosphoric acid of mineral phosphates available to cultivated plants? D. N. PRIANISHNIKOV (*Izv. Moscow Selsk. Khoz. Inst., 5 (1899), No. 1, pp. 90–110; Ann. Agron., 25 (1899), No. 4, pp. 177–187*).—The results of extensive pot experiments by the author may be summed up as follows: With regard to their behavior toward mineral phosphates plants can be divided into such as can, without the aid of the soil, dissolve and utilize the phosphoric acid of these materials and such as are not capable of doing this. To the former group belong the lupines, peas, buckwheat, and white mustard; to the latter belong the cereals. There exist of course plants which stand in an intermediate relation to these 2 classes.

Similarly, we must distinguish soils which are capable of decomposing the mineral phosphates from those which can not do this. For the mineral phosphates to be effective as fertilizers the cooperation of certain properties of the soil or of the plants is necessary. Certain soils have the property of rendering the phosphoric acid of mineral phosphates available for cereals and other plants. In the author's experiments the so-called "podzols" (which consist of very fine siliceous material mixed with some organic matter) were most effective in this respect, while forest and peat soils also possess the property to some extent. Certain black (chernozem) soils experimented with were without action on the mineral phosphates, and the author suggests that soils originally active in this respect may become inactive after a period of cultivation in which barnyard manure is used. The necessity of taking these facts into consideration in analyzing mineral phosphates to determine their fertilizing value is pointed out.—P. FIREMAN.

Notes on wood ashes, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 117–119*).—The variations in the composition of the wood ashes examined in 1897 and 1898 are discussed. In a large number of the samples analyzed in 1898 the potash was below the minimum guarantee (4.5 per cent), being inferior in this respect to samples examined in 1897.

Seaweed as a fertilizer (*Florida Agr., 26 (1899), No. 39, p. 600*).

Analyses of commercial fertilizers sold in Maryland, H. B. MCDONNELL ET AL. (*Maryland Agr. College Quart., 1899, No. 5, pp. 49*).—This number includes brief notes on the valuation of fertilizers, a partial list of fertilizers licensed in Maryland during 1899, and tabulated analyses and valuations of 408 samples of fertilizers examined, February–July, 1899.

Report on official inspection of commercial fertilizers and agricultural chemicals in 1898, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 105–114*).—Three hundred and sixty-three samples, representing 264 distinct brands of fertilizers, were examined in 1898. The agreement of the analyses with guarantees in 1897 and 1898 and the valuation of fertilizers are discussed and a list of fertilizer manufacturers securing certificates for sale and the brands licensed during the year ended April 30, 1899, is given.

Analyses of fertilizers, C. A. GOESSMANN (*Massachusetts Hatch Sta. Bul. 62, pp. 20*).—This bulletin reports analyses of 195 samples of fertilizers, including wood ashes, cotton-hull ashes, nitrate of soda, muriate of potash, kainit, tankage, ground bone, cotton-seed meal, flax meal, bone, acid phosphate, wool refuse, Jadoo fiber, soils, and mixed fertilizers.

Fertilizer analyses, R. C. KEDZIE and L. S. MUNSON (*Michigan Sta. Bul. 17[illegible], pp. 325–337*).—This bulletin gives the text of the State fertilizer law; a discussion of the objects and results of inspection and the composition and character of different classes of fertilizers; a schedule of commercial prices, with notes on the valuation of fertilizers; explanation of terms used in fertilizer analysis; and tabulated analyses of 68 samples of commercial fertilizers inspected during 1899.

Analyses of commercial fertilizers, B. W. KILGORE ET AL. (*Mississippi Sta. Bul. 59, pp. 29*).—This bulletin contains brief notes on the fertilizer trade in the State, terms used in analysis, valuation, and the provisions of the fertilizer law, with tabulated analyses and valuations of 166 samples of fertilizers collected during the season of 1897–98.

Commercial fertilizers, F. W. WOLL (*Wisconsin Sta. Rpt. 1898, pp. 209–219, 283, 284*).—This includes explanations of fertilizer terms, notes on valuation, tabulated analyses of 5 samples of fertilizers, with a brief discussion of fertilizers for lawns and text of the Wisconsin fertilizer law.

Gas, oyster-shell, and stone lime, H. B. MCDONNELL and F. P. VEITCH (*Maryland Agr. College Quart., 1899, No. 4, pp. 8*).—This article discusses briefly the chemical composition and relative agricultural value of different forms of lime and reports analyses of 16 samples of agricultural lime.

"The analyses show that stone and shell lime contain from two to three times as much actual lime as is contained in the same weight of gas lime. By measure the difference is still greater. This, together with the fact that in gas lime the lime is mostly in the form of carbonate and less active than quicklime, and also that the gas lime contains compounds which may act injuriously, leads to the conclusion that it is poor economy for the farmer to buy gas lime at 2 cts. per bushel when he can get oyster-shell lime for 5 cts., even not taking into consideration the question of the cost of transportation.

"Oyster-shell lime contains as much lime as the average stone lime, so that the stone lime, at 10 cts. per bushel, can not compete with the shell lime at 5 cts. on equal terms for agricultural purposes. Where transportation is largely in favor of the stone lime, however, it will be used."

Notes on fertilizers suitable for raising plants in pots and greenhouses, C. A. GOESSMANN (*Massachusetts Hatch Sta. Rpt. 1898, pp. 119–123*).—Analyses of samples (1 each) of plant food in pellet form and of liquid fertilizer are reported and general suggestions are made regarding the use of fertilizers in pots and under glass, with formulas for mixtures.

The situation of the nitrate of soda industry in Chile, MAIZIÈRES (*L'Engrais, 14 (1899), No. 18, pp. 420, 421*).

Perchlorate in 1898 (*Bul. Agr. [Brussels], 15 (1899), No. 4, pp. 252, 253*).—Reports determinations of perchlorate in 19 samples of nitrate of soda. The amount of this substance varied from 0.15 to 8.16 per cent.

The world's production of phosphates, MAIZIÈRES (*L'Engrais, 14 (1899), No. 42, pp. 995, 996*).

FIELD CROPS.

Report of the agriculturist, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1898, pp. 44–63, 76–85*).—This report gives the results of various field experiments in 1898. The experiments are mainly in continuation of former work (E. S. R., 10, p. 626).

Soil tests were made with corn and onions at the station and with oats in two other parts of the State. The soil test with corn was made on a field on which soil tests have been in progress for 10 years, the rotation having been as follows: Corn, corn, oats, grass and clover, grass and clover, corn followed by mustard as a catch crop, rye, soy beans, white mustard, and corn. The same fertilizer applications were made each year. This season the plats receiving only nitrate of soda, phosphoric acid, or potash yielded at the rate of 20.6, 18.5, and 19.8 bu. of corn per acre, respectively. The nitrate of soda and dissolved boneblack plat yielded at the rate of 30 bu. per acre, while the plat with nitrate of soda and potash yielded at the rate of 10.9 bu.

"The yield of the plat which for 10 years has received only phosphoric acid and potash (41.2 bu. per acre) illustrates in a striking way the comparative independence of the corn crop of supplied nitrogen upon this soil. The crop raised where nitrogen, phosphoric acid, and potash have been yearly applied . . . shows that profitable results may be obtained by the use of fertilizers alone. The yearly cost of the application to this plat has been from $10 to $12. The crops have not been much inferior to those on the plat to which manure at the rate of 5 cords per acre has been yearly applied. The two crops this year are, respectively, for the fertilizer, 55.9 bu.; for the manure, 67.7 bu. The extra 11 bu. of corn will not cover the added cost of the manure as compared with the fertilizer, and in earlier years the differences in yield have been relatively much smaller than this year."

The soil test with onions was made on land which had been used for this kind of work for 9 years. Heretofore the fertilizer application had been like those applied in the soil test with corn, but this season the quantities were doubled, nitrate of soda, dissolved boneblack, and muriate of potash being applied at the rate of 320, 640, and 320 lbs. per acre, respectively. The results show that the supply of phosphoric acid had a greater influence than either the nitrogen or potash. The plat fertilized with nitrate of soda and dissolved boneblack yielded at the rate of 116.9 bu., while the plats which had received muriate of potash in addition yielded only 16.3 bu. per acre. The author concludes that the results were influenced by injurious effects of muriate of potash.

Excessive rains interfered with the soil tests with oats in one case, but in the other the results were quite conclusive. Nitrate of soda alone and in all its combinations gave a marked increase in yield, while the use of other fertilizers, without nitrate of soda, was almost without effect. Barnyard manure, at the rate of 5 cords per acre, did not give profitable results.

Grass and clover were grown on plats manured with 1 cord of barnyard manure or ½ cord of barnyard manure and 40 lbs. of muriate of potash. The results were in favor of the manure alone, but the increase in yield of hay was not sufficient to cover the larger cost.

The details of the comparison of a special corn fertilizer and a fertilizer richer in potash on grass and clover have been previously described (E. S. R., 10, p. 626). The results this season show that the application of the fertilizer richer in nitrogen and phosphoric acid yielded at the rate of 150 lbs. of hay and 80 lbs. of rowen per acre more than the fertilizer richer in potash. The plats which received the larger amount of potash did not show a good development of clover, which is attributed to a difference in soil conditions and the long-continued use of liberal amounts of muriate of potash.

The plats on which leguminous crops as nitrogen gatherers had been tested (E. S. R., 10, p. 627), were plowed and treated with 200 lbs. per plat of partially air-slaked lime and with different fertilizer applications, and then sown to oats. Potash was applied in the form of muriate and sulphate. The average yields were as follows: Plats receiving no nitrogen, 21.40 bu. of grain and 900 lbs. of straw per acre; plats receiving muriate of potash, 32.05 bu. of grain and 1,595 lbs. of straw per acre, and plats receiving sulphate of potash, 35.20 bu. of grain and 1,416.7 lbs. of straw per acre. Unfavorable weather interfered with the harvesting of the crop and caused a loss of grain through shelling. The different sources of nitrogen, considering the yield of straw, ranked in effectiveness as follows: Nitrate of soda, sulphate of ammonia, dried blood, and barnyard manure. After harvest, without further manuring, the land was sown to Mammoth red clover which made an excellent growth during the fall.

Clover on soil fertilized with muriate of potash winterkilled badly as compared with clover on sulphate of potash plats, but additional seed sown on all plats without replowing in the spring gave fairly even results. Muriate of potash gave much better results as a fertilizer for corn than the sulphate, but it is believed that the apparent difference may not be due to the fertilizer. Sweet clover showed no difference between the 2 forms of potash. Analysis of sweet clover showed that from June 6 to July 10 the dry matter increased from 3,661.6 lbs. to 7,573 lbs., and the nitrogen from 136.8 lbs. to 192.5 lbs. per acre. As a seed producer the crop did not prove very successful.

Experiments in manuring grass lands with wood ashes, ground bone, muriate of potash, and barnyard manure in rotation have been in progress since 1893 on 3 plats, each over 2 acres in size. For the entire series the plats when dressed with manure, averaged 7,211 lbs. of hay and rowen per acre; when receiving ground bone and potash, 6,671 lbs., and when receiving wood ashes, 6,541 lbs.

Extensive variety tests were made with potatoes. A number of varieties were tested for the first time, and the best 25 varieties as indicated by previous tests were given further trial. Owing to blight, the yields were small and the results inconclusive. The author believes that King of the Earliest and Early Ohio, Salzer Earliest and Bliss Triumph, and Mills Banner and Livingston Banner are identical, and that White Beauty and Cambridge Russet differ but very slightly. A comparison of seed potatoes of Beauty of Hebron and Early Rose from different localities resulted in a variation of yield of about 50 per cent for each variety. The variation in productiveness of exact halves of tubers by weight with 5 eyes in the same part of the tuber amounted to over 37 per cent, and between tubers of the same variety to about 22 per cent.

Investigations on the potash requirements of barley, T. Remy (*Untersuchungen über das Kalidüngerbedürfnis der Gerste. Berlin: P. Parey, 1898, pp. 83*).—This book contains a discussion of the literature on the fertilizing of barley, and gives the detailed results of extended pot experiments with different forms of potash, used alone in varying amounts and combined with other commercial fertilizers, on soils of different origin to determine its effect on the yield, chemical composition, and water requirements of barley, the potash requirements of different varieties of barley, and the secondary effects of potash fertilizers in rendering available the nitrogen of the soil. A summarization of the experience obtained in the culture of barley for brewing purposes on light soils is given in the final chapter.

In all the experiments zinc pots 25 cm. in diameter and with a soil capacity of 15 kg. were used. The plants were watered with distilled water, both surface and subwatering being practiced. The moisture was held at from 40 to 60 per cent of saturation of the soil. The Hanna variety of barley, except when otherwise noted, was employed in all tests and 20 plants grown in each pot.

Experiment A (pp. 8–23).—This experiment was made to determine the potash requirements for barley culture of soils of different origin. Five kinds of soils were employed—3 clay diluvial sands having different percentages of fine earth, a thin, sandy diluvial clay, and a light, coarse sand from the Spree Valley. Mechanical analyses are given of the different soils in every case, and 5 series of experiments, including 8 pots in each series, were carried out with each soil. One series of pots served in each case as a control, and 0.5, 1, and 2 gm. of potash as carbonate were added to each pot in series 2, 3, and 4, respectively. The fifth series received 2 gm. of potash as carbonate per pot, and, in addition, 0.5 gm. of nitrogen in the form of ammonium nitrate.

The growth of the grain and straw and the amount of potash taken up by the crop in each series are tabulated in detail and discussed, and modifying factors noted. The following table is a summarization of this data:

Potash content and yield of barley grown on soils of different origin and fertilized with increasing amounts of potash.

Origin of soil.	Series I—No potash.		Series II—0.5 gm. potash.		Series III—1 gm. potash.		Series IV—2 gm. potash.		Series V—2 gm. potash + 0.5 gm. nitrogen.	
	Total yield.	Potash in crop.	Total yield.	Potash in crop.	Total yield.	Potash in crop.	Total yield.	Potash in crop.	Total yield.	Potash in crop.
	Gm	*Gm*	*Gm.*	*Gm.*	*Gm.*	*Gm*	*Gm.*	*Gm.*	*Gm.*	*Gm.*
Clayey diluvial sand from Löhme	144.3	0.85	166.5	1.28	169.1	1.72	161.1	2.09	165.1	1.93
Thin sandy diluvial clay from Lohenbrünzow	128.7	.89	135.0	1.25	142.4	1.61	147.0	2.07	151.0	2.07
Clayey diluvial white sand from Nenndorf.	88.3	.45	144.7	.97	142.5	1.39	142.7	1.96	151.0	2.09
Clayey diluvial sand from Sammenthin.	86.7	.43	126.3	.89	124.8	1.28	135.9	2.01	141.2	2.02
Light loamy sand from Berlin experimental fields	36.0	.14	83.0	.56	91.5	.81	95.8	1.02	182.0	1.55

A second experiment in connection with this work, to determine the effect of sudden variation in day and night temperature on the growth of barley and the availability of fertilizers for plant use, was carried out in pots surrounded with a sheath of wadding and set in saucers 10 cm. deep, filled with water, and compared with pots handled in the usual manner. On the whole, the largest crops were obtained from the pots handled in the usual manner. The differences, however, were considered too small to form a basis for definite conclusions.

Experiment B (pp. 23–27).—The dependence of the availability of potash for barley on the form of the potash and on the amount of nitrogen present in light soils, was determined in soils taken from a sandy field in which potatoes had been grown the preceding season. Three series of pots were used with 15 pots in each series. No potash was used in the first series. In the second series 1.5 gm. of potash in the form of kainit was added to each pot. In the third series each pot received the same amount of potash in the form of carbonate. The 15 pots in each series were divided into 5 groups. The first group received no nitrogen while 0.51, 1.02, 1.53, and 2.04 gm., respectively, of nitrogen in the form of ammonium nitrate were added to each pot in the remaining series. The detailed results of the experiment are given in tabular form and discussed. The average yield of plants grown in pots fertilized with kainit was 11.3 gm. more than those in the control series, while the excess yield of plants grown in pots fertilized with potash in the form of carbonate was only 2.3 gm. more than those grown in the controls. Increasing the amount of available nitrogen increased the vigor of the plants, the total yield of the crops, and the ability of the plants to better utilize the potash applied.

Experiment C (pp. 27–30).—This experiment was made for the purpose of determining the effect of different potash salts and of the ordinary impurities or secondary ingredients found in these salts, on the growth of barley on humus soils. Eight series of pots, with 4 pots in each series, were filled with soil from a cultivated field comparatively rich in humus. Series 1 were used as checks. Series 2 received 1 gm. of potash per pot in the form of sulphate; series 3, 1 gm. in the form of carbonate; series 4, 1 gm. in the form of kainit; series 5, potassium-free secondary constituents obtained from 7.9 gm. of kainit; series 6, the same as series 5 with the addition of 1 gm. of potash in the form of sulphate; series 7, the same as series 5 with the addition of 1 gm. of potash in the form of carbonate; and series 8, 1 gm. of potash in the form of sulphate plus 1.13 gm. of water-free soda. The yields in grain and straw are recorded for each pot in each series. The effect of the potash in any form was not very marked. Pots fertilized with the secondary constituents alone gave increased yields over the checks but hardly as good as potash alone. Pots fertilized with potash in the form of carbonate with the addition of the secondary constituents gave increased yields over those fertilized with potash in the form of sulphate plus the secondary constituents. Kainit proved a superior form of potash to either the sulphate or the carbonate.

Experiment D (pp. 30–33).—This was an experiment made to compare the potash requirements of Selchower, Heine Improved Chevalier, and Goldthorpe varieties of barley. The data for the tests are recorded in detail. The results were inconclusive.

Experiment E (pp. 33–36, 63–66).—In this experiment the relation of different potash manures to certain nitrogen fertilizers in the production of barley was studied, as well as the effect of potash on the water requirements of the crop. Quartz sand, practically free from nitrogen or potash, was employed. The test was made in 2 series of pots with 16 pots, divided into 4 equal groups in each series. Each pot received basal fertilizers of the essential elements, and, in addition, quicklime, magnesium sulphate, and chlorid of iron. Pots in series 1 received 0.65 gm. of nitrate nitrogen. Pots in series 2 received the same and, in addition, 0.65 gm. of poudrette. Group 1 in each series was used as a check, while each pot in groups 2, 3, and 4 received 0.75 gm. of potash as sulphate, as kainit, and as carbonate, respectively. The yield of grain, straw, and roots, number of heads matured, water requirements of each pot, etc., are shown in tabular form. The best yields throughout were obtained in the series fertilized with nitrate nitrogen alone, and the group fertilized with kainit gave better results than either the sulphate or carbonate groups. The water requirements of the crop were found to be considerably lessened by the use of potash fertilizers, the least amount being required by the crop fertilized with kainit.

Experiment F (pp. 36–39).—The effect of different magnesia compounds on the yield of barley was especially studied, 18 pots divided into 2 equal series, A and B, being used for this purpose. Each series received basic fertilizers, and each pot in series A received in addition 1 gm. of potassium carbonate and in series B 1 gm. of potassium sulphate. Three pots in each series were used as checks. Three others in each series were fertilized with 1 gm. of magnesium chlorid each, and the remaining 3 in each series were given 1 gm. of magnesium sulphate each. Plants in the pots fertilized with magnesium chlorid grew at first with difficulty. At the harvest period, however, they gave the greatest total yields in every case, the yields being on an average about 9 per cent greater than the checks and 5.3 greater than those fertilized with magnesium sulphate. Plants in the carbonate of potash series gave better yields than those in the sulphate of potash series.

In all the experiments the percentage of germination and energy of germination was normal, and no special influence of the potash on the structure, thickness, or fineness of the barley glumes or the color of the grain was apparent. The proportion of glumes to kernel was in inverse ratio to the starch content of the grain. The percentage of glumes to grain is tabulated for experiments A and B, and the weight in grams of 1,000 kernels of grain given for each pot in every experiment. In nearly every instance potash fertilizers increased the weight of the grain, but a steady decrease in weight of grain followed each successive addition of nitrogen beyond what was sufficient for the normal development of the plant. The protein and starch content of the grain were determined in each experiment. A steady decrease in protein content is noticeable throughout the test with each increasing amount of potash, and this is regularly followed by a nearly corresponding increase in the starch content. The data for all the experiments are arranged with regard to the potash content of the dry matter of the crop from each pot, and to the percentage of potash applied which was utilized in the development of the crop. The effect of potash fertilizers in rendering the nitrogen of the soil available to the plant was also studied in considerable detail. Results of this work lead to the conclusion that potash renders nitrogen available that otherwise would not be available, and that potash in the form of kainit is most efficient for this purpose.

Lupines for green manure, J. B. Davy (*California Sta. Bul. 124, pp. 31, pls. 5*).—Botanical descriptions and notes are given on the history, culture, and food and manurial value of 13 species or varieties of lupines, grown as agricultural crops in this and other countries; together with the results of culture experiments with 7 of the more important of these varieties grown at the station and substations, and a test of the relative rates of rotting of the same varieties when turned under for green manures. A bibliography of 20 works bearing on the subject is appended.

The record of the culture tests includes data on the seed sown, date of sprouting, flowering, and full flower, yield, and the weekly growth of each variety tested. The pink lupine (*Lupinus pilosus roseus*) and the large blue lupine (*L. pilosus cœruleus*) are considered the best of the different varieties tested for green manuring on the heavy, strong, calcareous soils of middle California. The small blue lupine (*L. angustifolius cœruleus*) was preeminently the best variety tested at the Chino Valley Substation, but is subject to root rot. For light, noncalcareous soils the yellow lupine (*L. luteus sativus*) is recommended because of its rapid decomposition when plowed under.

A portion of the lupine plats under observation were turned under March 18. On April 22 they were examined to determine the relative degrees of decomposition which the different varieties had undergone. The yellow lupines were thoroughly rotted. A considerable amount of fibrous matter of the succulent (*L. affinis*) and small white lupine (*L. angustifolius diploleuca*) still remained undecomposed. The pink and large blue lupines were not quite as well decomposed as these latter, but were somewhat better than the small blue or narrow leaved lupines (*L. angustifolius*), the foliage of which latter were well rotted but the stems still very fibrous.

The bulletin contains a short introduction on green manure crops by E. W. Hilgard.

How to get extra-early potatoes, W. L. HALL (*Kansas Sta. Press Bul., Mar. 6, 1899*).—Part of the work here noted was reported in 1897 (E. S. R., 10, p. 149). In 1898, one half of a lot comprising four varieties of early potatoes was placed in shallow boxes with the seed end up and packed around with sand as previously described, except that the sand was kept moistened. The other half was put in open boxes and placed in a light dry room having an average temperature of 50° F. Both lots were planted March 26. Parallel rows of potatoes from the storage cellar were planted with them at the same time for comparison. The sand-sprouted tubers gave the earliest yields. From the 2 years' experience the author concludes that whole tubers sprouted in rather moist sand and planted about March 25 give the best results and produce tubers suitable for table use 7 to 10 days earlier than the same variety planted at the same time but not so sprouted.

Progress of the sugar-beet industry in the United States in 1898, C. F. SAYLOR and H. W. WILEY (*Washington: Government Printing Office, 1899, pp. 162*).—The report is in continuation of the report for 1897 (E. S. R., 10, p. 741).

Report of special agent, C. F. Saylor (pp. 6–129).—This discusses in a comprehensive manner the increase in the use of sugar in this country, sugar-beet production in this country in 1898 by States, the conditions requisite for growing sugar beets, general cultural methods, factory conditions, the prospects for new factories in different States, the effect of the beet-sugar industry in promoting stock feeding and dairy industries, manufacture of alcohol from sugar beets, production of sugar beet seed, results of experiments in growing sugar beets in the different States in 1898, including analyses of the crop in some instances; gives a description of the process of manufacturing sugar from beets by G. S. Dyer; and a general account of the Island of Puerto Rico as regards its industries and exports, with special reference to sugar, labor, and other economic features.

The cost of growing, harvesting, and manufacturing cane sugar and shipping it to New York from Puerto Rico is estimated at from 1.82 to 2.044 cts. per pound, exclusive of import duty, or 3.5 to 3.724 cts. per pound with this item added. This estimate leaves out of consideration interest on the money invested in the plant and insurance on the sugar in transit. The sugar exports from Puerto Rico to this country are equal to about 3 per cent of our total importations. Under the best possible conditions it is thought this amount might be doubled. The difficulties confronting the Puerto Rico planters seem to be inefficient labor, undeveloped condition of roads, and, with but few exceptions, primitive methods of manufacture. The limited economic value of the sugar-cane by-products, as compared with sugar-beet pulp, places the production of sugar from beets in this country on a competitive basis with the cane-sugar industry, which will make it, in the opinion of the author, "master of the situation."

Report of the chemist, H. W. Wiley (pp. 131–155).—This is a report on the distribution of sugar-beet seed by the Department during the season of 1898, and on the analysis of sugar beets received from the different States. In all, 20,543 lbs. of seed were distributed to the different States, and 1,713 analyses were made. The analyses are tabulated by States and counties, and suggestions are made relative to the adaptability of the different States to the sugar-beet industry. The following table shows some of the results for some States from which the larger number of samples were analyzed:

Analyses of sugar beets grown in a number of States in 1898.

State	Number of samples.	Number of counties represented.	Average results.			Maxima.		Minima.	
			Weight.	Sugar in the beet.	Purity coefficient.	Sugar in the beet.	Purity coefficient.	Sugar in the beet.	Purity coefficient.
			Ounces.	*Per cent.*		*Per cent.*		*Per cent.*	
Colorado	50	20	22	13.7	80.1	17.6	92.5	10.0	[illegible]
Illinois	38	19	20	10.2	75.2	13.3	88.6	6.3	[illegible]

Iowa	147	32	25	11.4	76.1	15.7	87.3	3.9	48.7
Maryland	31	15	22	10.4	76.0	14.2	84.9	6.6	66.7
Michigan	34	18	28	13.2	81.9	18.6	89.3	9.8	50.4
Minnesota	21	9	22	12.7	78.7	16.2	88.0	9.6	68.8
Missouri	43	27	17	8.5	68.6	16.8	87.7	3.9	50.9
Nevada	42	1	12	18.5	85.9	21.7	91.7	14.8	79.8
New Jersey	33	7	20	11.1	77.5	14.2	88.2	7.5	66.5
New York	328	22	21	12.6	80.5	16.8	90.9	5.4	53.8
Ohio	409	64	24	11.0	77.1	15.7	91.9	6.0	58.0
Pennsylvania	81	21	21	11.6	78.1	15.7	87.3	6.2	[illegible]
South Dakota	24	8	16	13.9	78.6	17.9	89.5	9.1	67.0
Texas	49	23	25	9.5	69.8	15.0	82.7	3.4	[illegible]
Vermont	68	12	22	13.2	82.8	16.3	91.2	6.4	[illegible]
Virginia	43	15	20	8.9	72.4	14.3	83.9	4.9	51.5

The author calls attention to the fact that "in very few cases has the number of samples here been sufficiently large to justify a final decision in regard to the suitability of the locality for beet growth," and refers to the work done by the experiment stations for further data regarding particular States.

"So far experience has shown that south of the bounding area of the isotherm of 71 degrees for the months of June, July, and August the cultivation of the sugar beet can not be profitably extended very far. North of the limit of the belt, however, the extension of the culture of the beet can be pushed just as far as the climate will permit the ripening of the crop and the harvesting and the care thereof before the freezing of winter sets in. Our experience in this country has shown that the farther north, other things being equal, beet culture is practiced the better the quality of the beets produced."

The sugar beet in Montana, F. W. TRAPHAGEN (*Montana Sta. Bul. 19, pp. 53–90*).—This bulletin contains considerable data on the production and consumption of sugar in the United States and foreign countries; the climate, culture, and soil requirements of sugar beets; cost of growing in Montana, etc.; analytical data for sugar beets in Montana for each year from 1895 to 1898, with notes on the samples; and analyses of experiment station farm soil, and one sample of limestone. In 1898 the juice of the beets grown had a sugar content of 15.9 per cent, with a purity coefficient of 81.2. "Montana conditions are favorable to the production of sugar beets of high sugar content and standard purity. . . . Our experience, coupled with the results of cooperative experiments by farmers in all parts of the State, lead us to believe that we are justified in expecting yields of from 12 tons an acre upward."

Importance of the right amount and the right distribution of water in crop production, F. H. KING (*Wisconsin Sta. Rpt. 1898, pp. 117–122*).—Studies begun in 1888 on the yield of crops grown with natural rainfall, supplemented by irrigation water, were continued in 1898 (E. S. R., 10, p. 746). The rainfall of the growing season, from April 9 to August 30, was 18.63 in. This was considerably higher than usual, and its distribution was such as to permit the production of nearly maximum yields. "In many parts of the State second crops of hay have been cut which were nearly or quite as heavy as good first crops usually are."

Hay.—The yields of different cuttings of clover, oat, and alfalfa hays are given. The first crops of clover were produced by the natural rainfall, after which irrigation was practiced, but the amount of water applied is not stated. The average yield of clover on 2 plats at the first cutting was 2.58 tons, second cutting 1.45 tons, and third cutting 0.89 ton per acre. "A second crop of nearly a ton per acre could have been secured had no water been applied, but the third crop was made possible only by irrigation." Another feature of the experiment with hays was the spring seeding of 2 plats of oats to clover and alfalfa, respectively. The oats were cut for hay July 6. Three days later the plats were irrigated to force the alfalfa and clover. Three later irrigations followed. Both plats were cut for hay September 15. The alfalfa plat yielded 1.37 tons and the clover plat 2.19 tons of hay per acre. "It appears clear, therefore, that with plenty of moisture in the soil it is possible to seed ground to clover or alfalfa with oats or barley and cut the same season from 1½ to 2 tons of hay per acre from the same ground as a second crop."

Corn.—The yield of corn grown on plats which had been cropped with corn for 5 years in succession without fertilizers was at the average rate of 7,500 lbs. per acre with a natural rainfall of 11.02 in. and 7,106 lbs. per acre where 5.7 in. additional irrigation water was applied. These results, taken in connection with similar results obtained the previous year, suggest "that the fertility of the irrigated ground is being seriously impaired." In another test corn was grown in hills 30 in. apart each way; 4 kernels were placed in each hill on some plats and 2 in each hill on other plats. The thicker seeding received a double amount of irrigation water. With Pride of the North corn the yield of dry matter was at the rate of 7,908 lbs. per acre when 2 stalks in a hill were grown and at the rate of 10,015 lbs. where 4 stalks were grown. Better yields were obtained with a variety of White Dent, but the difference in increase of the thicker seeding was about the same.

Potatoes.—The potato plats in 1898 were divided into alternate subplats of 7 irrigated and 7 nonirrigated rows each. One row was left between each subplat and was irrigated only on one side. The lower ends of the plats were so flat that after one of the heaviest rains the water covered a large part of the ground, and in one instance this portion of the ground was left unirrigated. The total yield from the irrigated subplats of potatoes was at the average rate of 198.9 bu. per acre; of the half irrigated subplats, 192.2; and of the nonirrigated subplats, 182.7 bu. These results, taken in connection with those of previous years, seem to establish the fact that potatoes as well as hay in Wisconsin are benefited by irrigation, even in years of copious and well-distributed rainfall.

Catch crops, W. P. BROOKS (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 316–338*).—This popular lecture treats of the selection of catch crops, the value and methods of green manuring, and the adaptations of various crops for this purpose. Experimental data on variety tests of millets (E. S. R., 9, p. 341) and on the value of green manuring are tabulated and discussed.

Fall cover crops—their efficiency as green manure, P. P. DEHÉRAIN (*Prog. Agr. et Vit., 16 (1899), No. 41, pp. 428–431*).—Data on yields of potatoes and beets following a crop of winter vetch seeded in the fall on a wheat stubble field are given and discussed.

A new textile plant (*U. S. Consular Rpts., 1899, No. 229, p. 330*).—A brief description is given of a natural plant (*Apocynum venetum* or *A. sibericum*), the fiber of which is used in making cord, fish nets, etc. The plant is native to Japan and Siberia.

Some special cultures in Chile (*Mitt. Deut. Landw. Gesell., 14 (1899), No. 16, pp. 94–96*).—Some statistics are given of the fruit, tobacco, and sugar-beet yields and prices in Chile, with 3 analyses of sugar-beet lands.

Report on tests of varieties of cereals made by F. Heine during the year 1899, K. KITTLAUSZ (*Deut. Landw. Presse, 26 (1899), Nos. 78, pp. 889–891; 79, pp. 900, 901*).—Detailed data are given for tests of 11 varieties of rye. The most profitable sort was Heine Green-grain Zeeländer, followed closely by Heine Yellow-grain Zeeländer and Prof. Heinrich. Analyses showed 9.38 per cent albuminoids in Heine Common Zeeländer (old seed), 9.25 per cent in Heine Yellow-grain Zeeländer (new seed), and 10 per cent in Heine Green-grain Zeeländer (new seed).

The culture of barley at Princes Park (*Semaine Agr., 19 (1899), No. 960, pp. 325, 326*).—Data for fertilizer tests with phosphatic fertilizers of different origin on 3 varieties of 2-rowed barley grown on poor soil.

Valuation and culture of barley for brewing (*Deut. Landw. Presse, 26 (1899), Nos. 75, p. 856; 76, p. 864*).

Groninger winter barley, J. H. MANSHOLT (*Deut. Landw. Presse, 26 (1899), No. 62, p. 711, fig. 1*).—A note describing the variety.

Southern forage plants, F. LAMSON-SCRIBNER (*U. S. Dept. Agr., Farmers' Bul. 102, pp. 47, figs. 14*).—This bulletin contains popular information on the formation and care of pastures, as the preparation of the land, time of sowing, and application of fertilizers; and on soiling and fodder crops; and a discussion of the nature, value, and cultural requirements of the more valuable forage plants for the South, including 25 hay and pasture plants, 17 leguminous forage plants, and 6 miscellaneous crops.

"With reference to the selection of forage plants adapted to different regions, the soils of the South Atlantic and Gulf States may be classified as follows: (1) Yellow loam soils; (2) alluvial and river bottom soils; (3) black prairie soils; (4) pine woods soils.

"The forage plants most successfully grown for different purposes on these soils are enumerated below:

"*Forage plants for yellow loam soils.*—For permanent meadows on rich land, Bermuda grass; for a hay crop to occupy rich land 2 years, red clover; for a single hay crop on fair soils, cowpeas; on poor soils, lespedeza. For permanent pastures, Bermuda grass and lespedeza, to which may be added on dry soils, orchard grass, smooth brome grass, and bur clover; on wet soils the addition should consist of redtop, water grass, and alsike clover. Crimson clover, rescue grass, Terrell grass, and hairy vetch are recommended for winter pasture.

"*Forage plants for the alluvial and river bottom soils.*—For permanent meadows, Bermuda grass and red clover; on wet spots, redtop; and on well-drained soils, alfalfa. For a hay crop for a single season, lespedeza or German millet. For pastures, Bermuda grass, lespedeza, redtop, alsike clover, bur clover, alfalfa, Japanese rye grass, large water grass, and Terrell grass.

"*Forage plants for the black prairie soils.*—For hay, Bermuda grass, red clover, and sweet clover. For a hay crop for a single season, lespedeza. For a catch crop, following oats, potatoes, etc., cowpeas or German millet. For pastures, Bermuda grass, lespedeza, sweet clover, alsike clover, smooth brome grass, orchard grass, redtop, bur clover, and hairy vetch.

"*Forage plants for the pine woods soils.*—For hay, Bermuda grass, crab grass, Mexican clover, alfalfa, crimson clover, and lespedeza. For pastures, crimson clover, Japanese rye grass, orchard grass, carpet grass, and large water grass."

Grasses and other forage crops, C. S. PHELPS (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 184-217*).—A lecture delivered at a meeting of the Massachusetts State board of agriculture. Popular descriptions are given of a number of common grasses and legumes, and methods of culture for each are recommended. In this connection the results of field experiments to determine the effect of nitrogenous fertilizers on the yield and composition of corn, oats, and mixed grasses are reviewed (E. S. R., 2, pp. 200, 396).

The hop, from a botanical, agricultural, technical, and commercial standpoint, E. GROSS (*Der Hopfen in botanischer, landwirtschaftlicher, und technischer Beziehung sowie als Handelswaare. Vienna: Gerold's Son, 1899, pp. VII + 255, figs. 78*).

Millets, T. A. WILLIAMS (*U. S. Dept. Agr., Farmers' Bul. 101, pp. 28, figs. 6*).—Reprinted from the Yearbook for 1898 (E. S. R., 11, p. 443). Data showing the average chemical composition and digestibility of the different varieties of millets have been added.

Experiments on the culture of oats in Princes Park (*Semaine Agr., 19 (1899), No. 957, pp. 302, 303*).—Results of tests with phosphatic fertilizers on oats for the years 1895 and 1899. The data given show the kind of fertilizer used, yield of straw and grain per hectare, and profits realized on the different plats. The best results were secured on the plat fertilized with superphosphate. The amount of fertilizer applied per hectare is not recorded.

Experiments in the culture of oats, E. MARRE (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 40, pp. 395–398*).—Data as to soil, manures used, dates of seeding, germination, and harvest, and the yield of grain and straw are given for a number of cooperative comparative tests with 7 varieties of oats. The Gray Houdon oats gave the best results as regards yields of both grain and straw.

Belgian black oats, DECAMPINE (*Belg. Hort. et Agr., 11 (1899), No. 5, pp. 70, 71; Landbouwblad Limburg, 1899, p. 115*).

The most profitable method of fertilizing rye following potatoes, M. FISCHER (*Fühling's Landw. Ztg., 48 (1899), No. 19, pp. 736–741*).—Data and a discussion of fertilizer experiments with rye following a crop of potatoes are given. The following conclusions are reached: Nitrogen fertilizers should always be added to rye following a crop of potatoes. These fertilizers should be applied in the fall. Sulphate of ammonia is the most suitable form of nitrogen for this purpose. If fertilizers are used in the spring the best results will be secured with nitrate of soda applied at 2 different times. Superphosphate was used at a loss in these experiments.

Monstrosities in rye, W. RIMPAU (*Deut. Landw. Presse, 26 (1899), Nos. 77, pp. 878, 879, 881, figs. 4; 79, p. 901, figs. 2*).

Phosphoric fertilizers in sugar-beet cultivation (*Sugar Beet, 20 (1899), No. 10, pp. 138, 139*).—Summarization of some experiments with furnace slag and superphosphate carried out in France, in which the best results as regards sugar content and percentage purity were obtained by the use of furnace slag.

What the experiment stations have learned about raising and curing tobacco, E. H. JENKINS (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 18–50*).—A lecture delivered before the Massachusetts State board of agriculture in 1898. Tobacco soils are discussed and a complete review of the experiments with tobacco carried on at the Connecticut State Station for 5 years is given (E. S. R., 10, p. 240).

The best varieties of wheat, J. S. GORDON (*Farmers' Gaz., 58 (1899), No. 43, p. 930*).—Summarized results of test of 15 varieties. The varieties giving the largest yields were Scholey Squarehead Red, 58¼ bu. of grain and 2 tons 18 cwt. of straw; Webb New Standup, 61 bu. 13 lbs. of grain and 2 tons 6 cwt. of straw; and Carter Sunbrown, 50⅝ bu. of grain and 2 tons 13 cwt. of straw. These 3 varieties also produced the strongest and best standing straw.

Fall plowing pro and con, W. C. LATTA ET AL. (*Farmers' Voice, 12 (1899), No. 43, pp. 1228, 1229*).—Opinions of the authors on this subject.

French plowing with a steam plow (*Fühling's Landw. Ztg., 48 (1899), No. 17, pp. 653–657*).—Discussion of the desirable features of steam plowing, with notes on the cost.

Beet puller and topper, E. PAHER (*Jour. Agr. Prat., 1899, II, No. 41, pp. 529–532, fig. 1*).—A description is given of the machine which tops, pulls, and cleans beets, with an account of 3 trial tests in harvesting beets grown in 3 different kinds of soil. In humid sandy soil an average of 1 beet in 20 was irregularly topped and 1 in 200 was not pulled. The beets were well cleaned. Data are not given for the other tests. About 1.8 acres per day were harvested with this machine.

Tests of potato-harvesting machines (*Deut. Landw. Presse, 26 (1899), No. 79, p. 904*).—Data for tests of 11 potato-harvesting machines representing 8 different manufacturers.

HORTICULTURE.

Cold vs. warm water for plants, F. CRANEFIELD (*Wisconsin Sta. Rpt. 1898, pp. 250–268, figs. 4, pls. 2*).—This is a report on experiments in continuation of those begun in 1897 (E. S. R., 10, p. 775). Tests were made to determine the comparative influence of warm and cold water on plant growth. Tomatoes grown under glass were divided into 3 lots and watered with water at 32 to 36, 60, and 90° F., respectively. A record of the soil temperature showed that where the coldest water was used the soil suddenly dropped 15° in temperature and after 12 hours had not regained its original temperature. Water at 60° only slightly affected the temperature of the soil, while water at 90° increased it 6°, but it soon fell to a trifle below the original temperature. The 32° lot was the earliest and produced the largest number and greatest weight of fruit.

This experiment was repeated. Ten plants grown from seeds saved from the 32° lot in the first experiment were watered with water at 32°, 5 plants from the 60° lot with water at 70°, and 5 plants from the 90° lot with water at 100°. "In this case the 100° lot yielded the largest amount of fruit and the 32° lot was next in order, while the 70° lot yielded the least; but the difference is so slight that the results may be considered duplicates."

A crop of radishes was grown at the same time as the first crop of tomatoes and in the same house, separate plats being watered with water at 32, 45, and 70°. The 32° lot gave the poorest yields and the 70° lot the best.

Trials were also conducted with beans in benches, tomato plants in boxes and on raised bench, beans and radishes in wooden boxes, lettuce, and coleus cuttings. They were watered with water at 32, 40, 70, and 100° (beans and radishes in boxes, 110°). The beans in benches gave the largest yields from the 32 and 40° lots. The tomato plants in pots showed no effect that could be ascribed to the temperature of the water used, no difference as shown by the thermometer being apparent after 3 hours. In the case of the tomatoes on raised bench the 32° lot yielded more than the 70° lot, but less than the 100° lot. Lettuce showed a slight gain in favor of the 32° lot, but the weights varied so little that they might be taken as duplicates. The experiments with beans in boxes indicated that the warmer the water the less favorable it was to their growth. The largest yield of radishes in boxes was obtained from the 32° lot. With coleus cuttings the 100° lot at first showed a slight advantage, but later little, if any, influence could be ascribed to the temperature of the water.

The temperature of the soil about the roots was but slightly affected by the varying temperatures of the water applied. While the application of warm or cold water perceptibly raised or lowered the soil temperature for a time, it soon regained its original temperature. In order to observe the effect on growth when the temperature was maintained for a considerable time above or below the normal, 4 lots of water cultures of beans were grown in Sachs's nutrient solution. The temperatures of the water, which was changed daily, were 32, 40, 70, and 100°, respectively, when put in the jars, but gradually rose or fell to the temperature of the room.

The water cultures required more time than the soil cultures to regain their original temperatures. By weighing the various plants it was ascertained that the coldest solution checked the growth of the plants after the first 10 days, but those in the 40° lot made a greater gain than those in the 100° lot.

Experiments with tomatoes were also made under outdoor conditions. Half-barrel tubs of rich soil sunk into the ground were divided into 2 lots, one lot being watered with ice-water, the other from an irrigation system where the average temperature was about 75°. Drainage was good. In the tubs watered with the colder water the temperature was lowered only 5°, yet 28 hours elapsed before the normal temperature was regained. Up to October 3 the plants watered with ice water produced a greater weight of fruit and plants than those watered with warm water. The difference, however, was less marked during the first half of the ripening period than the second. The first half of the summer there was no apparent difference in health and vigor between the plants of the 2 lots, but during the latter half, when the weather had become cooler and the period of most vigorous growth had passed, the plants watered with cold water appeared unhealthy.

A plat of radishes and beans was divided into 3 equal sections, one of which was irrigated during the season with ice water, one with hydrant water, and the third not irrigated at all. The radishes watered with ice water exceeded in weight the ones watered with warm water by about 8 per cent, while those not irrigated at all weighed 18.6 per cent less than those watered with ice water. The rainfall during the season was regarded as nearly or quite sufficient for the development of crops well cared for. The beans showed little difference attributable to the temperature of the irrigation water.

"From the results of these and numerous other trials not here noted the conclusion appears fully warrantable that the growth of ordinary field and garden crops is not affected by the temperature of any water ordinarily available for irrigation purposes.

"The temperature of the soil about the roots of the plants so quickly regains its original temperature that no check to growth is likely to result.

"It is concluded from the results of the outdoor work that no harm can result from using for irrigation purposes water from the coldest springs or wells, for in Wisconsin the temperature of the water from these sources will not be less than 40° in any case when taken from the well or spring and by the means ordinarily employed in irrigation would be raised many degrees above this point before reaching the roots of the plants.

"It is concluded from the results of the greenhouse work that for vegetable and flowering plants commonly grown under glass well or spring water may be freely used at any time of the year without warming."

Fertilizers for garden crops, W. P. BROOKS and H. M. THOMSON (*Massachusetts Hatch Sta. Rpt. 1898, pp. 65-76*).—This is a continuation of work already reported (E. S. R., 10, p. 636). As heretofore, fertilizers were applied to the experimental plats in the form of sulphate of ammonia, muriate of potash, dissolved boneblack, nitrate of soda, dried blood, and sulphate of potash, at the rate of 50.4 lbs. of phosphoric acid, 60 lbs. of nitrogen, and 120 lbs. of potash per acre; but in addition, barnyard manure was also applied to each of these plats at the rate of 12 cords per acre, and a check plat received no other fertilizer except the same amount of barnyard manure. The growth of Clyde strawberries was vigorous and healthly on all plats. Hanson lettuce did best on barnyard manure. Long-standing spinach and Dewing Blood Turnip beet did slightly better on sulphate of potash than muriate of potash. All three were seriously injured by sulphate of ammonia, especially when combined with muriate of potash. Nitrate of soda showed much superiority as a source of nitrogen for both spinach and beets.

The results on tomatoes were similar, but the differences were less marked. Sulphate of ammonia did not, however, appear to affect this crop unfavorably. This is attributed to the fact that tomatoes make most of their growth when the season is well advanced, while spinach and beets make theirs early in the season.

Artificial fertilizers apparently produced a moderate increase in crops of Fottler Drumhead cabbage and Early Maine potatoes. Nitrate of soda appeared to be the best source of nitrogen for cabbage. Sulphate of potash was superior to muriate for potatoes. Sulphate of ammonia was by far the best source of nitrogen, followed in order by nitrate of soda and dried blood. The combination of sulphate of ammonia with muriate of potash, which has generally proved fatal to most crops, gave a fine crop of potatoes. The explanation suggested is the same as in the case of tomatoes. "It seems reasonable to suppose that, as the season advances, the injurious ammonium chlorid formed at first is either washed out of the soil or destroyed by further chemical changes." The results with Giant Pascal celery are to be published later. Spinach, lettuce, and beets were followed by White Egg turnips without further manuring. The artificial fertilizers were moderately beneficial. Sulphate of ammonia appeared to be the best source of nitrogen. "This is not strange, in view of these facts: (1) The plats to which this had been applied had produced but very small first crops, while the others had yielded heavily; and (2) the turnips made their growth so late in the season that the injurious compounds often formed by this salt had become dissipated or destroyed by further chemical changes."

Report of the horticulturist, S. T. MAYNARD (*Massachusetts Hatch Sta. Rpt. 1898, pp. 11–19*).—Notes are given on a number of varieties of fruits recently tested at the station. The author believes that the older varieties of apples are growing more and more feeble and that new varieties are needed to replace them. The case of the Baldwin apple is cited. This variety "has in many places in the last 2 or 3 years shown so great a tendency to the dry-rot spots under the skin long before its normal time for the breaking down of its tissues in the process of ripening that much of its fruit put on the market has had the effect of decreasing the demand and lowering the price." The following varieties of apples are recommended, and descriptive notes given of them: Sutton Beauty, Palmer, MacIntosh Red, Wealthy, and Gano.

Fewer varieties of pears are found profitable than a few years ago. Those recommended are: Bartlett, Bosc, Sheldon, Seckle, and Hovey.

Plums have shown a great tendency to rot. Those most liable to this malady are: Lombard, Washington, Gueii, Smith Orleans, and Victoria. Those that show the least tendency to rot are Bradshaw, Prince Englebert, Kingston, Grand Duke, Reine Claude, and Fellenberg. Newer varieties of promise are Kingston, Lincoln, and Fellenberg. These varieties are described.

Cherries rotted badly on account of extremely hot and moist weather at the time of ripening. This trouble may be successfully combated by thoroughly spraying immediately after each rain. Varieties most resistant to the rot are Governor Wood, Napoleon, Black Tartarian, and Early Richmond.

Recommended varieties of grapes for Massachusetts are Winchell or Green Mountain, Worden, and Delaware. Campbell Early is mentioned as a new variety of promise, and is described.

Meritorious new varieties of currants are Pomona, Wilder, and Red Cross. None, however, of the newer varieties of currants, blackberries, and red raspberries have surpassed the old standard sorts. Varieties of strawberries that gave best results on medium heavy loam are Brandywine, Gandy Bell, Glen Mary, Sample, and Howard No. 14. Of those grown under field culture on light land, Clyde, Cumberland, Glen Mary, and Howard Nos. 36 and 41 gave best results.

Notes are given on the strawberry-raspberry, and Loganberry.

Revised catalogue of fruits recommended for cultivation in the various sections of the United States and the British Provinces by the American Pomological Society (*U. S. Dept. Agr., Division of Pomology Bul. 8, pp. 63, map 1*).—This catalogue is similar in character, scope, and general plan to its predecessor (E. S. R., 9, p. 648). In this edition the number of fruit districts has been increased from 15 to 19, boundary lines of districts have been changed in some instances to conform to later advices, and the work increased in value by the added data obtained in a special study of the pomological conditions of the Pacific coast region. The data here presented are considered suggestive rather than conclusive for the different districts, and planters are cautioned against following them too closely. All of the more important species and varieties of fruits and nuts now grown in the United States and the adjacent British Provinces on the north are considered. The society's rules for exhibiting and naming fruits are given in the concluding chapter of the bulletin.

Morphology of the strawberry plant, E. S. GOFF (*Wisconsin Sta. Rpt. 1898, pp. 229–238, figs. 6*).—A study of the morphology of the strawberry plant, with especial reference to adaptation to environment, and its significance for the culturist. Application is made of the facts ascertained in enabling the author to give a rational explanation of why strawberry beds soon run out, as also of various cultural practices, as those of winter protection, removal or nonremoval of runners, etc. Contrary to the statement in numerous botanies, the author finds that the strawberry is not acaulescent, but has a short, thickened stem.

Grapevine fertilizer experiments, M. WIENER (*Deut. Landw. Presse, 26* (*1899*), *No. 78, pp. 891–893, figs. 10*).—The value of commercial fertilizers as manures for grapevines on sandy and clay soils was studied at the Altenburg Experiment Station in Hungary. One hundred and fifty sheet-metal cylinders, 1 meter long by 60 cm. in diameter and open at both ends, were sunk in the ground in 1894. Underneath the cylinder a layer of gravel 25 cm. in thickness was spread. Seventy-five cylinders were then filled with poor sand and 75 with clay soil containing lime. In the spring of 1895 a vine was set in each cylinder. Pots 2 to 18, which had been filled with sandy soil, received certain amounts, either alone or in different combinations, of superphosphate, nitrate of soda, sulphate of potash, and sulphate of ammonia, the purpose being to study the effect of relatively large amounts of fertilizers. Pots 19 to 36 were planned to test the effect of half the amount of the same fertilizers; pots 37 to 54, the effect of increasing or decreasing each of the essential elements in a complete formula; pots 55 to 57 and 59 to 69 to determine what amounts of chemically pure phosphoric acid, potash, and nitrogen fertilizers are necessary for the production of a full yield on a poor sandy soil; and pots 70 to 75 to determine the effect of phosphatic fertilizers when combined with organic nitrogen (night soil). Pots 1 and 58 were used as checks and received no fertilizers. The same fertilizers were applied in duplicate to the 75 pots filled with clay soil.

The results obtained during the 4 years of the experiment are discussed and the growth obtained in a number of pots is illustrated by photographs. The different effect of the same fertilizers on the two soils was very noticeable. On the clay soil the fertilizers had practically no observable effect, the harvest of grapes and the development of the vines being as good in the unfertilized pots as in those receiving fertilizers. In general the growth of the vines in the clay pots was much stronger than in the sand pots, but the yield was considerably less. The yield from vines in the pots filled with sand which received complete fertilizers averaged more than 1,000 gm. per vine, and in one instance was 3,182 gm., while the highest yield obtained from any vine in the clay soil was only 1,120 gm. and the yield from the others in the clay series was less than 1,000 gm. per vine. The effect of the complete fertilizers on the sandy soil was apparent to the eye and the results were such as to lead to the belief that a full yield of grapes can be obtained on sandy soil by the use of complete commercial fertilizers without resort to barnyard manures. The omission of one of the essential elements in a complete formula had a harmful effect on the development of the vine in the pots filled with sand, though the growth when only one element was employed was always greater than when no fertilizer was used. The poorest results in this series were obtained in the pots receiving nitrogen and potash alone, followed by the pots which had received only phosphoric acid. No difference was noticeable as to the growth and yield of pots 2 to 18, which received relatively large amounts of fertilizers, and pots 19 to 36, which received half the same amounts. The chemically pure fertilizers, while giving good results, proved too costly for general use. Night soil with phosphoric acid gave results practically identical with those obtained from phosphoric acid alone. It is believed, therefore, that the nitrogen requirements of grapes are slight and that good harvests can be obtained with potash and phosphoric acid fertilizers alone, even on soils poor in nitrogen.

The cultivation of monstrosities, H. DE VRIES (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 2, pp. 125-127; Gard. Chron., 3. ser., 25 (1899), No. 633, p. 88*).—For about 12 years the author has cultivated vegetable monstrosities with a view to studying their abnormalities. With the exception of virescence caused by parasites, they have proved to be hereditary and have produced by isolation and selection races of varying degrees of persistence. Some monstrosities show no greater tendency to revert than do ordinary varieties of cultivated plants, while others reproduce only one-third or one-fourth of the individuals true to type; but those plants that do revert to the normal type preserve certain characteristics of abnormality, though in different degrees. Often the anomalous structure is reproduced at the top of the stem or in the lateral branches. In perennials the abnormal forms have reappeared after 3 or 4 years. Sometimes plants appear to be absolutely normal but yet retain the ability to reproduce an ancestral abnormality in their seed. The less the fixity of the type, the more is its preservation dependent on environment; hence the necessity for careful cultivation. Monstrous varieties even in wild species require more careful culture than the most variable ornamental plants. Thorough cultivation is necessary, especially during the periods of germination and early growth. Monstrosities must have plenty of room.

From the standpoint of physiology, monstrosities may be classed as constant, precocious, or tardy. Constant monstrosities show no greater tendency to revert than common varieties and require the same culture. Precocious monstrosities are those that appear in very young plants. Tardy monstrosities are those that appear only after several weeks or months.

The development of monstrosities depends primarily on the vigor of the individual plant, especially in the early stages of growth. Selection of seed producers is of only secondary importance. Monstrosities require a sunny and healthful situation and plenty of manure. Annuals produce a larger proportion of abnormal forms if the seed is sown early and the young plants have abundant warmth and light. In biennials the number of fasciations and tortuous growths and their development are in proportion to the length and vigor to which the rosettes of radical leaves attain before the development of the stem. If very heavily manured, biennials winterkill. Species optionally annual or biennial are most variable. They form good fasciations only on biennial plants.

Why crops must have nitrogen and how it can be provided, G. C. CALDWELL (*Trans. Massachusetts Hort. Soc. 1899, I, pp. 56-74*).—A paper read by the author before the February meeting of the society in which the discovery of root tubercles and the use of leguminous plants and Nitragin in agriculture are considered at length.

Commercial fruit and vegetable culture in Australasia (*Gartenflora, 48 (1899), No. 17, pp. 466-468*).—Statistics of the fruit and vegetable production and of the imports and exports of the same for the different provinces of Australasia.

Watering plants in fields, F. CRANEFIELD (*Gardening, 8 (1899), No. 169, pp. 9, 10, figs. 3*).—Suggestions for irrigating gardens.

The culture of asparagus, L. PASSY (*Bul. Soc. Nat. Agr. France, 59 (1899), No. 4, pp. 249-288*).—This includes a discussion by de Vilmorin, de Salvandy, and Rolland.

Ginseng: Its cultivation, harvesting, marketing, and market value; with a short account of its history and botany, M. G. KAINS (*New York: Orange Judd Co., 1899, pp. 64, figs. 13*).

Catalogue of fruits for the use of planters, L. WOOLVERTON (*Ontario Fruit Expt. Stas. Rpt. 1898, pp. 177-192*).—Catalogue for the use of planters, showing values of the orchard and small fruits of Ontario and of their adaptability to different parts of the Province.

✓ **Fruits of Ontario,** L. WOOLVERTON (*Ontario Fruit Expt. Stas. Rpt. 1898, pp. 3-95, figs. 163*).—Descriptions, notes on the origin, character, and adaptability to Ontario, and natural size illustrations of 23 varieties of apples, 21 of cherries, 4 of currants, 9 of gooseberries, 2 of grapes, 18 of pears, 3 of peaches, 40 of strawberries, and 2 of quinces which have been successfully grown in the Province. The object of the work is to present an historical record of the size, color, general appearance, and real value of all fruits grown in the Province as a means of identification.

Fruit experiment stations of Ontario (*Ontario Fruit Expt. Stas. Rpt. 1898, pp. 97-175, figs. 2*).—Reports from some 15 fruit stations in the Province relative to culture experiments and variety tests, with descriptive notes on a large number of the fruits tested, and notes on the official inspection of the same stations. The comparative results obtained in certain pruning and spraying experiments and the selling price in 1898 of apples, pears, blackberries, raspberries, currants, grapes, and strawberries are also noted.

Observations on Russian fruits at the Central Experimental Farm, 1898, W. T. MACOUN (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 10-14*).—Notes are given on a number of varieties of apples, pears, plums, and cherries.

New and seedling fruits, H. L. HUTT (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 58-62*).—Notes on a number of new varieties of seedling apples, pears, plums, peaches, grapes, and cherries.

Promising new fruits, C. P. TAFT (*Pacific Rural Press, 58 (1899), No. 16, p. 244*).—The present status of the loquat and Loganberry are given, with suggestions as to cultural methods, and notes on miscellaneous small fruits.

Manitoba and the Northwest Territories as markets for Ontario and British Columbia fruit, W. SAUNDERS (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 39-48*).—Includes notes on the very limited native fruits of the region.

Export of fruit pulp, J. W. ROBERTSON (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 18, 19*).—It is believed that the export of fruit pulp to Great Britain is not profitable except in those cases in which the grower finds a surplus of unsalable fruit on hand.

Central Experimental Farm notes, I, W. T. MACOUN (*Canad. Hort., 22 (1899), No. 10, pp. 396, 397*).—Brief notes on apples, plums, grapes, and hardy shrubs at the Central Experimental Farms.

Seaweed for fruit borders, R. PARKER (*Garden, 56 (1899), No. 1457, p. 311*).—The substitution of seaweed for barnyard manure as a mulch for orchard fruits, vines, etc., is considered. Seaweed is considered especially valuable in dry seasons on light soils, because of its superior moisture-holding properties.

Protecting nursery stock in winter, N. H. ALBAUGH (*Florists' Exchange, 11 (1899), No. 43, p. 1081*).—Instead of the usual method of healing in nursery stock, the author recommends that it be corded up in a storage house. The roots should be packed with slightly damp moss, and where the building is very large one or two stoves is advised for use during the coldest weather. The details of packing and arranging the trees in the storehouse are given.

Whole versus piece roots (*California Fruit Grower, 24 (1899), No. 593, p. 5*).—In a test of whole *vs.* piece roots for grafting apples, whole roots were found the best for slow-growing sorts. Grafting 2 in. above the crown is advised.

The Cadillac graft, M. CAPUS (*Semaine Agr., 19 (1899), No. 957, pp. 299, 300*).—The Cadillac system of grafting is described and some results secured in a number of grafts in different species of grapes noted.

Fruit-tree pruning, G. QUINN (*Jour. Agr. and Ind., South Australia, 3 (1899), No. 2, pp. 116–139, pls. 32*).—Right methods of pruning apples, pears, and quinces are illustrated by numerous photographs and the process described.

Obtaining dwarf plants by means of cuttings (*Rev. Hort., 71 (1899), No. 17, p. 413*).—The author states that cuttings taken from the extremities of branches of plants which have reached complete development but have not produced flowers will take root under proper conditions and produce flowers without much further growth. If the plants to be dwarfed produce both terminal and axillary flowers, the cuttings should be taken from the least developed flower branches. The cutting should be made from 5 to 7 cm under a node in each case. Chrysanthemums, asters, roses, and several greenhouse plants have been thus dwarfed.

The grafting of coffee, cacao, and nutmeg trees, A. THIERRY (*Abs. in Rev. Cult. Coloniales, 5 (1889), No. 38, pp. 201–209*).—The relative values of different methods of grafting these trees are discussed.

Instructions as to seed time, culture, and profits of cacao (*Bol. Agr. Min. e Ind., 8 (1898), No. 5; abs. in Agricultor [Bogota], 15. ser., 26 (1899), No. 6, pp. 257–265*).—A discussion of suitable soils, nursery management, cultivation, harvesting, and profits in cacao culture.

Cacao culture in Ecuador (*U. S. Consular Rpts., 1899, No. 229, pp. 250–261*).—This article deals with the soil, methods of planting and cultivation, harvesting, marketing, cost of production, consumption, uses and botany of cacao as grown in Ecuador, with a table showing analyses of cacao from 4 countries.

The diœcism of the fig in its bearing upon caprification, W. T. SWINGLE (*Science, n. ser., 10 (1899), No. 251, pp. 570–574*).—Paper on this subject read by the author at a meeting of the American Association for the Advancement of Science at Columbus.

Zante currant in South Australia, F. C. SMITH (*California Fruit Grower, 24 (1899), No. 588, p. 3*).—Notes on the character, growth, and profits derived from the culture of this fruit in South Australia.

The tea industry (*Agr. Jour. [Natal], 2 (1899), Nos. 10, p. 305, figs. 2; 11, pp. 340, 342, fig. 1; 12, pp. 371–373, fig. 1*).—Notes on the history of tea with an account of cultural methods on the Kearsney estate and chemical analyses of 5 samples.

The mulberry, its culture and treatment, N. SHAVROV (*St. Petersburg: A. F. Devrien, 1899, 2. ed., pp. X + 200, figs. 142; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, p. 186*).—This book contains an account of the distribution of the mulberry in Russia, and general directions for its cultivation with special reference to silkworm culture.

Intensive fertilizing of vines, L. DEGRULLY (*Prog. Agr. et Vit., 16* (*1899*), *Nos. 40, pp. 381-388; 41, pp. 409-411*).—The amount of fertilizers applied in different provinces of France for the production of a hectoliter of wine and the amount of fertilizers taken up by the vines in the production of the same are tabulated and discussed. Data showing the value of fertilizing vines with all 3 essential elements are also given.

Packing vine cuttings, C. RIVIERE (*Rev. Cult. Coloniales, 5* (*1899*), *No. 3, pp. 198-201*).—Directions for packing vine cuttings for shipping in warm climates.

Some effects of the freeze of 1898-99 in Iowa, J. CRAIG (*Amer. Gard., 20* (*1899*), *No. 252, pp. 720, 721*).—A paper read by the author before the American Pomological Society at its meeting in Philadelphia. A general discussion is given of the subject, with a brief account of experiments in pruning and banking root-injured nursery stock. With apples the best results, 20 per cent of treated trees, were obtained when all the branches, including the leader, were cut back one-half. Ninety-five per cent of plums on native stock lived when the side shoots were cut back to the main stem and the leader left. Banking apples or pears was of no practical benefit, but with grapes 80 per cent were saved by cutting back severely and hilling deeply.

A new packing material for fruits (*Gard. Chron., 3. ser., 26* (*1899*), *No. 666, pp. 258, 259*).—A preparation of asbestus is reported to have kept apples shipped from Australia 5 months in perfect condition.

Crystallized and glacéd fruit (*California Fruit Grower, 24* (*1899*), *No. 587, p. 1*).—A statement of the method of preserving fruit in the crystallized, or glacéd, form known as the French process.

Preservatives for bottled fruits (*Canad. Hort., 22* (*1899*), *No. 8, pp. 326, 327*).—General directions for preserving exhibition fruit and formulas for a number of kinds.

Chestnut culture, J. B. EMERSON (*Virginia Hort. Soc. Rpt. 1898-99, pp. 93-99*).

A chapter on walnuts, HARRIS (*Florists' Exchange, 11* (*1899*), *No. 42, pp. 1056, 1057*).—Varieties *Juglans nigra*, *J. cineria*, *J. regia*, *J. cordiformis*, and *J. sieboldi* are described and suggestions given regarding their culture.

A new plant, O. AMES (*Amer. Gard., 20* (*1899*), *No. 248, p. 654*).—A desirable new hybrid orchid originated by W. Turner by crossing Selenipedium with Geralda is noted and measurements showing the lengths of the petals, dorsal sepals, and ovaries as compared with several other varieties and hybrids of Selenipedium are given. A technical description is given of the hybrid, together with a list of hybrids having *S. lindleyanum* as one parent.

Bamboo culture (*Agr. Jour. Cape Good Hope, 15* (*1899*), *No. 1, pp. 42-44*).—A popular article describing bamboo culture as it is carried on in southern Africa.

Clianthus dampreri, E. ANDRÉ (*Rev. Hort., 71* (*1899*), *No. 17, pp. 409, 410, fig. 1*).—The difficulty usually attendant in the culture of this plant has been overcome in part by grafting on a resistant subject, as *Colutea frutescens*. The grafting is performed by substitution of the plumule of the graft for that of the stock as soon as the cotyledons of the stock have opened.

Dillenia speciosa, L. A. BERNAYS (*Queensland Agr. Jour., 4* (*1899*), *No. 6, pp. 457, pl. 1*).—This fruit is noted as successfully growing in the garden of the Acclimatization Society. It is a native of India and the Malayan Islands, where it is found in dense forests. The trees attain a height of 40 ft. and are evergreen. The fruit is 3 to 4 in. in diameter and when fully ripe has an agreeable acid taste when eaten raw, cooked in curries, or made into sherbet. A glutinous matter which surrounds the seeds is used for making a palatable jelly, a cough mixture, or a cooling drink in fevers and otherwise. The bark and leaves are astringent and are used medicinally. The timber is valuable for gunstocks, handles, and such like, and is especially valuable for its durability under water.

Eucharis (*Gard. Chron., 3. ser., 26* (*1899*), *No. 665, pp. 238-240, fig. 1*).—Descriptive notes on 10 varieties with suggestions as to cultivation, forcing, and insect pests and diseases.

Sowing fern spores, A. HEMSLEY (*Garden, 56 (1899), No. 1450, pp. 186, 187*).—Directions for gathering and preserving fern spores, preparing the seed pots, care during early stages of growth, transplanting, watering, and the like are given. Subwatering rather than surface application is insisted upon.

The bush honeysuckle, J. DUNBAR (*Gardening, 8 (1899), No. 169, pp. 2, 3*).—Sixteen varieties of Lonicera are described and their individual values as ornamental shrubs pointed out.

Evergreen protection (*Wallaces' Farmer, 24 (1899), No. 39, p. 795*).—The results of tree planting for wind protection in Iowa are discussed. The Russian mulberry has proved an efficient wind-break planted in rows 10 ft. apart and 2 ft. distant in the row. For permanent groves and wind-breaks the green and the white ash are recommended above all others among deciduous trees and the Riga pines among evergreens.

DISEASES OF PLANTS.

Experimental investigations on some diseases of plants, E. LAURENT (*Ann. Inst. Pasteur, 13 (1899), No. 1, pp. 1–48*).—While studying the effect of large amounts of different fertilizers upon the production of potatoes, the author found that the tubers of one lot that had been grown upon a plat where the soil had received a large quantity of lime were badly attacked by bacteria, resulting in a bacterial rot, while the same varieties, but from other plats, were unaffected. This suggested investigations to ascertain the effect the medium in which plants grow may have in influencing their resistance to disease.

In 1897 several varieties of potatoes were grown in plats which were apparently of equal fertility. The different plats received the following fertilizers per hectare: Plat 1, 1,100 kg. of ammonium sulphate; plat 2, 2,200 kg. of kainit; plat 3, 2,200 kg. of calcium superphosphate, and plat 4, 15,500 kg. of fat lime; plat 5 being left as a check. As in the previous year, some months after harvest the tubers of the less resistant varieties in plat 4 were attacked by a bacterial growth. Upon isolation this proved to be a well-known saprophyte, *Bacillus fluorescens putidus*. Inoculations made upon cut tubers of the other varieties from the different plats failed to grow. Cultures made upon the susceptible variety after a time seemed to develop an increased virulence until all varieties from all plats could be readily infected, the last to yield being those from plat 3, where calcium superphosphate had been added to the soil. In order to secure this virulence, it was found necessary that the cultures should be continued for some time upon raw potatoes, and a single passage through cooked potato or a synthetic medium was sufficient to destroy the parasitism of the germs.

In 1898 8 varieties of potatoes were grown under conditions similar to the above. In this series plat 1 received at the rate of 500 kg. of sodium nitrate and 800 kg. of ammonium nitrate, and plat 4 received 40,000 kg. of lime per hectare, the other plats receiving fertilizers approximately as in the previous years. The tubers were harvested and experiments made with them as before, the organism used this time being *Bacillus coli communis*, and results analogous to the above were obtained. Carrots and chicory were also introduced into the experiments. In general it was found that lime diminished the resistant power of potatoes, carrots, and chicory toward the bacterial rot, while the phosphates increased their resistance. Nitrogenous and phosphatic fertilizers diminished resistance to a slight degree, while sodium chlorid increased it in about the same degree.

Experiments were conducted to ascertain the means by which the potato resisted the attacks of the organism. It was found that the potato owes its resistance to the presence of soluble substances in the cell sap of the tubers. This is destroyed by alkaline solutions and the total acidity of the cell sap does not correspond to the action of this protective substance.

The method by which the bacteria gain entrance into the tubers was studied, and it was found that it was by the intervention of certain unorganized ferments secreted by the organism. These were separated and some of their peculiarities are noted. Experiments indicate that these substances when properly manipulated, render plants resistant to disease, acting in the same way toxins do toward animals.

Experiments are also reported in which are shown the action of fertilizers in increasing or diminishing the resistance of potatoes toward attacks of *Phytophthora infestans.* Nitrogenous fertilizers seem to decrease the resistance of even the most resistant varieties of potatoes to attacks of Phytophthora. Lime also appears to exert a similar effect, but in this case it is indirect, the lime acting through the stimulating effect it has upon nitrification in the soil. The experiments with *Sclerotinia libertiana* reported were mostly made with artichokes, carrots, and chicory. The results obtained are analogous to those for the species of Bacillus reported above. In this case phosphatic fertilizers increased the tendency to disease.

In conclusion, it is shown that under certain conditions saprophytic organisms may develop pathogenic properties. As an essential for this development the natural resistance of the plant must be weakened by the improper use of fertilizers, and the virulence of the attack may be increased by systematic cultures in the living medium, the use of a synthetic medium, or any change in the medium being sufficient to destroy the acquired pathogenic properties. The different effect of the same fertilizers on different plants is explained by the fact that some organisms require an alkaline medium while others need an acid one for their development. Unless the proper conditions are present the diastases formed by the organisms can not dissolve the middle lamella of the cells and gain entrance into the host.

The author claims that in order to preserve cultivated lands from the injurious effects of constantly present micro-organisms, recourse must be had to procedures based upon the influence of fertilizers in promoting the resistance of plants toward their parasites.

Report of the botanists, G. E. STONE and R. E. SMITH (*Massachusetts Hatch Sta. Rpt. 1898, pp. 142–167*).—The principal investigations reported are those which have been conducted in connection with market garden crops such as are cultivated in greenhouses, the principal ones being lettuce, cucumbers, and tomatoes. The experiments which are being conducted, briefly outlined, are investigations of the control of "drop" in lettuce, "top burn," effect of mechanical condition of soil as influencing the growth of lettuce, and subirrigation as affecting lettuce diseases; experiments on the pruning of cucumbers as affecting the maturity and production of fruit, and also the various fungus diseases of this crop; experiments on the pruning of tomatoes, and the tomato diseases; experiments in the growth of violets; the use of gases and chemical solutions for disinfecting greenhouses, and on the relation existing between electricity and plant growth.

Brief reports are given on black spot of the maple (*Rhytisma acerinum*), the oak-leaf blight (*Glœosporium nervisequum*), the walnut-leaf blight (*G. juglandis*), and the leaf curl of the peach (*Exoascus deformans*).

A muskmelon disease is described, which is caused by a species of Alternaria. The presence of the disease is manifest by the wilting of the leaves, the center of the hill being usually the first point of attack. The leaves are covered with yellow spots, and in the worst cases exhibit dead areas of considerable size. When the disease was first noticed it had made considerable advancement, so that but little benefit could be expected from any treatment given it. Sprayings, however, were made with Bordeaux mixture and it is thought that they were followed with favorable results.

The rotting of cabbage in the field, caused by a species of bacteria, is reported as having been observed at the station grounds, and is also known to exist in several places throughout the State. This disease has been fully described (E. S. R., 9, p. 849).

In continuation of investigations previously reported (E. S. R., 10, p. 648), the authors give further information relative to the drop of lettuce due to *Botrytis* sp. It seems probable that this disease is not spread by distribution of the spores through the air, but by a mycelium growth in the soil itself. Experiments have been conducted along different lines to prevent the growth of this mycelium, chemicals and gases being used, and the effect of different layers of sand and sterilized earth are reported. The experiments showed that the heating method is the only absolute way of controlling the disease, although some gain is shown by covering the soil to a depth of about three-fourths of an inch with sand. When the sand was sterilized, better results were obtained than when unsterilized. This method gives promise of being practicable, but the authors are not yet satisfied that it is the cheapest that can be utilized, and other methods are being investigated.

The chrysanthemum rust has been studied to some extent, and the indications are that the disease can be controlled by proper methods of cultivation and management. It is claimed that the high August temperature had an injurious effect upon plants confined in pots, such plants being much more susceptible to disease. The rusted plants, although badly affected, produced blossoms apparently as good both in quality and quantity as the healthy ones, and the disease did not spread to other plants kept in close proximity to them. Judging from the year's experience, it seemed probable that a skillful gardener need have no fears from this disease.

A new pansy disease is described, in which the leaves and blossoms of the plant are badly affected by a fungus. This fungus is apparently undescribed, and the name *Colletotrichum violæ-tricoloris* is given it (E. S. R., 11, p. 257). Many plants were killed outright, and all affected ones were in very poor condition. The affected leaves first showed small dead spots, each surrounded by a definite black border, and the petals were often disfigured in a similar way. In other cases the flowers were malformed or only partly developed. This disease has been observed in a few localities in the State and is also reported from New Jersey. A portion of a diseased field was sprayed twice with strong Bordeaux mixture, but as it was late in the season and heavy rains prevailed at the time, little success was obtained. Some benefit, however, is thought to have followed the use of the fungicide, and it is believed that the disease could probably be kept in check by proper treatment.

A number of physiological disorders of plants are mentioned, among them some seasonal peculiarities of certain shade trees, in which the leaves were dropped early in the season; effect of overfeeding of plants, bronzing of rose leaves, wilt of cucumbers, and some of the difficulties which city shade trees have to contend with.

The bronzing of the rose, which is described at considerable length, is manifest by a mottled discoloration of the leaf, and its cause is of a physiological nature or due to structural weakness. These spots subsequently become more apparent, and infected portions of the leaves turn yellow and finally leaflets and leafstalks fall to the ground. An excessive deposit of calcium oxalate has been observed in the leaf cells, and it is thought that these leaves are more susceptible to fungus diseases than healthy ones. An examination of affected plants at a large conservatory near the station showed that all the leaves of plants were not equally affected, but that it seemed to be confined in every instance to two places: First, where a stem is cut and a new branch starts, the leaf at the base of the branch begins to bronze, and, second, where an eye or axillary bud is rubbed off, the leaf generally becomes bronzed. There is also a difference in susceptibility between young plants and old ones. Roses planted in the middle of June frequently showed bronzing the first of August, but the disease is scarcely noticed after the first year's growth. In conclusion, this disease is said to be a physiological disorder which falls under the domain of plant irritability.

The cucumber wilt, which is described, bears some resemblance to bacterial wilt, but is not due to any organism, being brought about by irrational methods of cultivation which give rise to defective transpiration. The methods for its prevention are apparent.

Bird's-eye of olives, U. BRIZI (*Staz. Sper. Agr. Ital., 32 (1899), No. 4, pp. 329–398, pls. 2*).—An extensive study on the disease of olives due to *Cycloconium oleaginum* is reported. The characteristics of the disease are described and the conditions under which attacks may be expected. An extensive investigation into the life history of the fungus is given and artificial inoculation experiments are reported at some length. A nearly related form of the genus is described under the name *C. oleaginum phillyreæ* as occurring on plants related to the olive.

Experiments are reported in which the disease was prevented by thorough applications of a rather weak Bordeaux mixture. A short bibliography concludes the report.

New studies of the brown rusts of grains and grasses, J. ERIKSSON (*K. Landt. Akad. Handl., 33 (1899), No. 3, pp. 172–206, charts 3*).—The extensive studies on this subject conducted by the author during late years are summarized in this paper, and a full account is given of the latest results obtained. The following conclusions are drawn:

The brown rust of wheat (*Puccinia triticina*) does not originate through infection from any other plant species. Two sources of its origin are possible—infection in the spring from the teleutospores of the fungus then growing, or a disease germ found in the seed grain and transmitted from the parent plant. Of these two sources of disease the latter is, in all probability, the principal one. Fresh brown rusted wheat straw should be avoided in manure which is spread on or near a field that will be sown to wheat the following year.

The brown rust of rye (*Puccinia dispersa*) can grow on the young winter rye plants in the late fall through infection from varieties of bugloss (*Anchusa arvensis* and *A. officinalis*) growing near by, which are affected with rust (*Æcidium anchusæ*); for this reason these weeds should not be allowed to grow in the neighborhood of rye fields. Two other sources of its origin are possible, as with the wheat rust. Rye in rare cases may be attacked by the forms of brown rust found on wheat and couch and brome grasses, but the source of the true brown rust of rye can not be sought in any of these grasses, especially as it is the earliest one of them all. Fresh brown rusted rye straw should be avoided in manure which is spread on or near fields intended for rye.

Puccinia bromina, *P. agropyrina*, *P. holcina*, and *P. triseti* are of little importance to grain raising, as none of them can be considered the source of the brown rust of either the wheat or rye.

In choosing brome grasses for meadows, varieties subject to attack of rust, like *Bromus mollis* and *B. arvensis*, are to be avoided (both these varieties are also particularly susceptible to smut, *Ustilago bromivora*), and such as *B. erectus* and *B. inermis* chosen, which are not only not susceptible to rust, but also give a much heavier yield of forage.—F. W. WOLL.

Club root, or finger-and-toe disease (*Rept. Agr. Expts. Cornwall County Council, 1898, pp. 27–42, pls. 7*).—Experiments are reported upon, in which the infectious nature of the organism causing club root is shown, and warnings are given of the danger of contamination through various means. Various remedies were investigated, from which it appeared that liberal applications of lime or basic slag were very efficient in checking the disease. The relative value of deep and shallow cultivation in connection with the application of lime, slag, etc., was investigated. Where 6 tons of lime per acre were applied and the soil frequently cultivated to a depth of 3 inches, the results were much more favorable than where an occasional cultivation to a depth of one-half inch was given. The total weight of the crop, as well as the increased number of sound roots, were in favor of the deeper cultivation.

Experiments are quoted in which 6 and 8 tons of lime per acre were compared, to the advantage of the latter amount. So far as clean roots were concerned, the proportion from the plats receiving 8 tons per acre was largely in excess of that from the plats receiving 6 tons. The total yield of turnips was practically the same in both cases. Superphosphate and basic slag were compared, indicating that superphosphate is without value as a preventive treatment of club root. The proper time of application of preventive treatments was investigated, June and autumn applications being compared. The superiority of the autumn treatment was quite evident. Copper sulphate as a means of prevention of club root was tried, but proved to be without any value in badly infested soils.

The possibility of infection through the presence of the micro-organism of the disease in the manure of animals fed on turnips is to be a subject for further investigation.

A text-book of plant diseases caused by Cryptogamic parasites, G. MASSEE (*New York: The Macmillan Co., 1899, pp. XII+458, figs. 92*).—The aim of this book is to enable those occupied with the cultivation of plants to determine the nature of diseases due to parasitic plants and in combating them to apply in the most approved manner those treatments which experience has shown to be most successful. A general discussion of parasitic fungi, lichens, algæ, slime molds, and bacteria is given, together with formulas for fungicides and directions for spraying.

The diseases are each briefly, though clearly, described, and preventive measures, where any are known, are given, followed by references to some of the more important literature bearing on the disease. The arrangement is that of grouping the different diseases according to the sequence of the orders of fungi rather than by host plants. After the enumeration and characterization of the various diseases, technical descriptions are given of the parasites causing them. There are also copious references to the literature.

Bacteria as the cause of plant diseases, G. A. NADSON (*Les bacteries, comme la cause des maladies des plantes. St. Petersburg, 1899, pp. 12*).

Protection of plants against fungi, T. BOKORNY (*Biol. Centbl., 19 (1899), pp. 177–185; abs. in Jour. Roy. Micros. Soc.* [*London*], *1899, pt. 4, p. 414*).—An enumeration is made of the various organic substances which serve to protect plants against attacks of fungi and schizomycetes. Of these the most widely distributed are the tannins, of which more than 1 per cent is necessary to be present in living plants in order to secure immunity against fungi or bacteria. Bacteria are said to offer less resistance to tannin than the mold fungi. The salts of oxalic acid are not poisonous to the lower fungi, while any free acid is injurious to the growth of them all. Essential oils are said to offer an effective protection against the attacks of all parasitic organisms.

Some diseases of our root crops, J. ERIKSSON (*K. Landt. Akad. Handl., 33 (1899), No. 2, pp. 63–76*).

The potato disease, H. TRYON (*Queensland Agr. Jour., 5 (1899), No. 1, pp. 57–63*).—Notes the occurrence of bacterial blight of potatoes, the same disease having been described in detail in this country by E. F. Smith (E. S. R., 8, p. 895). The disease was first noticed by the author and attention called to it in 1895. The identity of the two diseases is affirmed and the conclusions of the two authors are quite similar.

The diseases of hops, T. PETERSEN (*Natur, 47 (1899), No. 27, pp. 320, 321*).

Combating apple and pear scab, J. G. WEISS (*Vrtljschr. Bayer. Landw. Rath., 4 (1899), No. 4, pp. 373–377*).—Briefly describes the scab of apple and pear and suggests fungicides which may be profitably employed in preventing these diseases.

The cacao disease in Trinidad (*Bul. Roy. Bot. Gard. Trinidad, 1899, No. 21, p. 221*).—Briefly describes *Nectria bainii*, and says the disease has been recently found on pods growing on trees at the gardens. These pods were completely rotted. It was also observed on young shriveled and immature pods. Further investigation is required to determine whether the fungus is parasitic or saprophytic. It is associated with *Phytophthora omnivora*.

Combating true and false mildews, P. HELD (*Württemburg Wochnbl. Landw., 1899, No. 22, p. 341*).—Gives notes on the preventive treatment of *Oidium tuckeri* and *Peronospora viticola*.

On the browning of larch leaves, R. HARTIG (*Centbl. Gesam. Forstw. Wien, 25 (1899), No. 10, pp. 423–426, fig. 1*).—*Allescheria laricis* is described as new and is said to be the cause of considerable browning of larch leaves.

Abnormal growths on willow, peach, and apricot trees, P. MACOWAN (*Agr. Jour. Cape Good Hope, 15 (1899), No. 8, pp. 555–557, fig. 1*).—Attention is called to a number of abnormal growths occurring on willow, peach, and apricot trees. Roses are said to be attacked in the same way. The knot-like growths are soon followed by the death of the twigs bearing them. No definite cause is assigned, but the author thinks all excrescences should be burned and the general condition of the trees looked after.

On the manufacture of Bordeaux mixture, K. MOHR (*Mitt. Weinbau u. Kellerwirth, 1899, No. 5, pp. 70, 71*).

ENTOMOLOGY.

The temperature of insects according to observations made in Bulgaria, P. BACHMETJEW (*Ztschr. Wiss. Zool., 66 (1899), No. 4, pp. 521–604, figs. 5*).—The author, after making an extended experimental study of this subject, comes to the following conclusions: The temperature of insects may vary within wide limits without endangering the life of the insects. As the atmospheric temperature rises insects manifest no uneasiness at first, but at a temperature of 39° C. they begin to move rapidly and die at from 46 to 47° C. When the temperature of the air is lowered that of the insect rises, at first gradually, then rapidly, and later falls slowly. The point where the temperature suddenly rises is about the normal freezing point of fluids. By continued cooling insects die when the body temperature again sinks to the point at which the sudden rise took place. The manner of the thawing out of insects after their body fluids have been frozen has no noticeable influence upon their return to life, but only upon the intensity of their vitality. The critical point is not the same in different species, nor even in different individuals of the same species. The longer an insect has gone without food the lower is the normal freezing point of its body fluids. Repeated freezing lowers the critical point and also the normal freezing point of body fluids. The greater the proportion of fluid to the total weight of the body in different individuals of the same species the higher is the normal point at which heat rigor takes place. Twenty pages of this article are occupied with a discussion of the literature of the subject. A considerable number of species were used for these experiments, the majority being, however, Lepidoptera.

Problems of honeycomb, O. DAWSON and S. A. WOODHEAD (*Nat. Sci., 15 (1899), No. 93, pp. 347–350*).—The authors experimented with beeswax in thin sheets, heating it in a shallow tray and allowing it to cool slowly. It was found that the wax in cooling became arranged in hexagonal areas similar to those of natural honeycomb, but not quite so regular. With thin sheets of wax smaller hexagonal areas were formed than with thicker sheets. Sheets of wax cast in this manner were placed in observatory hives, and the bees, after excavating the slight quantity of débris which was formed within each hexagonal area, proceeded to work upon these plates as upon artificial foundation of the ordinary sort.

The extermination of mosquitoes, A. CELLI and O. CASAGRANDI (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 13, pp. 396–402; Authors' Abs. from Atti Soc. Ital. Studi Malaria, Rome, July, 1899*).—The authors conducted numerous experiments for the purpose of finding suitable materials for killing the mosquito in the egg, larva, nymph, and adult stages. Permanganate of potash was found to operate slowly, even when used in a 5 per cent solution. Lime, copper sulphate, and ammonia are also slow in their action. Corrosive sublimate in a 1 per cent solution kills the larvæ slowly, but not the pupæ. Sulphur dioxid proved a very effective remedy. Of vegetable substances, the most effective mosquito destroyers were found in tobacco leaves and powders made from the unopened flowers of chrysanthemum. Then follow in order of their effectiveness infusions of quassia, *Solanum nigrun*, and daphne. Of the anilin dyes the most effective were larycith III, gallol, and malachite green. For destroying the nymph water saturated with sulphur dioxid gave the best results. Formalin and lysol were not very effective. Petroleum and olive oil applied as a layer on the surface of the water are effective agents in destroying the nymphs. Common salt and caustic lime give good results only when used in strong solution. For fighting the adult mosquito turpentine, iodoform, tobacco, and sulphur dioxid were found most valuable. Menthol, nutmeg, camphor, garlic, fumes of chrysanthemum flowers, eucalyptus leaves, and pyrethrum were of some service. Most of these remedies are, however, altogether too expensive to be used on a large scale. The authors believe that from an economic standpoint petroleum and mosquito powders made from the flowers of chrysanthemums are to be most highly recommended.

Preliminary report of the State board of horticulture, California, 1897-98 (*Sacramento, 1899, pp. 158, pls. 31, figs. 36*).—This report is occupied mainly with a description of the work of the board of horticulture, particularly in the way of importation of foreign beneficial insects, the study of insecticide methods for scale insects, and the maintenance of quarantine regulations against dangerous foreign scale and other insects. Among successful importations may be mentioned *Novius koebelei*, *Rhizobius ventralis*, and *Cryptolæmus montrouzieri*. A number of foreign insects are considered especially dangerous to the horticulture of the State, and these insects are figured and described as apt to be introduced. Among these pests may be mentioned *Trypeta ludens*, *T. acidusa*, *Leptops hopeii*, *Doticus pestilens*, *Dindymus versicolor*, *Laverna herellera*, *Dacus oleæ*, *Tephritis tryoni*, and *Halyerophora capitata*.

Formulas are given for insecticides as approved and recommended by the State board. Notes are given on the life history and means of combating cankerworm, tent caterpillar, tussock moth, peach-root borers, willow aphis, and codling moth. The quarantine officer and entomologist to the board, Mr. Alexander Craw, contributes a report on the work of inspection in various parts of the State, a brief article on methods of preserving scale insects for cabinet specimens, an account of the new scale insects that have been detected on shipments of nursery stock and quarantined, and a brief article on the subject of horticultural legislation with regard to our new possessions in the Pacific.

Twenty-ninth annual report of the Entomological Society of Ontario 1898 (*Rpt. Ontario Ent. Soc., 1898, pp. 120, figs. 71, pls. 3*).—This report contains a large number of brief articles of a popular nature on the insect enemies of the farmer and gardener, together with book notices, obituaries, and an amendment to the San José scale act for the regulation and fumigation of nursery stock.

In an article on injurious insects in 1898 (pp. 75-86) James Fletcher gives brief notes on the wheat midge, the Hessian fly, and the wheat jointworm (*Isosoma tritici*). Two parasites were reared from this insect—*Homoporus chalcidiphagus* and *Eupelmus epicaste*. The remedies recommended are burning or deeply plowing the stubble field or the removal and destruction by feeding or otherwise of the straw. Considerable damage is reported to have been caused by the pea moth (*Semasia nigricana*). As a remedy against this insect the author recommends deep plowing and early sowing and the cultivation of early varieties.

With regard to the clover-seed midge, the author found that feeding-off or mowing the crop before June 20 was a very satisfactory remedy.

The carrot-rust fly (*Psila rosæ*) is reported as doing considerable damage. The methods of prevention suggested by the author are late sowing and preventive remedies, such as kerosene emulsion diluted 1:10, to be sprayed along the drills by a knapsack sprayer.

The corn worm (*Heliothis armigera*) is said to be increasing in economic importance from year to year in Canada. The remedy which the author recommends most highly is hand picking and destruction of the caterpillars while at work in the ears of corn.

Report on the extermination of the gypsy moth (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 411–481, pls. 11*).—The committee on gypsy moth reports on the general progress of its work. In reviewing the work, attention is again called to the fact that its effectiveness in the past has been impaired by lack of available funds at the particular times needed. C. H. Fernald, the entomologist to the State board of agriculture, gives an account of the present status of the gypsy moth and reiterates his belief that the moth can be ultimately exterminated.

The main part of the report is prepared by the field director, E. H. Forbush, who gives a detailed account of the apparatus used for destroying the gypsy moth and of the actual methods of conducting the various operations against this insect. An account is given of the winter and spring work, of the spring inspection, and of the extensive spraying operations with arsenate of lead. It is reported that during the year nearly 2,000,000 trees were burlapped. A machine has been invented for cutting rolls of burlap for use in winding the trees. Another device has been invented for rolling the cut strips into compact form. The cyclone burners are still used for burning over the ground of badly infested areas. It was found that stone walls and stone heaps could be as effectively treated by simple spraying with kerosene oil as with the cyclone burner. The former method is cheaper, and, all things considered, the best method yet devised for destroying the eggs in stone walls.

A general summary is given of the year's work showing the number of trees inspected, banded with insect lime, burlapped, sprayed, cut, trimmed, and acres of ground treated in various ways. A careful examination of extralimital towns disclosed the presence of a rather formidable colony of gypsy moth in Manchester, a locality from which the insect had not previously been reported. Vigorous operations were begun against this colony with good results.

A detailed account is given of the status of the gypsy moth in a large number of towns where it has been previously known. In general, the condition of affairs is better than heretofore, and with the larger appropriation which the committee has received, hopes are expressed of getting the insect entirely under control.

In an appendix to the regular report, E. H. Forbush figures and describes some improvements in spraying machinery. A pump has been devised by means of which one man can maintain a pressure of from 80 to 100 lbs. to the square inch. The pump can be used in any tank or barrel. The hose which is now used is ½ in. in size, and a special coupling has been invented which does not reduce the size of the hose at the joint. Considerable work has been spent in devising a telescoping extension tube for use in spraying high trees. The nozzle which has given best satisfaction is called the Monitor. It has 4 openings, 1 in front and 3 on the side, of equal size.

A. F. Burgess reports that *Anthrenus verbasci* is an enemy of the eggs of the gypsy moth. The larvæ of this beetle were found eating the eggs and also fed upon the eggs of the gypsy moth under confinement.

A. H. Kirkland reports the results of some experiments to determine the value of glucose in arsenical insecticides. The glucose had been used in the field in spraying for the gypsy moth upon the supposition that the insecticide was made to adhere much longer by the addition of glucose. Experiments made to determine that point were unfavorable in that it was found that the insecticide adhered almost equally well without the glucose, and the glucose is too expensive for insecticide use.

The San José scale in Massachusetts, A. H. KIRKLAND (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 295–315, figs. 3*).—This paper contains a general account of the distribution of this scale, together with a description of the insect, a list of its food plants, and mention of its more common natural enemies. *Adalia bipunctata* and *Chilocorus bivulnerus* are recorded as enemies of this insect.

The well-known remedies, such as burning of badly infested trees and treatment with whale-oil soap, kerosene, and fumigation are described. The author experimented with whale-oil soap and water at the rate of 2 lbs. to 1 gal. upon young pear trees. A few scales survived the treatment.

Attention is called to the difficulties in the way of keeping the San José scale out of nurseries or of exterminating it when once a nursery has become infested. General directions are given for the guidance of nurserymen and purchasers.

Methods of improving the efficiency of spraying apparatus, E. S. GOFF (*Wisconsin Sta. Rpt. 1898, pp. 239–249, figs. 5*).—A device is described in which Bordeaux mixture as it is pumped out of the reservoir is taken from practically the whole depth simultaneously. Only so much stirring is necessary as to prevent the formation of a layer of sediment. In the ordinary pump and barrel arrangement there was substituted for the rubber suction tube a piece of gas pipe provided at its middle with a tee and reaching with a straight elbow at its lower end just to the bottom of the barrel. At this point a movable joint attaches another piece of gas pipe at right angles, to the farther end of which a float is attached. The latter pipe has an opening cut the whole length on one side. A third pipe reaches from the air chamber of the pump to the bottom of the barrel. When the pump is worked agitation enough is set up in the bottom of the barrel to prevent the formation of a layer of sediment.

The apparatus may also be used for spraying with kerosene and water. Opposite the suction pipe is erected a small iron rod, to which is attached a closed tin can of a gallon or more capacity in such a way that it is free to slide up and down the rod. Kerosene is poured into the can, which continues to float. The can is connected with the tee in the middle of the suction pipe by rubber tubing. The flow of kerosene is controlled by a stopcock and may be made sufficiently uniform for practical purposes.

Anticipated swarming, DEVAUCHELLE (*L'Apiculteur, 43 (1899), No. 10, pp. 440–445*).—An outline of methods for preventing natural swarming.

The determination of the sex of bees, B. SPOERER (*L'Apiculteur, 43 (1899), No. 10, pp. 437–440*).—This is a discussion of the Dzierzon-Dickel controversy.

Honey-bearing plants of agricultural importance, V. AGEENKO (*St. Petersburg, 1899, 2. ed., pp. 47; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, p. 184*).—Among the plants which are considered important as producers of honey are mentioned alfalfa, esparcet, white clover, phacelia, and melissa.

On the parasitic fly of silkworms in China, C. SASAKI (*Annot. Zool. Japonenses, 3 (1899), No. 1, pp. 25–27, figs. 3*).—The parasite is believed to be *Tachina rustica*.

The part played by insects, arachnids, and myriapods in the propagation of infective diseases of men and animals, G. H. F. NUTTALL (*British Med. Jour., 1899, Sept., pp. 642–644*).—This article discusses the part which insects may play in the spreading of various diseases, such as anthrax, plague, cholera, typhoid fever, etc. Insects may serve as intermediate hosts and under such circumstances they play a passive part in spreading disease when they are devoured by a host of the parasite which they contain. On the other hand, the cattle tick and the mosquito play an active part in transmitting infectious diseases of which they are the intermediate host.

Spider bites and "kissing bugs," L. O. HOWARD (*Pop. Sci. Mo., 55 (1899), No. 1, pp. 31–42, figs. 6*).—Probably only one species of spider in the United States can inflict a serious bite, *Latrodectus mactans*. Of the true bugs, the bites of a number of species are known to be more or less poisonous. Among them may be mentioned *Opsicoetes personatus, Melanolestes picipes, M. abdominalis, Conorhinus sanguisuga, Rasatus biguttatus*, and *R. thoracicus*. The press account of kissing bugs was much exaggerated, many supposed cases being the result of ordinary mosquito bites.

Lice on poultry and how to destroy them, F. V. THEOBALD (*Hoard's Dairyman, 30 (1899), No. 30, p. 596*).

Report of the entomologist, C. H. FERNALD (*Massachusetts Hatch Sta. Rpt. 1898, pp. 102–104*).—Brief notes are presented on the San José scale, grass thrips, small clover-leaf beetle (*Phytonomus nigrirostris*, and *P. punctatus*), and the carpet beetle. Arsenate of lead was tried in conjunction with the Bordeaux mixture with good results. The arsenate of lead was used in the proportion of 5 lbs. to 150 gal. of water. The apple scab was pretty effectively checked and various insects were destroyed.

Entomological notes for 1898, W. W. FROGGATT (*Agr. Gaz. New South Wales, 10 (1899), No. 9, pp. 873–879, pls. 2*).—*Phyllotocus macleayi* is reported as robbing beehives of their honey. *Galleruca semipulata* depredates on the leaves of *Ficus macrophylla*. A species of thrips is recorded as an enemy of the persimmon. *Agromyza phaseoli* tunnels in the stem of beans. *Cacœcia postvittana* is reported as attacking the rind of oranges. *Cryptophaga unipunctata* is a serious enemy of cherry trees, making tunnels in the trunks and branches.

Report on economic entomology for 1898, V. H. CARPENTER (*Reprinted from Rpt. Council Roy. Dublin Soc. 1898, pp. 14, figs. 13*).—This paper contains notes on the turnip beetle (*Phyllotreta nemorum*), cockchafer (*Melolontha vulgaris*), bean beetle (*Bruchus affinis*), cherry aphis (*Myzus cerasi*), *Bryobia prætiosa*, spruce aphis (*Chermes abietis*), pine aphis (*Lachnus piceæ*), and the pine sawfly (*Sirex gigas*).

An improved method of studying underground insects, J. B. SMITH (*Sci. Amer., 81 (1899), No. 7, p. 102*).—Moistened plaster of paris is poured into the burrows and allowed to set when it can be unearthed so as to show the exact form of the burrow.

The wings of insects (chapter IV concluded), J. H. COMSTOCK and J. G. NEEDHAM (*Amer. Nat., 33 (1899), No. 391, pp. 573–582, figs. 8*).—In this paper the authors discuss the tracheation of the wings of orthoptera and the homologies of the principal tracheæ in the wings of this order. The evidence as to the systematic position of the orthoptera which is to be obtained from a study of their wings, leads the authors to place the orthoptera second in the list of insect orders, with the Blattidæ as the lowest of the orthopterous families.

On the vitality of insects, E. ROY (*Nat. Canad., 6 (1899), No. 6, pp. 85–87*).—Gives observations on the effects of low temperatures in winter on insects.

Animal and plant gall formations, O. APPEL (*Schr. Phys. Oekon. Gesell. Königsberg, 39 (1898), pp. 82–139, pl. 1*).—This paper has for its purpose the systematic arrangement of our knowledge of the structure and origin of the various forms of plant galls. The author gives a classification of gall formations according to their external appearance and internal structure. The animals which are known to produce galls are classified and briefly discussed. The same method of treatment is given to various orders of plants which produce galls upon other plants. The plants which bear galls are listed with remarks upon comparative immunity of certain plants from galls. A brief discussion is given of the histology of galls. The author discusses in detail the development of the gall which is caused by the dipter *Hormomyia fagi* and also the various galls upon willows.

Contribution to the knowledge of galls produced by insects in Italy, A. TROTTER (*Riv. Patol. Veg., 7 (1898–99), Nos. 9–12, pp. 281–310, pls. 2*).—This article contains descriptions of gall formations caused by insects on species of Acer, Prunus, Pyrus, Quercus, and Salix.

Contribution to a knowledge of the insect galls of Juniperus communis, G. LAGERHEIM (*Ent. Tidskr., 20 (1899), No. 2–3, pp. 113–125, figs. 4*).

Diseases of cultivated plants in the Province of Groningen in 1898, J. RITZEMA-BOS (*Bijdragen Kennis Provincie Groningen, 1 (1899), No. 1, pp. 33–62*).—Notes on various parasitic fungi, injurious insects, limax, and nematode worms.

The beetles of Middle Europe, L. GANGLBAUER (*Die Käfer von Mitteleuropa. Vienna: C. Gerold's Son, 1899, pt. 2, pp. 409–1046, figs. 16*).—A monographic account of the beetles in this region belonging to the following families: Sphæritidæ, Ostomidæ, Byturidæ, Nitidulidæ, Cucujidæ, Erotylidæ, Phalacridæ, Thorictidæ, Lathridiidæ, Mycetophagidæ, Colydiidæ, Endomychidæ, and Coccinellidæ.

Wireworms (*Rpt. Agr. Expts. Cornwall County Council, 1898, pp. 45–48*).—Experiments were made on 2 farms, 13 plats being treated on each farm for the destruction of wireworms. The substances used were rape cake soaked in an arsenic solution, rape cake dusted with arsenic, rape cake alone, arsenic alone, mustard dross, mustard cake, and castor oil seed cake. None of these substances had any appreciable effect upon the wireworms. The remedies which seem to be practicable and at the same time effective are fall plowing and a rotation of crops. The wireworm winters over in a nearly adult stage within an earthen cell which was made for the protection of the pupæ. It was found that whenever these cells were broken the wireworms perished. Deep and thorough plowing is therefore recommended for holding these pests in check.

Preliminary report on insect enemies of clover and alfalfa, L. BRUNER and W. D. HUNTER (*Nebraska State Bd. Agr. Rpt. 1898, pp. 239–285, figs. 67*).—This is a biological account of the insects most injurious to clovers and related forage legumes, with biographical references for 175 species reported as depredating upon these plants.

Insects and other pests injurious to cotton in Egypt, G. P. FOADEN (*Jour. Khed. Agr. Soc. and School Agr., 1 (1899), No. 3, pp. 85–96*).—Gives economic and biological notes with suggestions for treatment against *Prodenia littoralis*, *Earias insulana*, *Aphis ulmariæ*, *Oxycarenus hyalipennis*, and a fungus disease caused by a member of the Uredineæ.

The coccid genera, Chionaspis and Hemichionaspis, R. A. COOLEY (*Massachusetts Hatch Sta. Spec. Bul., Aug. 10, 1899, pp. 57, pls. 9*).—This bulletin contains a monographic account of the genus Chionaspis in a restricted sense, and of Hemichionaspis as including a number of species previously referred to Chionaspis. Synoptic tables are given for the identification of species and brief biological notes in connection with the species which are of economic importance. Bibliographies are given in connection with each species.

The most common scales introduced upon American fruits, L. REH (*Illus. Ztschr. Ent., 4 (1899), No. 14, pp. 209–211, fig. 1*).—The San José scale is considered as the most dangerous enemy, and is figured and described.

Notes on the Mediterranean fruit fly and Queensland fruit fly, A. M. LEA (*Bul. Dept. Agr. Tasmania 1899, pp. 6, pl. 1*).—The author reports that the Mediterranean fruit fly, *Halterophora capitata*, has been introduced in fruit from Sidney into Tasmania. The first shipment of fruit which was seen to be infested with the Mediterranean fruit fly was destroyed by boiling, but, as a number of the larvæ of the fly had already escaped from the decaying fruit, the ground was thoroughly treated with kerosene oil. Two gardens became infested from fruit which was shipped in, and the ground underneath the trees was also thoroughly sprayed with kerosene so that it became moist to a depth of 2 in. No serious fear is entertained concerning the Queensland fruit fly (*Tephritis tryoni*), for the reason that it has so far not appeared to thrive except in tropical climates.

Peach borer, M. BURRELL (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 15–17*).—Gives observations on the habits of this moth and notes on remedies which were used against it.

Phylloxera of the grapevine, BLUNNO and FROGGATT (*Agr. Gaz. New South Wales, 10 (1899), pt. 5, pp. 377–379, pls. 4*).—Gives the life history of the different forms of this insect, with an account of the use of carbon bisulphid as an insecticide.

The chestnut weevils, G. H. POWELL (*Amer. Gard., 20 (1899), No. 235, p. 444*).—Gives a description and the life history of the weevil. The methods of control which are suggested are the following: Planting chestnut orchards some distance from native chestnut trees, jarring the weevils from young trees in the orchard, the use of trap trees, and the destruction of the burs from them.

Description of Agromyza phaseoli, a new species of leaf-mining fly, D. W. COQUILLETT (*Proc. Linn. Soc. New South Wales, 24 (1899), No. 93, pp. 128, 129*).—It is reported as having caused considerable damage to French beans.

A new tea pest from India, E. E. GREEN (*Ent. Mo. Mag., 2. ser., 10 (1899), No. 118, pp. 225, 226, figs. 6*).—A description of *Cerococcus ficoides* with brief notes on its habits.

The development of Ceroplastes roseatus, C. H. DOLBY-TYLER (*Trans. Ent. Soc. London, 1899, No. 3, pp 277–280, pl. 1*).—A detailed record of the changes of form, of the habits and rate of growth of this scale. It is parasitized by *Lecaniobius cockerelli* and is preyed upon by *Azya luteipes*.

Epicometis hirta, S. A. MOKRZHETZKY (*Odessa, 1899, pp. 24; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, pp. 180, 181*).—The author discusses in a critical manner the literature relating to this insect, and from personal observations describes the habits and appearances of the insect throughout its different stages of development. Appropriate remedies are recommended against its devastations.

The Hessian fly, E. P. FELT (*Country Gent., 64 (1899), No. 2428, pp. 668, 669*).—Gives biological notes on the insect, and advises rotation of crops as a remedy against its ravages.

Injuries caused by Hylastes trifolii, G. CECCONI (*Riv. Patol. Veg., 8 (1899), Nos. 1–6, pp. 160–165, pl. 1*).—Besides injuring trees by making galleries under the bark, this insect is reported as depredating to a considerable extent upon common clover.

Hyponomeuta malinella, G. BARBUT (*Prog. Agr. et Vit., 16 (1899), No. 37, pp. 305–309, fig. 1*).—The habits of the insect on apple trees are described. Its natural enemies are mentioned and an account is given of several remedies which are to be used against it.

The Lantana bug (Orthezia insignis), E. E. GREEN (*Roy. Bot. Gardens Ceylon Circ., 1. ser., 1899, No. 10, pp. 83–94*).—Popular notes on its injurious activity and a discussion of remedies.

Lymantria monacha, S. LAMPA (*Ent. Tidskr., 20 (1899), No. 2–3, pp. 81–88, pl. 1*).—An account of its habits, life history, natural enemies, and of remedies which were tested for exterminating it.

Mindarus abietinus on the white fir, O. NÜSSLIN (*Allg. Forst u. Jagd. Ztg., 75 (1899), pp. 210–214, figs. 5*).—Contains detailed notes on its life history with figures of its different stages and of its injury. The distribution of the insect is discussed.

The Oestridæ and their economic significance, A. BERGMAN (*Ent. Tidskr., 20 (1899), No. 2–3, pp. 133–155, pls. 2*).—A study of the injuries suffered by domesticated animals from the attack of these insects.

A pasture problem, H. FRIEND (*Gard. Chron., 3. ser., 25 (1899), No. 651, pp. 391, 392, figs. 5*).—An Oligochæt worm of the family Enchytræidæ, and known as *Fridericia agricola*, is reported as being found apparently injuring grass. The details of the external and internal anatomy of the worm are described and illustrated.

Phylacteophaga eucalypti, W. W. FROGGATT (*Proc. Linn. Soc. New South Wales, 24 (1899), No. 93, pp. 130–134, pl. 1*).—This insect is described as new, with an account of its depredations upon the foliage of *Eucalpytus globulus*.

Notes on the oak caterpillar (Phryganidia californica), P. SERRE (*Jour. Soc. Nat. Hort. France, 3. ser., 21 (1899), Aug., pp. 756–761, figs. 4*).—The life history of the insect is given. *Pimpla behrensi* is said to be parasitic on it. Paris green and London purple are recommended as remedies.

The purplish-red borer, L. ZEHNTNER (*Verslag Proefsta. Suikerriet, West Java, 1898, pp. 27–29*).—Brief notes on the appearance and habits of *Sesamia nonagrioides*.

Contribution to the study of the anatomy and biology of Trama radicis, G. DEL GUERCIO (*Nuova Relaz. R. Staz. Ent. Agr., 1. ser., 1899, No. 1, pp. 195–206, figs. 6*).—This article contains an account of the structure of the insect and is accompanied by figures illustrating the different stages. The biology of the insect is also considered from an economic standpoint, and the use of bisulphid of carbon and other remedies is recommended.

Life habits of Xyleborus cryptographus, H. EGGERS (*Illus. Ztschr. Ent., 4 (1889), No. 19, pp. 291, 292, fig. 1*).—A study of the galleries and of the life history of this insect.

The wood leopard moth (Zeuzera æsculi) (*Jour. Bd. Agr. [London], 6 (1899), No. 2, pp. 195–198, fig. 1*).—A brief description is given of the insect in its several stages as well as an outline of its life history. Few remedies are effective in controlling its depredations. While the burrows of the larvæ are still small, solutions of carbolic acid and similar substances have been forced into the openings without very good results. A number of species of birds are known to attack the insect in the larval condition, and a still greater number feed upon the adult insect.

Fungus disease of plant lice in the summer of 1896, G. LAGERHEIM (*Ent. Tidskr., 20 (1899), No. 2–3, pp. 127–132*).—*Empusa aphidis* and *E. fresenii* are reported to have greatly reduced the numbers of plant lice.

Remedies for sugar-beet insects, E. D. SANDERSON (*Michigan Sugar Beet, 1 (1899), No. 17, p. 1, figs. 4*).—Popular notes on remedies to be used against the more destructive insects which attack sugar beets.

The spraying of fruit trees (*Jour. Bd. Agr. [London], 6 (1899), No. 1, pp. 1-4*).—General recommendations and formulas for the common insecticides.

How to kill grasshoppers, L. BRUNER (*Breeders' Gaz., 36 (1899), No. 4, p. 92*).—Recommends the protection of native birds and reptiles and use of the hopperdozer.

Spraying for orchard pests, J. FLETCHER (*Ontario Fruit Growers' Assoc. Rpt. 1898, pp. 77-85*).—Economic and biological notes on the codling moth and the San José scale.

Remedies against Cochylis (*Prog. Agr. et Vit. (Éd. L'Est), 20 (1899), No. 24, pp. 709, 710*).—Recommends the use of an insecticide made as follows: Black soap 70 gm., rape oil 45 gm., and essence of lavender, 75 gm. The whole to be emulsified in 1 liter of water.

Instructions in spraying (*Ontario Dept. Agr. Spec. Bul., March, 1899, pp. 32, figs. 39*).—This bulletin contains formulas and directions for making the more common insecticides, with notes on their application, together with a list of the more common insect and fungus diseases of garden and fruit crops. The most common injurious insects found upon these crops are figured, briefly described, and remedies suggested in each case.

A table of the most frequently used compounds (insecticides and fungicides) in combating the insect and fungus diseases of fruit gardens, S. A. MOKRZHETZKY (*Simferopol, 1899, 2. ed., pp. 15; abs. in Selsk. Khoz. i Lyesov., 194 (1899), July, pp. 180, 181*).—This work gives in tabular form directions for preparing a number of insecticides and fungicides, among which may be mentioned barium chlorate, Bordeaux mixture, Raupenleim, copperas, lime and tobacco dust, kerosene emulsion, carbolic emulsion, creosote, and Paris green.

FOODS—ANIMAL PRODUCTION.

"Sticky" or "slimy" bread and its cause, H. L. RUSSELL (*Wisconsin Sta. Rpt. 1898, pp. 110-113*).—The author states that during the two preceding summers a number of complaints were received at the station that bread became slimy when kept for a short time. A sample received at the station when first baked showed no signs of an abnormal character; in fact, a part of the quantity baked "had been consumed before the change became apparent. In the course of 3 or 4 days after baking, the bread began to change in color slightly, assuming a light brown tint. It had a sweetish taste and a peculiar odor. When touched it appeared sticky, a condition that later became so marked that it would string out in long threads several feet in length."

A bacteriological examination showed that this trouble was due to the potato bacillus (*Bacillus mesentericus vulgatus*). The temperature of the interior and exterior of the loaf during the baking of Graham gems and wheat bread was determined, and it was found that it was not sufficiently high to destroy the bacilli.

> "After baking for an hour and a half, the temperature at no time had been sufficiently high to destroy this organism, if it had been in a spore stage. These experiments on the insufficiency of the baking temperature to destroy the germ in a latent condition, in connection with the experiment already mentioned where infected yeast was used, show conclusively that these bacteria would not be destroyed under ordinary treatment.
>
> "Undoubtedly if the yeast is impure, as it appears to have been in these cases, such troubles will be more or less common, especially if the weather should be such as to favor bacterial growth. . . .

"Until greater care is used by the yeast manufacturers in the preparation of their yeasts, such troubles are likely to occur during the hot summer weather. The only help that can be suggested is to hold the bread at a low temperature after it is baked, so that the spores that are present in the same will not germinate so rapidly. This combined with small bakings that are used up within 2 to 3 days will materially diminish the difficulty.

"Just how such foreign organisms find their way into the yeast has not yet been studied. The trouble need not cause any special alarm from a sanitary standpoint, for the organism causing the change is a saprophytic form that is widely spread. As soon as the fermentative change begins to be well marked it is apparent enough to the taste, so that bread affected with the same would be quickly rejected as food. Considerable losses, however, are reported, and from the economic standpoint the matter during this past year is by no means an insignificant one."

Digestion experiments, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Rpt. 1898, p. 43*).—During the past 3 years about 40 successful digestion experiments have been made at the station, in the majority of cases with concentrated feeding stuffs. The experiments have not been published in detail. Some of the coefficients of digestibility have been previously reported; others follow:

Coefficients of digestibility of different feeding stuffs.

Kind of feed stuff.	Number of trials.	Dry matter.	Protein.	Fat.	Extract.	Fiber.	Ash.

Cleveland flax meal vs. the old-process linseed meal for early lambs, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Rpt. 1898, pp. 24–27*).—The comparative value of Cleveland flax meal and old-process linseed meal was tested with 10 grade Southdown lambs divided into 2 lots of 5 each. The lambs were dropped by 6 ewes. The ewes and the lambs were fed separately.

The lambs in lot 1 were fed all they would eat of a grain mixture of flax meal, bran, and corn meal, 3:3:4. After about two weeks the ration was changed to flax meal, bran, and corn meal, 2:1:1. When the lambs had reached about 40 lbs. in weight, the ration was again changed, and a mixture of equal parts of the grains was fed. Lot 2 was fed the same rations, except that old-process linseed meal was substituted for flax meal. The lambs were kept in pens with the ewes and had the run of a large yard during the warmer part of sunny days.

The average duration of the test with lot 1 was 79 days, the average weight of the lambs 5 days after dropping, 10.95 lbs., and the average gain, 42.25 lbs. The average duration of the test with lot 2 was 76 days, the average weight of the lambs when dropped, 10.15 lbs., and the average gain, 39.85 lbs.

At the close of the test the lambs were slaughtered. The following conclusion was drawn:

"The flax meal had no injurious effect either upon the growth or dressed appearance of the lambs, and both sets of lambs produced the same average daily growth, and were both in the same average condition when slaughtered. In addition to inherited constitution and plenty of milk, it is very essential, in order to secure rapidity of growth, that early lambs should be housed in a warm, dry barn, and have a maximum amount of sunlight from a southern exposure."

Farm grains for fattening lambs before and after weaning, W. L. Carlyle (*Wisconsin Sta. Rpt. 1898, pp. 17–23*).—A test was made to compare different farm grains for lambs before and after weaning. Four lots were used in the trial, each made up of 4 grade Shropshire ewes and 6 lambs. For 2 weeks before the beginning of the test proper, the ewes and lambs were fed a mixture of cracked peas, bran, oats, and corn meal to accustom them to grain, since it has been found that there is some difficulty in getting young lambs to consume corn meal or bran alone. The food consumed and gains made during this period are recorded.

The test proper began May 27 and covered 2 periods, i. e., 5 weeks before and 5 weeks after weaning. Lot 1 was fed cracked peas, lot 2 bran, lot 3 whole oats, and lot 4 corn meal. Before weaning, the lambs were given all they would eat up clean. After weaning, the ration was limited to ½ lb. of grain per day for each lamb. While the lambs were with the ewes, they were turned out every day on a blue grass pasture, and were kept in yards at night. Two pens were provided for each lot, the one for feeding the lambs being separated from the other by a "creep," which allowed the lambs to pass back and forth at will, but did not admit the ewes to the feeding pens of the lambs.

The financial statement is based on oats at 20 cts., corn 30 cts., and peas 45 cts. per bushel, and bran at $13 per ton.

The principal results of the trial are shown in the following table:

Results of feeding farm grain to lambs before and after weaning.

	Before weaning.			After weaning.			Whole test.		
	Total gain.	Average daily gain.	Grain eaten per pound of gain.	Total gain.	Average gain.	Grain eaten per pound of gain.	Total gain.	Grain eaten per pound of gain.	Cost per pound of gain.
	Lbs.	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Lbs.*	*Cent.*
Lot 1 (peas)	102.5	2.67	0.71	205.0	1.72	1.69	308	1.10	0.82
Lot 2 (bran)	96.0	2.57	.53	195.5	1.21	2.30	265	1.10	.72
Lot 3 (oats)	109.5	3.01	.52	211.0	1.87	2.20	307	1.05	.65
Lot 4 (corn meal)	120.0	3.10	.55	208.5	1.80	1.60	343	.96	.51

"As far as cost is concerned, corn gave the best results, with oats ranking next and bran in the third place, while peas were the most expensive feed. It would seem that cracked peas are very expensive feed when fed to young lambs, as they evidently consume more of them than they can properly assimilate or give returns for. . . . It is our purpose to repeat the experiments along this line until sufficient data have been gathered to establish some facts about the comparative value of different farm grains for lamb feeding."

Corn meal vs. hominy meal, and corn meal vs. cerealine feed for growing pigs, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Rpt. 1898, pp. 27–42*).—Corn meal and hominy meal were compared with 2 lots of grade Chester White pigs from the same litter. Lot 1 was made up of 4 pigs, and lot 2 of 3 pigs. Before the test all of the pigs were fed skim milk alone.

The test began November 23, 1896, and covered 98 days. At the beginning the pigs in lot 1 were fed from 7 to 10 qts. of skim milk per head daily and from 3 to 6 ozs. of corn meal per quart of milk, the amount depending on the appetite and stage of growth of the pigs. As the test progressed the quantity of grain was increased. The pigs in lot 2 were fed the same ration, except that hominy meal was substituted for corn meal.

During the test the pigs in lot 1 consumed on an average 1,925.49 lbs. of skim milk and 255.44 lbs. of corn meal. The average weight of the pigs at the beginning of the test was 55.5 lbs., and the average gain per pig 125.75 lbs., the pigs requiring 3.2 lbs. of dry matter per pound of gain (live weight).

The pigs in lot 2 consumed on an average 1,926.39 lbs. of skim milk and 255.19 lbs. of hominy meal. The average weight of the pigs at the beginning of the test was 57.75 lbs., and the average gain per pig 136.66 lbs.; 3.06 lbs. of dry matter were required per pound of gain (live weight).

The pigs were slaughtered at the close of the test. The average loss in weight in dressing lot 1 was 18.28 lbs. and lot 2, 21.67 lbs. In the authors' opinion the very slight difference between the gains made by the 2 lots is within the limits of error.

Corn meal vs. cerealine feed (pp. 32–36.)—Two tests of the comparative value of corn meal and cerealine feed are reported. The first, which began April 12, 1897, and covered 106 days, was made with 6 grade Chester White pigs divided into 2 lots of 3 each. The pigs were about 7 weeks old at the beginning of the test.

Lot 1 was fed from 6 to 9 qt. of skim milk per head daily and 3 oz. of corn meal per quart of milk. As the test progressed the amount of meal was gradually increased until about 4 lbs. was fed per head daily. Lot 2 was fed the same ration except that cerealine feed was substituted for corn meal. At the close of the test the pigs were slaughtered. During the test each lot consumed on an average 1,608.84 lbs. of skim milk and 243.63 lbs. of corn meal.

The average weight of the pigs in lot 1 at the beginning of the test was 47.67 lbs. and the average gain 137.75 lbs., 2.6 lbs. of dry matter being required per pound of gain (live weight). The average weight of the pigs in lot 2 at the beginning of the test was 44.75 lbs. and the average gain 132.58 lbs., the average amount of dry matter required per pound of gain being 2.77 lbs. (live weight).

In the authors' opinion the figures show a slight difference in favor of the corn meal as compared with cerealine feed, rather less dry matter of the former being required to make a pound of gain than of the latter.

The second test, which began October 25, 1898, and covered 78 days, was made with 2 lots of 3 each of Poland-China Chester White pigs. They were about 9 weeks old at the beginning of the test. The experimental conditions were similar to those in the previous test. During the test the pigs in each lot consumed on an average 1,020.24 lbs. of skim milk. In addition to this the pigs in lot 1 were fed on an average 220.5 lbs. of corn meal, and those in lot 2 225.2 lbs. of cerealine feed.

At the beginning of the test the pigs in lot 1 weighed on an average 67.67 lbs. and gained on an average 104.83 lbs., requiring 2.81 lbs. of dry matter per pound of gain (live weight). The pigs in lot 2 weighed on an average 66.58 lbs. at the beginning of the test and gained on an average 97.75 lbs., requiring 3.05 lbs. of dry matter per pound of gain (live weight).

On the basis of these 2 tests the authors believe that corn meal is from 5 to 10 per cent more valuable than cerealine feed for feeding in connection with skim milk to young and growing pigs.

The composition of the feeding stuffs used in the above tests is given.

The cost of pork production (pp. 36–42).—The cost of production of pork is discussed at some length, the object being to ascertain "the price that skim milk has returned per quart; the cost of feed required to produce a pound of live or dressed weight, taking the various grains at a reasonable range of market prices, and allowing either ¼ or ½ ct. per quart for the milk."

The discussion is based on a large number of tests made at the station with 140 pigs, weighing on an average 37 lbs. at the beginning of the tests and 183 lbs. at the close. The pigs were fed from 5 to 7 qt. of skim milk per head daily and 3 oz. of corn meal or other feeding stuff rich in carbohydrates. Some of the pigs were fed about the same quantity of skim milk together with from 3 to 6 oz. of corn meal per quart of milk, and in addition enough of a mixture of equal amounts of corn meal, wheat bran, and gluten meal to satisfy their appetites. "We rarely had more than from 5 to 7 qt. of milk daily for each pig. The animals did well with this amount of milk. If they did not secure this quantity, their growth was noticeably slower."

The average price obtained for skim milk, with other feeding stuffs and dressed pork at different prices, is shown in the following table:

Average price obtained for skim milk per quart and per 100 lbs. when fed to pigs.

Average price per ton of other feeding stuffs.	Returns per quart of skim milk with pork at—			Returns per 100 lbs. of skim milk with pork at—		
	Five cents.	Six cents.	Seven cents.	Five cents.	Six cents.	Seven cents.
	Cent.	*Cent.*	*Cent.*	*Cents.*	*Cents.*	*Cents.*
Corn meal and other starchy feeds, $15; "other grains," $17.50	0.50	0.67	0.83	23.07	30.73	38.19
Corn meal and other starchy feeds, $17.50; "other grains," $20	.45	.61	.78	20.66	28.14	35.86
Corn meal and other starchy feeds, $20; "other grains," $22.50	.39	.56	.78	18.08	25.82	35.70

The average cost of feed per pound of growth is shown in the following table:

Average cost of feed per pound of growth produced.

	Live weight.	Dressed weight.
	Cents.	*Cents.*
With corn meal at $15, "other grains" at $17.50, milk at ¼ ct. per quart	2.78	3.47
With corn meal at $15, "other grains" at $17.50, milk at ⅓ ct. per quart	4.00	4.99
With corn meal at $17.50, "other grains" at $20, milk at ¼ ct. per quart	3.04	3.79
With corn meal at $17.50, "other grains" at $20, milk at ⅓ ct. per quart	4.25	5.31
With corn meal at $20, "other grains" at $22.50, milk at ¼ ct. per quart	3.63	4.53
With corn meal at $20, "other grains" at $22.50, milk at ⅓ ct. per quart	4.51	5.63

Rape vs. clover for growing pigs, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1898, pp. 21–29*).—A test which is a continuation of previous work (E. S. R., 10, p. 773) was made with 2 lots of pigs to compare rape and clover. Each lot was made up of 6 pure-bred Poland Chinas and 14 grade Poland Chinas. There were 8 sows and 12 barrows in each lot. The pigs were from 5 to 6 months old at the beginning of the test and nearly uniform in size and weight. The test began September 6, 1897, and covered 9 weeks. It was divided into 4 periods of 2 weeks each and 1 of 1 week. One pig was dropped from each lot in the third period on account of sickness.

Lot 1 was hurdled on rape, being allowed the run of a very small area at first to guard against trampling down and wasting the rape. After a time the area was increased. The pigs were fed twice a day a liberal quantity of corn meal and shorts, 2:1, mixed with water to a thick slop. They also had access to a small blue-grass plat with some trees which afforded shade. Lot 2 was allowed the run of a 10 acre field of clover. It had been cut early in July, and one-half of the field was again cut about the middle of August. Owing to dry weather, the clover was much withered. There was an abundance of shade in the field. The pigs were fed the same grain ration as lot 1. Both lots received plenty of fresh water and were given the same care and management. During the test lot 1 ate the rape from about two-thirds of an acre.

At the beginning of the test lot 1 weighed 2,111 lbs. and lot 2, 2,091 lbs. Lot 1 gained 1,043 lbs., consuming 4,083.75 lbs. of grain in addition to the rape. Lot 2 made a total gain of 941 lbs., consuming the same amount of grain in addition to the clover.

"This experiment would seem to indicate that pigs averaging about 6 months old when pastured on rape will make a more rapid gain than a similar lot pastured on clover, the feed and management in other respects being the same. . . .

"The pigs on the rape were remarkably thrifty all through the experiment. They evidently relished the rape during the whole period and it apparently had a beneficial effect in regulating the bowels. . . .

"Farmers not having a suitable clover pasture for their brood sows and young pigs will do well to sow a small piece of rape at successive periods during the spring months. These may be pastured off in turn. When a plat is eaten off and the hogs removed, the rape immediately starts to grow again from the root and will usually be ready to feed off again in from 6 to 8 weeks under favorable conditions of soil and season. In the manner given the pigs (and sheep as well) may be supplied a succulent feed throughout the growing season."

Whole corn compared with corn meal for fattening swine, W. A. HENRY (*Wisconsin Sta. Rpt. 1898, pp. 8-16*).—In continuation of previous work (E. S. R., 10, pp. 776, 777) 2 tests are reported comparing whole corn and corn meal for pigs. The first test, which began December 8, 1897, and covered 12 weeks, was made with 2 lots of 8 grade Berkshire and Poland China pigs. They were about 8 months old at the beginning of the test.

Previous to the trial the pigs had been pastured on rape or red clover and were given some grain in addition. The test proper was preceded by a preliminary period of 7 days' duration. Lot 1 was fed corn meal and wheat middlings 2:1, mixed together with warm water to a thick slop. Lot 2 was fed shelled corn and wheat middlings 2:1. The corn was fed first. After it was eaten, the middlings were given mixed with warm water to a thick slop. The pigs were supplied freely with salt, water, and soft-coal ashes.

Lot 1 weighed 1,496 lbs. at the beginning of the test and lot 2, 1,474. The gains made by the 2 lots were 992 and 830 lbs., respectively. Lot 1 consumed 3,132 lbs. of corn meal and 1,566 lbs. of wheat middlings. Lot 2 consumed 2,758 lbs. of shelled corn and 1,379 lbs. of wheat middlings.

The second trial was regarded as a duplicate of the first in all particulars. The lot fed corn meal weighed 1,474 lbs. at the beginning of the trial and gained 1,030 lbs., consuming 3,078 lbs. of corn meal and 1,539 lbs. of wheat middlings. The pigs fed shelled corn weighed 1,471 lbs. at the beginning of the trial and gained 799 lbs., consuming 2,609 lbs. of shelled corn and 1,304½ lbs. of wheat middlings.

From these tests and previous work of the station some general deductions are drawn. The trials, extending over 3 years, show that—

"The pigs fed whole shelled corn made an average daily gain of 1.34 lbs., while the lots which were fed corn meal made an average daily gain of 1.63 lbs. This is a difference of 0.29 lb. daily, or about 2 lbs. per week greater increase through feeding corn meal.

"Coming to the last item in the table we learn that 459 lbs. of the corn-meal ration produced 100 lbs. of gain, live weight, with these pigs, while 498 lbs. of the ration containing shelled corn were required for the same gain. Thus by grinding corn to meal 39 lbs. of grain were saved on 498 lbs. This shows that about 8 per cent of the grain may be saved by grinding when feeding old corn in combination with middlings to fattening swine.

"A study of the total quantity of feed required by the different lots of pigs in these trials as summarized in the tables shows that the pigs getting corn meal uniformly consumed a larger quantity of feed daily than those fed whole corn. Through the larger consumption of feed the pigs were enabled to make a more rapid daily gain than those getting whole grain. . . .

"It is shown by these trials that corn meal effected a saving of 8 per cent over whole corn and the pigs receiving the corn meal gained about 2 lbs. per week more than the others.

"Practical feeders who examine these figures will probably be surprised at the comparatively small saving in the amount of corn through grinding. The higher value placed on corn meal in comparison with whole corn by feeders generally is perhaps largely due to the more rapid gains made by pigs receiving meal instead of whole grain."

Poultry experiments, W. P. BROOKS (*Massachusetts Hatch Sta. Rpt. 1898, pp. 85–101*).—In continuation of previous work (E. S. R., 10, p. 675) experiments are reported on the effect on egg production of (1) condition powder, (2) animal meal *vs.* cut fresh bones, (3) wide *vs.* narrow rations, and (4) the presence of the cock with the flock. Each test was made with 2 lots of 20 well-bred barred Plymouth Rocks hatched in April. Each lot occupied a separate house with roosting room and scratching shed and were permitted the run of large yards in favorable weather. All the fowls were marked with leg bands. All the lots were fed grain, the meals and clover being fed in the form of a mash. During the early winter it was mixed at night with boiling water and fed at a temperature of about 70°. Later in the season the mash was mixed with boiling water in the morning and fed hot. The whole grain fed was scattered in the straw with which the sheds were littered. The chickens were at all times supplied with water, crushed oyster shells, and grit, and about twice a week were given cabbage.

The composition of the feeding stuffs is reported. The financial statement of the test is based on the following prices per 100 lbs.: Wheat, $1.75; oats, $1; wheat bran, 60 cts.; wheat middlings, 75 cts.; gluten feed, $2; animal meal, $2; cut clover rowen, $1.50; cabbage, 25 cts.; cut bone, $2; gluten meal, 80 cts.; corn meal, 85 cts.; and corn, 85 cts.

The effect of condition powder upon egg production (pp. 88–90).—A test of the influence on egg production of condition powder was begun December 12 and closed April 30. Both lots of pullets were fed wheat, oats, bran, middlings, gluten feed, animal meal, clover, and cabbage. In addition lot 1 was fed condition powder, about 8 lbs. of which was consumed, which would cost at retail $4. The results of the test are summarized in the table following.

Results of feeding poultry with and without condition powder.

	Food consumed.		Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
	Lbs.	*Ozs.*	*Cent.*		*Ounces.*	*Cents.*
Lot 1	647	11	0.32	745	1.95	1.15
Lot 2 (condition powder)	666	15	.32	719	1.96	*a* 1.30

a Including the condition powder.

The quality of the eggs was tested by 2 families. One family reported no difference; the other found the eggs from the hens receiving no condition powder much preferable to those from the other lot. The author notes that in this test and those previously reported the difference in egg production of the lots fed condition powder and those not receiving it has been small.

> "In favor of the condition powder we have 1 experiment, against it we have 2 experiments. It is not, however, . . . claimed that the powder is injurious, but simply that it is not beneficial. This the 4 experiments, carried out with the utmost fairness and with every care, certainly prove. In the light of these results it is believed that poultry keepers throw away money expended for condition powder."

Animal meal vs. cut bone for egg production (pp. 90–93).—The test to compare animal meal and cut bone for egg production was begun December 12 and closed April 30. Both lots were fed wheat, oats, bran, wheat middlings, clover rowen, and cabbage. In addition lot 1 was fed gluten feed and animal meal and lot 2 gluten meal and cut bone. The health of the fowls fed animal meal was, in general, good; 1 fowl became ill and was killed. Bowel troubles were not uncommon in the lot fed cut bone; 2 fowls in this lot died and 1 was killed owing to a disjointed leg. Only 0.27 oz. of bone was fed per hen daily. The author found it impossible to feed a larger amount without serious bowel trouble. The principal results of the test are shown in the following table:

Animal meal vs. cut bone for egg production.

	Food consumed.		Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg
	Lbs.	*Ozs.*	*Cent.*		*Ozs.*	*Cents.*
Lot 1 (cut bone)	621	8	0.35	728	1.95	1.14
Lot 2 (animal meal)	640	11	.33	812	1.98	1.04

A test of the quality of the eggs raw and boiled was made. The eggs from the fowls fed animal meal were inferior in color and flavor to the others. From this test and those previously reported the following conclusions are drawn:

> "We have now carried through 5 experiments, comparing these 2 feeds. Two have given results slightly favorable to the bone in number of eggs; one a similar result in favor of the animal meal; and 2, the two last, which have been the most perfectly carried out, have been most decisively favorable to the animal meal. The latter has also been found the safer food. The greatly preponderating weight of the evidence afforded by these experiments, which have been most carefully conducted, is therefore in favor of the animal meal."

Narrow vs. wide rations for egg production (pp. 93–98).—Two trials are reported. In both the nutritive ratio for lot 1 was narrow and that for lot 2 wide. The first trial (in the winter) began December 12 and closed April 30; the second (in the summer) began May 1 and closed October 4. In both trials the 2 lots were fed wheat, oats, bran, animal meal, and green food (cabbage and cut clover in winter and lawn grass in summer). In addition in the first test lot 1 was given middlings and gluten feed and lot 2 corn meal and corn, the nutritive ratio for the 2 lots being 1:4.7 and 1:5.6, respectively. In the second trial lot 1 was given middlings in addition to the foods mentioned above and lot 2 corn meal and corn. Both lots received some gluten feed also. The principal results of the 2 tests are summarized in the following table:

Influence of narrow vs. wide rations on egg production.

	Food consumed.		Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
Test 1 (winter):	*Lbs.*	*Ozs.*	*Cent.*		*Ozs.*	*Cent.*
Lot 1 (narrow ration)	638	5	0.33	860	1.98	0.99
Lot 2 (wide ration)	566	5	.26	1,071	1.95	.61
Test 2 (summer):						
Lot 1 (narrow ration)	545	0	.32	859	1.98	.88
Lot 2 (wide ration)	594	8	.26	1,095	1.90	.61

In both trials the health of the fowls remained good, with the exception that in the second test one of the hens in lot 1 was sick for a few days. At the close of the test the condition of the plumage of the fowls was judged by an expert. They were then slaughtered. The principal conclusions follow:

"The hens on the wide (rich in corn) ration laid a great many more eggs in both the winter and in the summer experiments than those on the narrower ration.

"The difference in favor of the wide ration amounts to 25 per cent in the winter trial and to 33⅓ per cent in the summer trial, upon the basis of equal number of hen days.

"The total cost of feeds was less for the wide ration and of course the cost per egg was much less. In the production of 100 doz. eggs the saving on the basis of our winter test would amount to $4.56; on the basis of the summer test to $3.24.

"In average weight of the eggs produced there is a small difference in favor of the narrow ration, but in quality the weight of family evidence shows the egg produced by the corn-fed hens to have been somewhat superior. They were deeper yellow and of a milder flavor than the eggs from the narrower ration.

"The fowls on the wide ration gained somewhat in weight and were heavier at the close of the experiment than the others, notwithstanding the much larger number of eggs laid. . .

"The average weights before and after dressing were as follows: Narrow-ration fowls 5.07 lbs., dressed weight 4.37 lbs.; wide-ration fowls 5.44 lbs., dressed weight 4.81 lbs. The narrow-ration fowls gave 86 per cent dressed weight; the others, 88 per cent. The dressed fowls were judged by a market expert who pronounced the corn-fed fowls slightly superior to the others.

"The results are thus greatly in favor of the ration richer in corn meal and corn; and so important will a knowledge of this fact prove (if confirmed by further trials), because of the cheapness of these foods as compared with wheat, that the experiment is being repeated this year with 3 different breeds of fowls, using corn more largely than last year."

The influence of the cock on egg production (pp. 98–101).—Two tests of the influence of the cock on egg production were reported. These tests were made with the fowls used in the test mentioned above on the effect of condition powder and cut bone on egg production. In each test 2 lots of 16 fowls each were used. In both cases a White Leghorn cock was placed with lot 1. Experimental conditions were the same in both tests. The fowls were fed wheat, oats, bran, gluten feed, and animal meal. The principal conclusions are shown in the following table:

Influence of the cock on egg production.

	Food consumed.		Cost of food per day per fowl.	Number of eggs produced.	Weight per egg.	Cost of food per egg.
	Lbs.	*Ozs.*	*Cent*		*Ozs.*	*Cent.*
Test 1:						
Lot 1 (with cock)	404	0	0.29	631	1.96	0.88
Lot 2	400	0	.31	630	1.95	.87
Test 2:						
Lot 1 (with cock)	385	12	.30	629	1.98	.83
Lot 2	364	4	.30	526	1.97	.93

In both tests the health of the poultry remained good. The author's conclusion was that the cock was without apparent influence upon egg production.

> "In one respect only is there agreement in the results of the 2 trials; the average weight of the eggs from the hens with which a male was kept was slightly the greater in both trials. It seems not impossible that this effect may be due to the fact that the eggs had been fertilized. The difference, however, is exceedingly small and would be wholly without significance to the producer of eggs for market or for table use."

Banana flour (*Dietet. and Hyg. Gaz., 15 (1899), No. 11, pp. 648, 649*).—A brief note on the subject.

Vichka seed as a famine food, A. H. CHURCH (*Agr. Ledger, 1899, No. 1 (Veg. Prod. ser., No. 46), pp. 3*).—The composition of Vichka seed (*Cyanotis axillaris*) is reported and its food value discussed.

Ragi tailings as a prison food in the Madras Presidency, A. H. CHURCH (*Agr. Ledger, 1899, No. 4 (Veg. Prod. ser., No. 49), pp 5*).—The composition of ragi tailings (the outer seed coat of millet, *Eleusine coracana*) is reported and its food value discussed.

Report on prison dietaries, J. C. DUNLOP (*Glasgow: James Hedderwick & Sons, 1899, pp. 134*).—The report is an exhaustive study of prison dietaries in Scotland, with suggestious for reform. An appendix contains notes on the Scottish poorhouse dietaries and prison dietaries in other countries.

The equipment of camps and expeditions, C. H. SNOW (*Pp. 31, table 1; reprinted from Trans. Amer. Inst. Mining Engineers, 1899*).—A paper read before the American Institute of Mining Engineers at a meeting held in New York in February, 1899. Among other things the author discusses the food requirements of persons engaged in various expeditions in regions where there is little or no local food supply. Different condensed and prepared foods are described and a number of rations made up of such foods are suggested.

The danger of formaldehyde adulteration (*British Food Jour., 1 (1899), No. 10, p. 297*).—Remarks on the action of weak solutions on gelatinous and albuminous substances in retarding digestion, etc.

A new respiration calorimeter and experiments on the conservation of energy in the human body, W. O. ATWATER and E. B. ROSA (*Phys. Rev., 9 (1899), Nos. 3, pp. 129–163, figs. 12; 4, pp. 214–251, figs. 2*).—This apparatus has been described in another publication (E. S. R., 9, p. 863; 11, p. 372).

The food value of sugar (*Beet Sugar Gaz., 1 (1899), No. 7, pp. 15, 16*).—The article is based on a paper read by F. Strohmer at the recent annual meeting of the Central Association of the Beet Sugar Industry of Austro-Hungary.

Nutritive value of maize, R. LOPEZ Y PARRA (*Bol. Soc. Agr. Mexicana, 23 (1899), No. 36, pp. 710–713*).—A general article, pointing out the value of maize for Mexico.

The food value of olive-oil cake, M. DYBOWSKI (*Bul. Soc. Nat. Agr., France, 59 (1899), No. 7, pp. 510–518*).—The composition of olive-oil cake is reported, as well as tests of its feeding value for domestic animals. It was found to be a satisfactory food for pigs when combined with maize. Satisfactory results were not obtained with other animals.

Comparative feeding value of hay and alfalfa, MÜNTZ and GIRARD (*Jour. Agricole [Paris], 10 (1899), No. 111, pp. 112–116*).—A discussion embracing the chemistry, composition, and digestibility of alfalfa and hay, based upon experiments previously reported (E. S. R., 10, p. 379).

Experiments with salt-marsh hay, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Rpt. 1898, p. 42*).—Brief reference is made to the experiments with salt-marsh hay reported in a previous publication (E. S. R., 10, p. 472).

Poplar leaves for feeding animals, C. SARCE (*Belg. Hort. et Agr., 11 (1899), No. 18, pp. 274, 275*).—The successful feeding of poplar leaves in time of drought is noted.

The making of silage, STUTZER (*Fühling's Landw. Ztg., 48 (1899), No. 20, pp. 745–749*).—A general discussion.

The reputed value of alcohol as a protector of protein, R. ROSEMANN (*Arch. Physiol. [Pfluger], 77 (1899), No. 7–8, pp. 405–424*).—A controversial article.

Investigations on the use of beets in feeding animals, L. BRETIGNIERE and DU PONT (*Ann. Agron., 25 (1899), No. 6, pp. 257–281, fig. 1*).—The yield and composition of tankard, collet rose "rich," and collet rose "intermediate" beets is reported, as well as feeding experiments with sheep in which these beets constituted a considerable part of the ration.

The freezing of feeding stuffs (*Landw. Wchnbl. Schleswig-Holstein, 49 (1899), No. 43, pp. 791–793*).—This article, taken from the *Landwirtschaftliche Zeitung für Westfalen und Lippe,* discusses the chemical changes produced in potatoes, beets, and other feeding stuffs by freezing, quoting the work of a number of investigators.

The formation of sugar from protein, R. COHN (*Ztschr. Biol., 28 (1899), No. 1–2, pp. 211–218*).—Experiments with rabbits are reported which, in the author's opinion, show the formation of glycogen from leucin.

New investigations on the heat of formation and combustion of various nitrogenous and other compounds, M. BERTHELOT and G. ANDRÉ (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 16. pp. 959–971*).—The bodies used include cholesterin, xanthin, nicotin, indol, etc.

Two new reactions for distinguishing between peptic and pancreatic digestion, V. HARLAY (*Jour. Pharm. et Chim., 6. ser., 9 (1899), pp. 468–470*).

The relation of the composition of the ash of young guinea pigs to the ash of the milk they have consumed, E. ABDERHALDEN (*Ztschr. Physiol. Chem., 27 (1899), No. 4–5, pp. 356–367*).

The relation between rapidity of growth and composition of milk consumed in nursing dogs, pigs, sheep, goats, and guinea pigs, E. ABDERHALDEN (*Ztschr. Physiol. Chem., 27 (1899), No. 4–5, pp. 408–462*).—This is a continuation of a previous investigation.[1]

The cattle of Kumaon, G. K. WALKER (*Agr. Ledger, 1899, No. 7 (Veg. Prod. ser., No. 28), pp. 7*).—The appearence, characteristics, and the suitability of these native

---

[1] Ztschr. Physiol. Chem., 26, No. 5, p. 487.

Indian cattle for dairy purposes and as draft animals are discussed as well as their feeding, care, breeding, etc. They are said to resemble in appearence the Kerry-Dexter cattle of Great Britain and Ireland.

Measuring cattle, P. CAGNY (*Prog. Agr. et Vit., 16 (1899), No. 36, pp. 286–291, figs. 5*).—A method of measuring the external conformation of cattle.

Fattening sheep for freezing (*Agr. Gaz. New South Wales, 10 (1899), No. 9, p. 901*).—A note on the successful and profitable fattening of sheep on such crops as pumpkins, prairie grass, alfalfa, and rape in New Zealand. The mutton is kept for shipment in cold storage.

Horse feeding (*An. Soc. Rural Argentina, 34 (1899), No. 5, pp. 142, 143*).—The subject is discussed with reference to local conditions.

Annual reports of the poultry associations of the Province of Ontario, 1898, (*Ontario Dept. Agr., 1899, pp. 68, fig. 1*).—In addition to the usual statistics this bulletin contains a number of articles on poultry and poultry raising by different contributors.

Poultry raising from an English standpoint, F. HOOD (*Fühling's Landw. Ztg., 48 (1899), No. 20, pp. 749–753*).—A popular article.

Egg production, L. C. VERRY (*Jour. British Dairy Farmers' Assoc., 14 (1899), pt. 1, pp. 21–29*).—A general discussion with special reference to English conditions. Many statistics are quoted.

Poultry feeding, A. DE VILLÈLE (*Rev. Agr. Réunion, 5 (1899), No. 8, pp. 353–357*).—A general article quoting recent work and discussing local conditions.

Foods for poultry (*Jour. Jamaica Agr. Soc., 3 (1899), No. 10, pp. 574–577*).—Discusses the subject with reference to local conditions.

The influence of freezing on the development of the embryo in hen's eggs, E. RABLAUD (*Compt. Rend. Acad. Sci. Paris, 128 (1899), No. 19, pp. 1183–1185*).—Low temperature produced marked changes in the embryo. When the eggs hatched, monstrosities were numerous.

DAIRY FARMING—DAIRYING.

Experiments to ascertain the effect of different amounts of protein upon the cost and quality of milk, J. B. LINDSEY ET AL. (*Massachusetts Hatch Sta. Rpt. 1898, pp. 42, 43*).—A brief preliminary report on 2 experiments with 12 cows, made to study the effect of rations containing 1.5, 2, and 2.5 lbs. of digestible protein. The total amount of digestible nutrients was the same in each of the 3 rations. The first experiment lasted 9 weeks and the second 4 weeks.

"About 5 per cent more milk was produced on 2 lbs. and 10 per cent more on 2.5 lbs. of protein daily, than when the animals received 1.5 lbs. each. The quality of the milk was scarcely changed. . . .

"It is believed that a continuous feeding of 2 or 2.5 lbs. of protein daily tends, to some extent, to develop the milk-producing capacity of the cow. . . .

"The writer is of the opinion that animals weighing from 800 to 1,000 lbs., producing from 10 to 15 qts. of milk per day, should receive about 2.5 lbs. of digestible protein and 15 to 16 lbs. of total nutrients daily. This is in accordance with Wolff's rations. When protein is costly, it might be advisable to reduce the amount to 2 lbs. daily."

On the composition of the milk yielded morning and evening by cows at Glasneven government agricultural institutions, C. A. CAMERON (*British Food Jour., 1 (1899), No. 6, pp. 168, 169*).—The data were secured in connection with an experiment on the economy of flaxseed *vs.* linseed cake for milch cows, not yet completed. The yield and composition of the milk of each of 8 cows is given for 6 days during April. The mean composition of the milk of the 8 cows for the 6 days was as follows: Morning—total solids, 12.1; solids-not-fat, 9.2; fat, 2.9 per cent; evening—total solids, 13.88; solids-not-fat, 9; fat, 4.88 per cent.

> "In the 48 specimens of morning's milk the nonfatty solids never were so low as 8.5 per cent, the minimal standard, while in 18 of the specimens the fats were below the minimal standard of 2.75 per cent.
>
> "In the 48 specimens of evening's milk the solids-not-fat never sank below the minimal standard, but in 18 instances they were less than 9 per cent.
>
> "It will be seen, then, so far as these 96 specimens of milk are concerned, the standard of 8.5 per cent of nonfatty solids holds good; but that the standard for fats fails in the case of the morning's milk. The morning's milk was rich in nonfatty solids and poor in fats, while the evening's milk was rather poor in nonfatty solids and very rich in fats. In some instances the percentage of fat was more than twice as large in the evening's milk as in the morning's.
>
> "There was only 8 hours' interval between the times of milking; if the interval were longer, the difference between the morning's and evening's milk might not be so great."

The animals were fed for 2 weeks on rations which "seem to have been insufficient." The cows lost in weight, and in some cases there was a slight shrinkage in yield of milk, but the composition remained practically unchanged, indicating that "it is the flesh of the animals that first declines when the aliment is insufficient."

The acidity of milk, A. L. TOURCHOT (*Abs. in British Food Jour., 1 (1899), No. 7, p. 199*).—The author advocates the determination of acidity in addition to the chemical composition. In order to ascertain the average acidity of fresh milk he examined a large number of samples of known origin. The acidity was found to be fairly constant in milk under 12 hours old, from 1.4 to 1.6 cc. of decinormal soda solution being required to neutralize 10 cc. of milk.

> "The normal quantity being placed at 0.126 to 0.144 per cent lactic acid, a weaker acidity indicates watering, or a milk consisting partly of cream. A greater acidity than the foregoing figures may be caused by the milks being too old or unclean, or having been derived from freshly-calved cows. With regard to milk from the latter source, the observations tend to show that it possesses a higher acidity than ordinary milk (sometimes reaching 1.8 cc. deci-normal soda, for 10 cc. milk), and that this high acidity continues for 2 weeks after calving, such milk still retaining its peculiar odor. . . . If its acidity when sold exceeds a certain degree—say 1.7 cc. deci-normal soda to 10 cc. milk in summer, when the cows are on pasture, and 1.6 when being stall-fed—it should be rejected as unfit for food. . . . If, on the other hand, the acidity falls below 1.2 in winter and 1.4 in summer, it is an indication of a fraudulent addition of water, or of the presence of an unhealthy cow in the herd, which, of course, renders the milk unfit for food. These figures are the mean results of observations for Canada."

Properties of galactase, a digestive ferment of milk, S. M. BABCOCK, H. L. RUSSELL, and A. VIVIAN (*Wisconsin Sta. Rpt. 1898, pp. 77–86*).—Previous experiments (E. S. R., 10, p. 785) to determine the properties of a digestive ferment in milk, for which the name galactase is proposed, have been repeated on a more extended scale, and a preliminary report of the work, including methods and results, is given. Galactase is considered as allied in some respects to trypsin, and possesses in common with other enzyms the property of attaching itself to finely divided particles in suspension. Accordingly it occurs in larger proportions in cream and in separator slime than in milk. Concentrated extracts of galactase were prepared from separator slime. It rapidly decomposes hydrogen peroxid. As shown by digestion experiments in milk, the proteolytic action was greater at a temperature of 37 to 42° C. than above or below this range. Heating for 10 minutes at 71° C. reduced its action, and heating for 10 minutes at 76° C. destroyed the ferment.

Enzym solutions $\frac{1}{10}$ and $\frac{1}{25}$ normal alkaline, neutral, and $\frac{1}{10}$ normal acid were used in digestion experiments in gelatin. The neutral or slightly alkaline reaction was most favorable to liquefaction, the decinormal solutions of acid and alkali retarding it. Tested by Fermi's method, none of these solutions after being heated at 65 to 80° C. for from 10 to 60 minutes showed any liquefying action on gelatin. As determined by Storch's test (E. S. R., 10, p. 384), hydrogen peroxid was decomposed in the neutral and alkaline gelatin when the temperature of heating did not exceed 75° C. for 60 minutes or 80° C. for 10 minutes.

Galactase is destroyed by mercuric chlorid, formalin, phenol and its derivatives, and carbon bisulphid. Chloroform was found the most satisfactory antiseptic in milk which would still permit the action of the enzym. Decomposition products formed by galactase are similar to those formed in tryptic digestion.

Distribution of galactase in cow's milk, S. M. BABCOCK, H. L. RUSSELL, and A. VIVIAN (*Wisconsin Sta. Rpt. 1898, pp. 87-92*).—The quantity of galactase in the milk of 5 cows as measured by the amount of soluble proteids formed was determined at different periods of lactation. The results are tabulated, and show but "little difference during the advancing period of lactation, the milks taken at different periods varying in no regular manner." The amount of soluble proteids, however, was slightly increased during the beginning of the colostrum period as compared with the normal milk of the same animal. This difference increased with the age of the sample, indicating a more rapid digestion of proteids in colostrum milk. Milk from 7 cows at the same stage of lactation treated with 5 per cent chloroform and kept at an approximately uniform temperature was analyzed at different times for 6 months. The results are tabulated and shown in a diagram. In the fresh milk the nitrogen in soluble form ranged from 0.04 to 0.05 per cent, or 8 to 10 per cent of the total nitrogen present. "The progressive formation of soluble nitrogenous compounds as the milks increase in age is strikingly apparent."

Distribution of galactase in different species of Mammalia, S. M. BABCOCK, H. L. RUSSELL, and A. VIVIAN (*Wisconsin Sta. Rpt.*

1898, pp. 93–97).—A study similar to the above was made with human milk and milk from the cow, sheep, goat, sow, mare, burro, and grade buffalo. Analyses of the milks when fresh and at different intervals are tabulated. Diagrams show the percentage of soluble nitrogenous products in the various milks and the percentage of total nitrogen in soluble form for 6 months. "The results show that the presence of a proteolytic ferment is not confined to cow's milk, but is found in the milk of all species of animals which we have examined." No relation was discovered as existing between the action of galactase and the maternal function.

The antiseptic value of certain chemicals in milk, S. M. BABCOCK, H. L. RUSSELL, and A. VIVIAN (*Wisconsin Sta. Rpt. 1898, pp. 98–103*).—In connection with investigations on the enzyms in milk, a study was made of the antiseptic value of a number of chemicals which have been considered as acting upon organized ferments without materially affecting the unorganized ferments or enzyms. The following chemicals were used in 2 series of experiments with milk of 0.08 and 0.11 per cent acidity: Benzol, chloroform, ether, toluol, xylol, anilin, arsenious acid, oil of origanum, thymol, sodium fluorid, phenol, sodium chlorid, oil of cloves, oil of cassia, oil of Ceylon cinnamon, turpentine, and oil of mustard. The results are tabulated, from which "it is evident that there is a marked discrepancy between the ability of these substances to prevent bacterial changes in milk and their reputed efficiency as antiseptics." This is explained on the theory that they form insoluble compounds with the butter fat, thus lessening their antiseptic properties. The efficiency of 2 antiseptics was similarly diminished in experiments in which olive oil was added to bacterial cultures.

"Of the number of different chemicals tested, only 4, viz., chloroform, ether, benzol and toluol, are to be recommended in studying these inherent enzyms.

"With these 4 antiseptics, distinction should be made between the curdling and the proteolytic action. Ether retards the curdling of milk, while scarcely any difference exists in the time of curdling with the other 3 antiseptics. This effect alone suggested to us the possibility of a curdling enzym in milk that was different from the digesting ferment.

"All of these substances undoubtedly exert some repressing action on the proteolytic changes. Small increments in the amount of antiseptics employed, indicates, almost without exception, that a retardation in the rate of digestion took place. This is especially marked in the case of chloroform where a variation from 5 to 12 per cent diminished the amount of soluble products 17 per cent. Chloroform and ether seem to affect the digestive changes least of all. Chloroform is undoubtedly the best agent for work upon this enzym, as 2 to 3 per cent keeps milk perfectly. Also, on account of its high specific gravity, and its affinity for fat, the cream is thereby submerged, thus rendering possible more accurate sampling."

Effect of varying strengths of rennet extract in curdling milk, J. W. DECKER (*Wisconsin Sta. Rpt. 1898, pp. 31–34*).—Solutions were made of Hansen's rennet extract by diluting 5, 10, 15, 20, and 25 cc. of the strong commercial extract to 50 cc. A rennet test was made with each of these solutions in which 5 cc. was used to coagulate 160 cc. of the same milk at 86° F. The Monrad rennet test was used. The time required for coagulation with the solution of 5 cc. in 50 was 90 seconds. Assuming the time required for coagulation to vary inversely as the strength of the solution, the time required with the other solutions should have been 45, 30, 22, and 18 seconds, respectively. The actual time required, however, was 51, 41, 32, and 28 seconds, respectively. The power of the rennet extract was, therefore, not proportional to the degree of the dilution. Similar results were obtained in 4 series of experiments in curdling larger quantities of milk in a cheese vat.

"Viewing the results obtained practically, we must conclude that the usual method of comparing the money values of 2 brands of rennet extract, in which these values are considered as proportioned to the times required in an ordinary rennet test, is not correct. The relative amounts of the extracts required to coagulate the same quantity of the same milk, at 86° F., should determine their relative money values."

The action of rennet in watered milk, J. W. DECKER (*Wisconsin Sta. Rpt. 1898, pp. 35, 36*).—Two experiments are reported. These were conducted with the Monrad rennet test (in which 5 cc. of the commercial rennet extract is diluted to 50 cc. and 5 cc. of this dilute solution used to coagulate 160 cc. of milk at 86° F.). In the first experiment 96 seconds were required to coagulate undiluted milk, and 345 seconds to coagulate the same milk diluted one-half with water. In the second experiment with milk diluted one-half, one-third, one-fourth, and one-fifth, the time required for coagulation was 21 seconds for the undiluted milk, and for the diluted 35, 26, 23, and 22 seconds, respectively. "The time of coagulation is shown by these experiments to be increased by the addition of water to milk, but the amount of such adulteration in a factory would probably not be enough to make a noticeable difference."

Relative absorption of odors in warm and cold milk, H. L. RUSSELL (*Wisconsin Sta. Rpt. 1898, pp. 104–109*).—The following method was employed in several series of experiments to determine the relative absorption of different odors by warm and cold milk.

"A large box with a tight-fitting cover was taken and in the bottom of the same were placed 2 jars, one filled with warm water and the other with ice or cold water. On the surface of each receptacle was then placed a basin filled with milk. The relatively large body of warm and cold water maintained the respective milk samples at temperatures above and below that of the surrounding air. In the bottom of the box was then placed samples of various substances that were to be tested as to their odor-yielding properties. In passing judgment on the relative absorption of odors, the samples of milk that had been exposed were placed in glass bottles and then brought to the same temperature, care being taken to thoroughly mix the samples so that no physical difference could be detected that would enable the scorers to recognize the respective samples as they tested them from day to day."

Trials were made with corn silage, horse manure, urine of cows, and the oils of cinnamon, wintergreen, and peppermint. The results on the whole are considered as showing that, contrary to general belief, warm milk absorbs odors more rapidly than cold. The relative absorption of the different odors is discussed. Peppermint was absorbed the most readily.

On the use of boric acid and formic aldehyde as milk preservatives, S. Rideal and A. G. R. Foulerton (*Public Health, 11 (1899), No. 8, pp. 554–568*).—From experiments made by Thomson and by the authors the latter fix the minimum quantity of these preservatives sufficient to preserve milk for 24 hours at not less than 1 part in 50,000 of formaldehyde, and not less than 35 grains per gallon (0.05 per cent) of a mixture of boric acid and borax. They report experiments on the effect of boric acid and formaldehyde on artificial digestion, using different amounts of the preservatives, from which they conclude that—

> "Neither boric acid mixture in the proportion of 1 in 2,000, nor formaldehyde 1 in 50,000, has any appreciable effect on the proteolytic action of the peptic and pancreatic enzyms. The amylolytic action of saliva is distinctly retarded by the boric acid mixture, but to a much less extent by formaldehyde. It must, however, be borne in mind that salivary digestion does not exist in infants, and has possibly only a minor importance in the metabolic economy of adults.
>
> "Taka diastase is interesting as being a mold ferment, and because of the marked influence which the boric acid mixture has on retarding its amylolysis.
>
> "The preservatives have no marked effect on the digestibility of the food after contact for 20 to 24 hours prior to the action of the enzym."

The effect of formalin of different strengths on 3 kittens, a rabbit, and 2 guinea pigs was studied for periods covering nearly a month and a half. The authors conclude from these experiments that "formaldehyde in quantities necessary for the preservation of milk has no marked effect upon proteid metabolism, as evidenced by the variation in weight of the animals experimented on, or by waste of ingested nitrogen."

The authors mention that fish were not noticeably affected by being kept in water containing 1 part of formaldehyde in 50,000 for 6 days, changing the water daily, and that frogs suffered no apparent inconvenience from being kept for 2 hours in a solution of 1 part in 20,000.

> "We therefore are of the opinion that, so far as our present knowledge is concerned—
>
> "(1) Boric acid in the proportion of 1 in 2,000 and formaldehyde in the proportion of 1 in 50,000 are effective preservatives for milk for a period of 24 hours;
>
> "(2) That these quantities have no appreciable effect upon digestion;
>
> "(3) That these quantities have no appreciable effect upon the digestibility of foods preserved by them; and
>
> "(4) That formaldehyde in the above proportion, so far as our investigations have extended, does not appear to have any injurious action upon animal tissues or on nutrition."

The use of boric acid and formaldehyde as food preservatives, O. Hehner (*British Food Jour., 1 (1899), No. 5, p. 132*).—This is a criticism of conclusions 2, 3, and 4 in the above article. It is claimed that the author's own figures show, in nearly every case, an inhibiting influence on digestion of both the boric acid and the formaldehyde in the proportions recommended, although usually small. The experiments with animals are criticized on the ground that there were no control animals with which the gains of the subjects could be compared, and from the results as stated the critic is inclined to infer that the preservatives added to the diet had a depressing and injurious influence upon assimilation.

The effect of pressure in the preservation of milk, B. H. Hite (*West Virginia Sta. Bul. 58, pp. 15-35, figs. 6*).—This is a preliminary report on investigations to determine the effect of pressure in the preservation of milk, and contains the details and results of a large number of experiments.

The general method employed was as follows: A sample of milk was inclosed in a collapsible tin tube, placed in a hollow steel cylinder, the remaining space in the cylinder being filled with water, and subjected to hydraulic pressure applied to a piston fitted to the cylinder. The different pieces of apparatus employed in the progress of the work are described and in some cases figured. A 100-ton hydraulic press was used. Considerable difficulty was experienced in obtaining cylinders that would withstand the higher pressures.

Several hundred samples of milk in all were subjected for various length of time to pressures ranging from a few hundred pounds to 100 tons. In every experiment a duplicate sample received the same treatment, except pressure, and the results in the 2 cases are compared.

In the experiments carried on at room temperature, pressures lower than 10 tons to the square inch did not materially delay the souring of milk as compared with check samples. Milk subjected to pressures of 10 to 15 tons for 2 weeks was sweet at the end of the test. Pressures of 30 tons for 1 hour delayed the souring of milk 24 hours, and pressures of 70 to 95 tons for from 5 minutes to 1 hour delayed souring 2 to 7 days. "The best results from a practical standpoint were doubtless those obtained with pressures of 10 to 15 tons for as many days."

In a number of experiments the samples of milk enclosed in the cylinders were kept at temperatures of 140 to 170° F. for 5 minutes to 4 hours by means of a water bath. Pressures of 5 to 20 tons in these tests gave much better results than corresponding pressures at lower temperatures. In one test several tubes were filled with milk that had been allowed to remain in a loosely covered can all day. These samples were subjected to pressures of 7 to 12 tons at temperatures of 152 to 160° F. for 1 to 3 hours. After being kept at the room temperature for 10 days a number of the samples were opened and found to be sweet. Six of the remaining samples were shipped to New York City and back, after which 2 were opened, and these and the other samples opened later were sweet.

"The results obtained by the use of pressure alone would seem to indicate that in the usual method of heating milk to temperatures above the boiling point of water the slight pressure developed at these temperatures would of itself fall far short of sterilizing the milk. It would also appear that by using much higher pressures (10 tons) sterilization may be effected at much lower temperatures."

In none of the experiments were the bacteria in the milk found to be completely destroyed by pressure. While the souring of the milk was prevented in many cases, other changes were sometimes indicated by a "musty" odor or a change in color. Germs of anthrax, typhoid fever, tuberculosis, and bubonic plague and *Proteus vulgaris*, which had been added to the milk, were not killed by pressures of 10 to 15 tons for 8 days. The pathogenic germs were found more resistant to pressure than those concerned in the souring of milk.

Provision is being made at the station for continuing the experiments with larger quantities of milk.

On butter and some changes in the same, J. HANUŠ (*Listy Chemické, 23 (1899), pp. 27, 67; abs. in Chem. Ztg., 63 (1899), No. 68, Repert., p. 257*).—The author examined 25 samples of butter sold in Prague and made in the mountains, Hohenelbe, etc. The following range was observed: Acid number—unmelted butter 2.56 to 20.82, melted butter 2.57 to 20.18; Reichert-Meissl number, 24.03 to 31.57 (average, 26.69); saponification number, 223 to 235.3 (average, 227.4); Hehner number, 85.26 to 92.34 (average 87.9); iodin number, 29.6 to 43.36 (average 36.05); water, 11.02 to 29.71 per cent; ash, 0.09 to 0.18 (including salt 1.82) per cent; fat, 64.66 to 85.34 per cent; milk sugar and casein, 1.94 to 6.39 per cent; specific gravity at 100° C., 0.867 to 0.868. The ash content is regarded as very low.

The author studied the possibility of estimating the rancidity from the amount of free volatile acids, but with negative results. In the process of becoming rancid the glycerids of the higher insoluble fatty acids seemed to be decomposed much more rapidly than the glycerids of the acids of lower molecular weight.

Under the influence of air and light the saponification equivalent and the acid number of butter fat increased, the iodin number decreased, and the Reichert-Meissl number was not materially changed. From the data obtained the author concludes that lactone is formed from the unsaturated fatty acids by the action of air. Butter subjected to the action of light and air gradually lost its yellowish color, becoming lardy in appearance, smelled very rancid, and had a sharp, tallowy taste.

The properties of some butter kept in a moist room for 4 months, until it became covered with mildew, are described. The action of the mildew caused a different change from that of light and air. In this case only the glycerids of the saturated acids were decomposed, those especially of lower molecular weight being apparently fully oxidized, while the unsaturated acids were practically unchanged. A small amount of aldehyde was formed, probably through oxidation of oleic acid.

Investigation on the effect of salt (NaCl) on rennet action, J. W. DECKER (*Wisconsin Sta. Rpt. 1898, pp. 37–41*).—Several investigations were carried on during the year to determine the influence of common salt on rennet action. Milk was diluted with different proportions of brine containing 15 per cent of salt. The rennet test of the undiluted milk was 30 seconds and of the same milk diluted with 9, 10, 11, 12.5, 14, and 16.7 per cent of brine was 135, 155, 200, 210, 230, and 310 seconds, respectively. The rennet test of milk diluted with 25 per cent of water was 21 seconds, and of milk diluted with 25 per cent of brine containing 1 per cent of salt was 34 seconds. This retarding effect of salt upon the action of rennet was also shown by adding salt directly to the milk. The addition of 5 per cent of salt to the milk stopped coagulation entirely and smaller quantities hindered it greatly.

"If only the usual amount of rennet is used and salt is added to the milk, we will get the effect of adding too little rennet, namely, a slow-curing and very likely a corky cheese. It is therefore our opinion that salt should not be added to milk that is to be made into Cheddar cheese, and for brick cheese it will be preferable to add the salt to the curd and not to the milk."

Rennet test solutions made up with water and with 5 per cent of brine required in one trial 20 and 31 seconds, respectively, to coagulate 160 cc. of milk, and in another trial 22 and 28 seconds. Chemical analyses of 4 commercial rennet extracts showed a salt content ranging from 16.04 to 17.21 per cent. In studying the effect of salt used in extracts as a preservative, an extract was prepared free from salt, which gave a rennet test of 35 seconds. The addition of salt to this extract reduced its coagulable power, 40 seconds being required when 5 per cent of salt was added, and 52 seconds when 20 per cent was added. Boric acid and formalin in the milk also retarded the action of the rennet. Rennet tests were made using a salt-free extract and milk diluted one third, one-half, and three-fourths with water. As with commercial extracts the power of the rennet was increased with the dilution, and it is therefore concluded that "the phenomenon of an increased proportional curdling power of dilute rennet extracts is independent of the salt that may be in the extracts."

Method of handling sour milk in making cheese, J. W. DECKER (*Wisconsin Sta. Rpt. 1898, pp. 42–44*).—Milk containing 0.25 to 0.32 per cent of lactic acid was used in 4 comparisons of firming curds in water and by stirring on racks. The data are tabulated and show that 2 per cent of fat and from 0.108 to 0.144 per cent of lactic acid were washed out in the water used in firming.

"Several batches of cheese made on the same days by the 2 methods of handling, were kept together for 2 months in the curing room The cheese in which the acid was washed out by water developed ragged gas holes, and a flavor similar to cheese which is made up in summer without developing acid before pressing, and afterwards kept in a warm curing room. The cheese in which the whey was expelled by stirring was close in texture and of a very good flavor."

A study of dairy salt, F. W. WOLL (*Wisconsin Sta. Bul. 74, pp. 45, pls. 5, fig. 1*).—The author presents in tabular form chemical and mechanical analyses of 81 samples of dairy salt, with a discussion of the data; gives the results of a number of experiments in salting butter; outlines the methods of manufacture, and discusses the comparative value of the Ashton, Diamond Crystal, Genesee, Vacuum Pan, and Worcester brands of dairy salt; and discusses, among other topics, the production of dairy salt, ideal butter salt, the use of salt in butter making, composition of salted and unsalted butter, salt as a butter preservative and as a flavor producer, and the use of salt in cheese making.

The samples analyzed included 55 domestic and 25 foreign dairy salts, representing in all 37 brands. In the author's discussion of results, it is stated that—

> "The leading brands of [American] dairy salt in general contain 98 to over 99 per cent of pure sodium chlorid, 0.5 to 1.5 per cent calcium sulphate, 0.1 to 0.5 per cent calcium chlorid, a trace of 0.2 per cent magnesium chlorid, none to 0.3 per cent moisture, and none to below 0.1 per cent of insoluble impurities. . . . If we compare the analyses of domestic and foreign dairy salts, we are at once struck by the great variations in the composition of the latter salts, and also by the fact that the leading brands of our American dairy salts are equally pure, and in some cases purer than any brands which rank highest in foreign dairy countries."

Of the American salts, 41 showed a content of pure sodium chlorid above 98 per cent, while of the foreign salts only 13 came above that limit.

The mechanical examination consisted of determinations of the size of grain, apparent specific gravity, and relative rate of solubility of the different samples. The water absorbing power of salt was shown by experiment to increase with the content of calcium and magnesium chlorids. Photo-micrographs of salt crystals of 24 leading brands are shown in plates.

In discussing the effect of the various brands of salt on butter, opinions from 13 butter judges, commission men, and creamery and cheese-factory companies, are quoted, from which it would appear that "no special brand stands first in all respects, but that there is in general a fair choice between several of our leading dairy salts."

A summary of a large number of analyses of salted and unsalted butter is given to show that the addition of salt lessens the water content of butter. In this connection analyses made by the author of 28 samples of foreign and 7 of American butter exhibited at the National Buttermakers' Convention, held in Sioux Falls, S. Dak., January, 1899, are given. The foreign butters were from 12 countries and showed a salt content ranging from 0.79 per cent (the average of 2 samples from France) to 2.86 per cent (the average of 7 samples from Ireland).

A summary of 12 comparisons of fine-grained and coarse-grained salt in butter making showed 1.8 per cent greater loss in weight of butter during working when fine-grained salt was used, with no marked difference in flavor of butter. The average composition of the 12 samples of butter in each series is given, and also of 8 samples worked on a Mason table worker and 12 worked in a Victor combined churn and worker.

How can New England compete with the West in dairying? J. L. HILLS (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 156–181*).—In an address before a public meeting of the Massachusetts State board of agriculture the author pointed out the advantages possessed by eastern and western dairymen and offered suggestions for the meeting of western competition.

Forage and soil crops for dairy cows, T. SHAW (*Creamery Gaz., 24 (1899), No. 11, p. 6*).—A discussion of rye, mixed grains, and cowpeas for pasture, and oats and peas, alfalfa, soy bean, sorghum, and corn as soiling crops for dairy cows. It is believed that sugar-beet pulp can be fed more advantageously to cattle and sheep that are being fattened than to dairy cows.

Tests of dairy cows, J. W. DECKER (*Wisconsin Sta. Rpt. 1898, p. 30*).—The results of official tests of 10 cows made by the station for the Holstein-Fresian Association are tabulated.

Milk secretion of cows under the influence of rations rich in fat, F. FALKE (*Halle, 1898; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 2 (1899) No. 2, p. 234*).—The author fed 2 cows with a mixture of meadow hay and fat-free rape cake, and in different periods added emulsions of sesame, cocoanut and almond oils in the form of drink. The fat contents of the milk increased in every case when the emulsified oils were given, but the yield of milk decreased.

(For effect of this feeding on the butter see E. S. R., 10, p. 685.)

Does a transmission of copper from food to milk take place? F. WIRTHLE (*Chem. Ztg., 23 (1899), No. 77, p. 803*).—Several samples of milk were examined which were of quite blue color and were believed by the senders to be colored by copper sulphate, as the cows producing them had been partially fed on clover which had been sprayed with that material. A slight trace of copper was found in one case and none whatever in the others. The food is not believed to have had any influence on the milk.

Influence of pasture land on the quantity and quality of milk, C. B. DAVIES (*Jour. British Dairy Farmers' Assoc., 14 (1899), pt. 3, pp. 217–223*).—A summary of answers received from dairymen to a list of questions bearing on this subject.

Analyses of milk in Holland, A. LAM (*British Food Jour., 1 (1899), No. 10, pp. 299–300*).—This is the report for 1898 of the official analyst at Rotterdam, giving the results of about 150 analyses arranged by months. For the year the total solids ranged from 11.20 to 13.64 and averaged 12.25 per cent; the fat ranged from 2.94 to 4.53 and averaged 3.62 per cent; and the milk sugar from 8 to 9.38, and averaged 8.63 per cent. The acidity (Soxhlet-Henkel) 20 hours after milking ranged from 3.2 to 4, averaging 3.65. The results are compared with the averages for 4 years past.

Milk and cream, J. B. LINDSEY (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 346–368*).—A popular discussion of the formation and composition of milk, changes in milk due to bacteria, pasteurization, separation of cream, and methods of handling and marketing milk and cream.

Milk and milk preparations, A. HEUBNER (*Ztschr. Diätet. u. Phys. Ther., 3 (1899), No. 1, pp. 3–17*).

Goats for the supply of milk to cottagers, H. S. HOLMES-PEGLER (*Jour. British Dairy Farmers' Assoc., 14 (1899), No. 1, pp. 16–30*).—Gives the yields of milk by a number of goats, and remarks on composition and breeds.

A new process for the improvement of inferior butter (*British Food Jour., 1 (1899), No. 2, pp. 31, 32*).—A description of the Haines process, as employed by the Irish Aerated Butter Company.

Butter salt, TIEMANN (*Chem. Ztg., 23 (1899), No. 87, p. 942*).—In connection with a butter exhibition in Dresden, it was found that butter from Posen frequently had a bitter taste, which investigation showed to be due to an excessive amount of magnesia in the salt used. A subsequent examination of the dairy salt on the market showed that it was quite possible to procure salt suitable for use in butter making.

Formaldehyde as a milk preservative, A. G. YOUNG (*Sanitarian, 43 (1899), Dec., p. 524*).—In a paper read before the recent meeting of the American Public Health

Association the author concluded, as the result of an examination of all available literature on the subject, that formaldehyde used as a preservative tended at least to impair the nutritive value of milk; that the tendency was also to interfere with the digestive processes; and that it would be unwise and unsafe to encourage or to suffer the use of formaldehyde in the public milk supply even under any possible restrictive regulations.

The cause and prevention of infant mortality, E. WENDE (*Sanitarian, 43 (1899), Dec., pp. 522–524*).—In a paper read before the recent meeting of the American Public Health Association the author paid particular attention to the subject of milk supply. He believed that the whole system of milk supply from the dairy to the consumer should be under both State and municipal control. He advocated a rigid inspection of herds, sanitary conditions, food, etc., and other regulations which would insure proper and cleanly handling of milk.

Tuberculosis and the milk supply, G. M. WHITAKER (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 339–345*).—A popular discussion.

Camembert cheese, G. E. LLOYD-BAKER (*Jour. British Dairy Farmers' Assoc., 14 (1899), No. 3, pp. 224–227*).—An account of visits to several farms in Normandy where this cheese is made.

VETERINARY SCIENCE AND PRACTICE.

Ticks and Texas fever, H. A. MORGAN (*Louisiana Stas. Bul. 56, 2. ser., pp. 127–141, pls. 9*).—This bulletin discusses from an anatomical and biological standpoint the cattle tick (*Boophilus bovis*), the lone star tick (*Amblyomma unipunctata*), the wood tick (*Dermacentor americanus*), and another species known as *Ixodes ricinus*.

The female of the lone star tick was observed to deposit from 3,230 to 6,519 eggs. Eggs were deposited during a period of nearly 2 months. A fully engorged female captured June 1 began laying eggs June 5. The eggs began hatching July 4 and the seed ticks were placed upon the animal July 16. On July 20 the ticks were much distended but began to disappear, just previous to the second molt. The author believes that the lone star ticks do not molt the second time upon cattle.

The wood tick was observed to deposit as many as 7,378 eggs. The author believes that this species is parasitic upon other animals during its first and second stages and is parasitic upon cattle only during its third stage. A number of experiments with the lone star tick and wood tick, in which they were placed upon susceptible cattle, demonstrated that they do not transmit the germs of Texas fever. So far as can be judged from actual experiments the cattle tick is the only species responsible for the transmission of the disease. The author recommends not only the usual cattle dips for the destruction of ticks upon cattle, but a rotation of crops and pasture lands in such a manner as to starve the ticks.

The Borna horse disease, F. A. ZÜRN (*Fühling's Landw. Ztg., 48 (1899), No. 11, pp. 417–421*).—This disease receives its name from the name of the town in which a large number of cases occurred. It has been shown to be caused by a coccus germ. The symptoms of the disease are yawning, sleepiness, hanging of the head, and a lack of appetite. At first there is no fever. The skin is sensitive, but the general consciousness is dull, and there is manifested an unnatural lax carriage of the body.

The disease is compared with cerebro-spinal meningitis. It differs, however, from this latter disease in that the membranes surrounding the brain and spinal cord are not strictly inflamed as in meningitis. In the Borna horse disease the veins of the membranes surrounding the central nerve system are congested. During the latter stages of the disease there is an elevation in temperature, a more frequent pulse, and an acceleration of the rate of breathing. There are also manifested various nervous irregularities, chills, involuntary twitching of various muscles about the head and other parts of the body. The muscles of the larynx are frequently paralyzed so that swallowing is impossible. The disease lasts from 10 to 18 days. The paralysis gradually extends over the whole body and death results. A recovery seldom occurs. From 70 to 80 per cent of the horses attacked with this disease in Borna died.

As preventive measures, the author recommends the immediate isolation of horses which begin to manifest the symptoms of the disease, and a thorough disinfection of the stalls.

Materials for the study of hemorrhagic septicæmia (swine plague), K. Z. KLEPTSOV (*Uchen. Zapiski Kazan Vet. Inst., 16 (1899), No. 4, pp. 247–334*).—In different parts of Russia there are yearly outbreaks of infectious swine diseases in the form of an enzooty or an epizooty. In 1896 the ravages from these diseases were especially large. The greater part of the author's observations were made in the Moscow stock yards and slaughterhouses. The author devotes 25 pages of the paper to a discussion of the literature of the subject, and a bibliography is given in this connection. His experimental investigations are reported under the following headings: (1) Pneumonic forms, including catarrhal or broncho pneumonia, croupous pneumonia, and caseous pneumonia; (2) pleuritis; (3) caseous replacement processes in the lymphatic glands; (4) pseudotuberculous forms; and (5) intestinal forms. In acute cases the temperature varied from 40.8 to 41.2°, pulse from 110 to 150, respiration from 60 to 90. Numerous cultures of the pathogenic organism were made and control experiments were carried out by inoculation of rabbits and guinea pigs. In a concluding section of the article the author gives a detailed account of his studies on the morphology and biology of the Schütz-Löffler bacillus.

Researches on spirillum disease of geese, J. CANTACUZÈNE (*Ann. Inst. Pasteur, 13 (1899), No. 7, pp. 529–557, pls. 2*).—The two diseases which are known to be caused by the rapid multiplication in the blood of micro-organisms belonging to the genus spirillum are intermittent fever of man and a form of septicæmia of geese. The present paper is an account of experiments undertaken to determine the question of the manner and means of disappearance of the spirillum at the crisis of the disease. The two views which are commonly held concerning the disappearance are that the spirillum is destroyed by a bacteriacide substance in the blood and that the spirillum is surrounded by the phagocyte cells. The technical methods which the author adopted may be stated as follows: Small bits of the organs to be studied were fixed in dilute Flemming's fluid, the tissue is left 24 hours in the fixing reagent. It is then washed in water for 24 hours; embedded in paraffin; sectioned, and colored on the slide in a stain made as follows: Fuchsin solution of Ziehl, 2 parts; neutral glycerin, 1 part. The fuchsin solution of Ziehl may be replaced by Magenta. The sections are mounted in Canada balsam. The author maintains that imperfection of method has led to results which indicated the destruction of the spirillum in the blood by means of an antitoxic serum. The author also obtained similar appearances by overheating the tissue, but believes that the granulations to be seen under such circumstances and which are supposed to be disintegrated remains of spirillum are really artificial products.

The author experimented upon geese and young chickens. Adult gallinaceous fowl are not susceptible to the disease, but young chickens are seldom able to withstand the disease when produced by inoculation. The author concludes that the conditions of the medium in which the spirillum lives, when observed in glass vessels, are so different from those under which the spirillum is found in living animals that no conclusions can be drawn from observations made under the former conditions and be applied to the action of spirillum upon living organisms. The author further maintains that the sudden disappearance of the spirillum in the drawn blood of diseased geese is due to products which arise in the blood after being drawn from the body and that this phenomenon is never witnessed in the living organism. The author was able to observe the immobilization, agglomeration, and disintegration of spirillum in drawn blood when under observation in glass vessels, but maintains that these processes are very seldom seen in living organisms.

The author's conclusions as to the agent which is most active in destroying the spirillum may be stated as follows: Spirillum is not destroyed in the blood. It is found immediately after the crisis of the disease almost exclusively in the spleen and red marrow of bone. The glandular cells of the spleen are very active in destroying the spirillum from the beginning of the disease. The activity of these cells increases rapidly until the crisis in temperature, which frequently occurs after the actual destruction of the spirillum.

Report of the board of cattle commissioners (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 485–550*).—This report contains an account of the general operations of the board for the year, including statistical tables of the indemnities for animals killed for tuberculosis, the expenses of inspectors in various parts of the State, an account of the percentages of tuberculous animals in Massachusetts, and a discussion of the advisability of keeping up quarantine on the cattle from outside of the State.

During the year 385 horses have been killed as being glanderous. The tests used were the mallein and guinea pig tests, the latter being preferred.

In regard to rabies the board recommends more drastic measures, such as destroying all suspected dogs, and a more careful enforcement of the license law for dogs, which will have a tendency to reduce the great number of stray dogs. The board recommends the establishment of a Pasteur Institute in Boston.

An appendix to the report gives outlines of the inspection laws for cattle in various foreign countries and the States of this country.

Stable disinfection, J. B. Paige (*Massachusetts State Bd. Agr. Rpt. 1898, pp. 369–377*).—Proper stable disinfection is necessary in order to prevent the spreading of infectious diseases. The author calls attention to the value, as a germicide, of direct sunlight. For disinfecting instruments about the stable, dry heat may be applied. Twenty minutes' exposure at a temperature of 300° F. will destroy any pathogenic organism. For materials that can not be exposed to dry heat, moist heat may be applied in the form of boiling water or steam. As a disinfectant upon woodwork and other materials about the stable, the author recommends carbolic acid in a 5 per cent aqueous solution. This may be used for the disinfection of walls, floors, mangers, and harness.

Among other disinfectants are mentioned creolin, lysol, disinfektol, corrosive sublimate, sulphur dioxid, and chlorin. Both sulphur dioxid and chlorin are more effective in moist than dry atmosphere.

A summary of the most important Italian works in the field of general pathology and pathological anatomy during the year 1898, O. Barbacci (*Centbl. Allg. Path. u. Path. Anat., 10 (1899), No. 13–14, pp. 504–558*).

Outlines of animal diseases and parasitic infections for farmers and students, H. Kästenbaum (*Grundriss der Thierseuchen und der Parasitenkrankheiten für Landwirte und Studierende. Vienna and Leipsic: W. Braumüller, 1899, pp. 281, figs. 39*).—This work contains a general account of the conditions of health, inflammation, fever, the general purposes of therapeutics, and vaccination. The greater part of the book is occupied with a discussion of special diseases. The more important infectious diseases of domesticated animals are treated with reference to their etiology, symptoms, pathology, prognosis, therapeutics, prophylaxis, and serum inoculations. The author also discusses the more important diseases of domestic animals which are caused by parasitic round and flat worms, and various species of mites.

To what extent ought expenses and losses caused by contagious diseases of farm animals be compensated by the State, J. Lundgren (*K. Landt. Akad. Handl., 33 (1899), No. 2, pp. 107–121*).

The regulation of compulsory quarantine for animals imported from foreign countries, A. Vrijburg (*Veeartsenijk. Bladen v. Nederl.-Indië, 12 (1899), No. 1, pp. 31–34*).—A statement and justification of the law.

An arrangement for municipal ownership of slaughterhouses, L. Pearson (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 4, pp. 199–204*).—A plan is suggested for city ownership of slaughterhouses with official inspection of animals and meat. It is believed that the price of meat will not be increased and that the quality will be better.

Sanitary regulations for animals, E. PERRONCITO (*Giorn. R. Accad. Vet.*, *48* (*1899*), *No. 16*, *pp. 361–365*).—Advises the use of all immunizing sera and toxin tests for determining the presence of infectious diseases with a view to their final extermination.

Some remarks on the hygiene of cattle, C. VAN DAMME (*Rev. Gén. Agron.* [*Louvain*], *8* (*1899*), *No. 8–9*, *pp. 377–385*).—A general discussion of the construction of stables; the airing, lighting, and heating of the same; and the feeding, pasturing, and reproduction of cattle.

The science of feeding green fodder, A. REUL (*Ann. Med. Vet.*, *48* (*1899*), *No. 6*, *pp. 304–318*).—Contains a series of recommendations with regard to the time of turning animals upon green pasture and with regard to the hygienic value and action of green grass.

The application of Roentgen rays in veterinary practice, M. A. MALTZEV (*Arch. Vet. Nauk*, *St. Petersburg*, *29* (*1899*), *No. 6*, *pp. 291–298*).—This paper contains a description of the apparatus necessary for the application of X-rays to the study of veterinary science, with a suggestion of cases in which it would be of service.

Urinary calculi of domesticated animals, M. KLIMMER (*Arch. Wiss. u. Prakt. Thierh.*, *25* (*1899*), *No. 5*, *pp. 336–366*).—A general discussion of the chemical constitution of calculi, of theories concerning the method of their formation, and of the etiology, with a bibliography of 126 titles.

A preliminary note on the morphology and distribution of the organism found in the Tsetse fly disease, H. G. PLIMMER and J. R. BRADFORD (*Proc. Roy. Soc.* [*London*], *65* (*1899*), *No. 418*, *pp. 274–281*).—This paper contains a description of the adult form of Trypanosoma, its distribution in the body of normal animals, in the blood, lymphatic glands, spleen, and bone marrow. A brief discussion is given of the methods of reproduction and the various forms under which the organism appears during its life history, including amœboid, plasmodial, and flagellate forms.

Cotton-seed disease, F. C. MCCURDY (*Jour. Comp. Med. and Vet. Arch.*, *20* (*1899*), *No. 9*, *pp. 560–567*).—Describes the general symptoms of poisoning by overfeeding with this substance, and the lesions in the eyes of animals so poisoned.

Cornstalk diseases, A. BOSTROM (*Jour. Comp. Med. and Vet. Arch.*, *20* (*1899*), *No. 6*, *pp. 336–339*).—Cornstalks when infested with fungi may cause acute tympanitis, indigestion, gastritis, and fungus poisoning.

Tympanitis in cattle, S. BIELER (*Chron. Agr. Canton Vaud*, *12* (*1899*), *No. 17*, *pp. 379–383*).—Wild mustard when eaten by cattle is said to check the action of the stomach and thus favor fermentation. Volatile alkalies are recommended for mild tympanitis and ruminotomy for advanced cases.

The possibility of tuberculous infection of the lymph system through milk and milk products, H. JAEGER (*Hyg. Rundschau*, *9* (*1899*), *No. 16*, *pp. 801–817*).—The author believes on the basis of a large number of observations that the great majority of the cases of tuberculosis come about from infection through the alimentary tract. Experiments showed that many young animals in which no physical signs of tuberculosis could be recognized responded to tuberculin, and a *post-mortem* examination always revealed the presence of tubercle bacilli in glands of the lymph system. The author considers it an important matter to prevent the use of tuberculous milk either by human beings or as food for domesticated animals.

Stamping out tuberculosis (*Breeders' Gaz.*, *35* (*1899*), *No. 24*, *p. 712*).—Contains Nocard's regulations for exterminating tuberculosis from an infected herd.

Tuberculosis in cattle, D. MCEACHRAN (*Agr. Gaz.* [*Tasmania*], *6* (*1899*), *No. 11*, *pp. 217–219*).—Discusses the nature of the disease, indemnity, danger from milk infection, symptoms and diagnosis of tuberculosis, and tuberculin tests.

Further experimental investigations on the serotherapy of tuberculosis, MAFFUCCI and DI VESTEA (*Centbl. Bakt. u. Par.*, *1. Abt.*, *25* (*1899*), *No. 23*, *pp. 809–815*).—The authors experimented upon calves and dogs with the purpose of producing, if possible, antitoxic effects upon the tubercle bacillus, as has been done with some other diseases. The results were encouraging.

The real value of the tuberculin test, M. Kühnan (*Berlin. Tierärztl. Wchnschr., (1899), No. 23, pp. 275–278*).—This article gives a record of a large number of cases where the tuberculin test was used, with a discussion of the results.

The differences between the bacillus of chicken tuberculosis and that of man which are shown in growth upon vegetable, gelatin, and agar-agar culture media, T. Matzuschita (*Centbl. Bakt. u. Par., 1. Abt., 26 (1899), No. 4–5, pp. 125–135*).—This article contains a technical description of the different appearances of these bacilli upon various culture media.

Cattle plague in Turkey, Réfik-Bey (*Ann. Inst. Pasteur, 13 (1899), No. 7, pp. 596–608*).—This article contains a discussion of the more important epidemics of the cattle plague in Turkey; of the clinical forms which the disease assumes and the rate of mortality. Aphthous fever and bovine malaria are discussed as being frequently associated with cattle plague. The author gives an account of the government regulations for the use of serum treatment and the success attending its treatment.

On immunization against cattle plague (*Selsk. Khoz. i Lyesov., 192 (1899), Feb., pp. 421–422*).—A brief description of the method of producing a mild form of the disease with virus and of thus conferring immunity.

The results of vaccination for protection against blackleg in Canton Freiburg, M. Strebel (*Giorn. R. Accad. Vet. Ital., 48 (1899), No. 21, pp. 110–121*).—Gives a description of the methods of vaccination. The animals were vaccinated near the end of the tail. Tables are given showing the percentages of cases in vaccinated and unvaccinated animals. The results were favorable for vaccination.

Contribution to the study of blackleg, L. Schöberl (*Berlin. Tierärztl. Wchnschr., 1889, No. 28, pp. 336, 337*).—Calls attention to difficulties in the way of studying blackleg and outlines the unsolved problems in connection with its study.

Contributions to serum therapy, W. Kolle (*Berlin. Klin. Wchnschr., 36 (1899), No. 24, pp. 520–521*).—Discusses the limitations of antitoxin treatments and gives a statistical table showing the effect of serum in treatment of Rinderpest. The results were favorable. The doses varried from 20 to 50 cc.

Regulations for the control of contagious diseases of live stock, C. Curtice (*North Carolina State Bd. Agr. Bul., 20 (1899), No. 7, pp. 9–11*).—A statement of regulations adopted by the State Board of Agriculture against Texas cattle fever.

Preventive inoculation against red water, D. Hutcheon (*Agr. Jour. Cape Good Hope, 14 (1899), No. 11, pp. 722–725*).—General directions for producing immunity in herds.

Treatment of milk fever with iodid of potash, E. Turkin (*Arch. Vet. Nauk, St. Petersburg, 29 (1899) No. 6, pp. 331–334*).

A new treatment of milk fever, A. S. Alexander (*Breeders' Gaz., 35 (1899), No. 5, p. 116*).—The author recommends the potassium iodid treatment of Schmidt and gives details of the technique of its use.

Serotherapy of aphthous fever, H. Mastbaum (*Arch. Rural, Portugal, 4 (1899), No. 5, pp. 71–73*).—Gives directions for the preparation of the antitoxin and method of application.

Diseases of the udder and teats, W. H. Austin (*Jour. Comp. Med. and Vet. Arch., 20 (1899), No. 8, pp. 488–490*).—Since many cases of mammitis are tubercular, the use of the tuberculin test is recommended in all suspicious cases of udder disease.

The scab in sheep, H. Stewart (*Country Gent., 64 (1899), No. 2421, p. 492*).—Discusses the nature and cause of the disease and methods of preventing or curing it by various dips.

Ticks and "louping-ill," E. G. Wheeler (*Sci. Gossip, 6 (1899), No. 64, pp 106–110, figs. 7*).—The conclusion of the author's paper on this subject with notes on *Ixodes plumbeus*, *I. hexagonus*, and *I. reduvius*).

Geel-dikkop investigations, Dixon (*Agr. Jour. Cape Good Hope, 14 (1899), No.*

12, pp. 782–784).—A disease of sheep and goats characterized by swelling of the head and yellow exudations. Gives symptoms, *post-mortem* appearances, and reports that large doses of calomel gave good results.

Experimental swine plague, M. PRETTNER (*Centbl. Bakt. u. Par., 1. Abt., 25 (1899), Nos. 21, 22, pp. 744, 745*).—The hog is shown to be exceedingly susceptible to subcutaneous inoculations of swine plague.

Treatment for swine diseases, I, D. E. SALMON (*Breeders' Gaz., 35 (1899), No. 4, pp. 88, 89*).—Gives statistics of losses from swine diseases and recommendation of the serum treatment.

The practical application of the Pasteur prophylactic inoculations against hog cholera, O. I. MARKEVICH (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 6, pp. 321–331*).

Combating hog cholera, FOTH (*Berlin. Tierärztl. Wchnschr., 1899, No. 29, pp. 347–351*).—The paper discusses the effect of serum upon diseased swine and experiments to determine the duration of immunity produced by serum treatment.

Serum as a remedy for hog cholera, J. D. SPRAGUE (*Jour. Comp. Med. and. Vet. Arch., 20 (1899), No. 6, pp. 342–346*).—Records the results of tests on 7 herds of hogs, and gives recommendations as to time for giving the serum and the amount to give.

Inoculation in utero, D. B. SAYRE (*Breeders' Gaz., 35 (1899), No. 5, pp. 117, 118*).—Reports successful experiments in inoculating sows with a mild form of hog cholera so as to produce complete immunity in their offspring.

The diagnostic value of mallein injections, N. A. SHADRINE (*K voprosu o diagnosticheskikh inektziyakh malleina. Moscow, 1898, pp. 161; rev. in Selsk. Khoz. i Lyesov, 192 (1899), March, pp. 705, 706*).—During the years 1893–1896, 226 horses which were suspected of having glanders were tested with mallein. From these experiments the author obtained results which led him to the conclusion that while mallein is not absolutely infallible as a diagnostic agent for glanders, it can be thoroughly relied upon in the hands of a veterinary practitioner.—P. FIREMAN.

Experiments with a serum treatment of contagious pleuro-pneumonia of horses, E. N. USOLTZEV (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 1, pp. 49–62*).—Experimental work has been carried on with some success, and other experiments are to be made to determine the duration of immunity and the best method of preparing the serum so that it can be kept ready for use during a considerable time.

A dangerous poultry pest, E. S. ZÜRN (*Fühling's Landw. Ztg., 48 (1899), No. 16, pp. 625–627*).—An account of chicken tuberculosis, with suggestions of means for controlling it.

Nematode worm disease of fowls (*Geflügel Züchter, 4 (1899), No. 38, p. 344*).—Biological notes on species of Filaria, with a brief statement of symptoms of disease caused by these worms.

Serum therapy in roup of chickens, D. V. DEVEL (*Arch. Vet. Nauk, St. Petersburg, 29 (1899), No. 1, pp. 30–49*).—A report of experiments in which temporary immunity was produced by inoculations.

The trichina inspector, H. A. JOHNE (*Der Trichinenschauer. Berlin: P. Parey, 1898, pp. XIV+170, figs. 125*).—This book gives a general account of the anatomy of the animal body microscopic technique, cestode, trematode, and nematode worms and their identification in meat. A statement is added of the regulations regarding meat inspection in different parts of the German Empire.

On the influence of common salt upon bacteria which are concerned in cases of meat poisoning, E. STADLER (*Arch. Hyg., 35 (1899), No. 1, pp. 40–82*).—Contains a record of experiments in subjecting various bacteria to solutions of common salt with the purpose of determining whether pickled meats may be considered sterilized. The results show that *Bacterium coli communis* subjected to 7 to 8 per cent solution of common salt was still alive after 6 weeks. *Bacillus morbificans bovis* in a solution of 8 to 10 per cent of common salt was dead after 3 weeks. *B. enteritidis*, in a solution of 7 to 8 per cent of common salt, died after 4½ weeks. *Bacillus proteus vulgaris* in an 8 to 10 per cent common salt solution did not die after a 3 weeks' exposure.

AGRICULTURAL ENGINEERING.

Description of the new dairy and stock-judging building, W. L. CARLYLE (*Wisconsin Sta. Rpt. 1898, pp. 269-282, figs. 15*).—The building is a frame structure, consisting of the barn proper, 50 by 86 ft., 3 stories high; and 2 wings, one 50 by 70 ft., the other 30 by 70 ft., and each 2 stories high (fig. 3). A class room for stock judging, 40 by 70 ft., well lighted and heated and provided with a tan-bark floor and seats along one side, is located between the wings. At one corner is a circular silo of brick, terminating in a water tower. A steel trestle furnishes a driveway with a moderate grade (7 ft. to 100) to the third story of the main building. All material for filling the silo and for feeding and bedding the stock is taken to the third floor, weighed, if desired, on the scales at the entrance, and then passed with little work to the stables below. The silage and feed cutters and mills for grinding are on this floor.

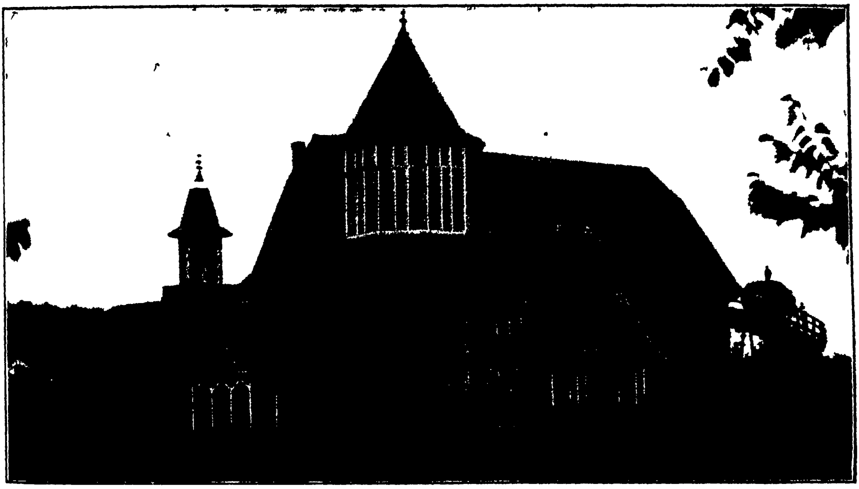

FIG 3.—Dairy barn and stock judging building, College of Agriculture, University of Wisconsin.

"The motive power for machinery is a 10-horsepower electric motor placed on a small truck which runs on an iron track, so that it may be shifted at a moment's notice from one side of the barn to the other. The car is provided with clamps, which grip the rails, so that it can be held in place at any point desired."

The ground plan of the building is shown in the accompanying illustration (fig. 4).

The cow stable, which is 40 by 70 ft., is lined with corrugated galvanized-iron sheeting. The floors are of Portland cement and crushed granite (fig. 5).

"The manure gutters behind the cows (H) are 16 in. wide with the bottom sloping ½ in. to the rear side and 1½ in. of slope towards the center of the stable, where a trap can be opened, connected with a sewer, to be used only in flushing out the stable with water. The floor of the cow stalls is raised 4 in. above the other parts of the stable floor, including the walk behind the cows (fig. 5), making the manure gutter 8 in. deep on the side to the cow and only 4 in. deep on the side to the passage behind. . . . The mangers are built up from and composed of the same material as the floor. . . . The side of the manger next to the cow is 8 in. high and 3 in. thick, rounding down into the bottom, as shown at (E). The front side of the manger is 16 in. high and built in a similar manner. This manger is 2 ft. 6 in. wide and reaches from one end of the stable to the other. It is used both as a feeding manger and as a watering device."

The stalls, 36 in number, 18 on either side of the stable, are constructed of gas-pipe posts anchored in the cement foundation, with framework of gates and panels of channel iron supporting a mesh of No. 7 woven steel wire. In fig 5, C indicates the framework extending in front of each row of stalls to support the front part of the side panels and give them rigidity; and D indicates the swinging panel which may be moved to suit the length of the cow. The side panels of the stalls are hinged to accommodate the milkers and allow the cows to pass out without backing over the manure gutter.

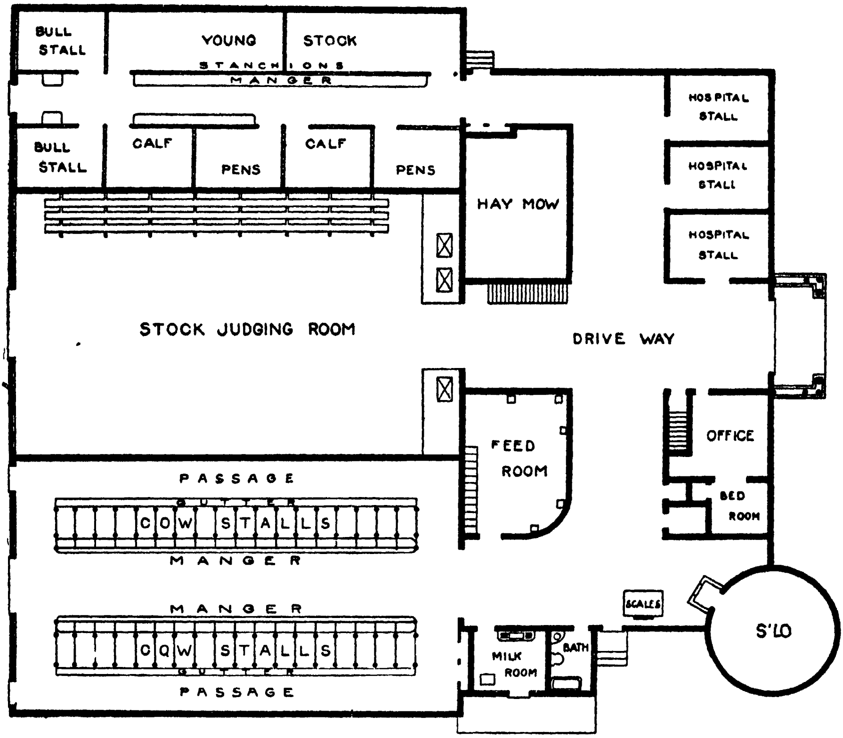

FIG 4.—First floor of barn, showing stables, stock judging room, etc.

The right wing of the barn, 70 by 30 ft., is designed for young stock and bulls. The lining of the walls and the construction of the floors is the same as in the cow stables.

"The partitions of the stalls are gas pipe imbedded in the cement floor at one end. This stable also has mangers of cement except for the very young calves. . . . Every fourth bar in the partition separating the stalls from the passageway is a swinging bar or stanchion. . . . The bull stalls are similar to those for the young stock with the exception of there being but one heavy stanchion. The bars are heavier and stronger and the gate to the stall is made of iron gas pipe. . . .

"Under the main part of the barn is a basement divided into 2 rooms. One of these is for the storage of roots and other products, while in the other is located the heating plant, the farm workshop, and the artesian well with a power pump operated by a 3-H. P. electric motor. This pump forces water into a large steel tank above the silo from which a supply is drawn through under-ground pipes to all the farm buildings."

The silo, 18 ft. in diameter and 33 ft. deep, is a frame structure lined inside and out with brick, the inner lining being covered with a heavy coating of Portland cement, which makes the silo practically water-tight.

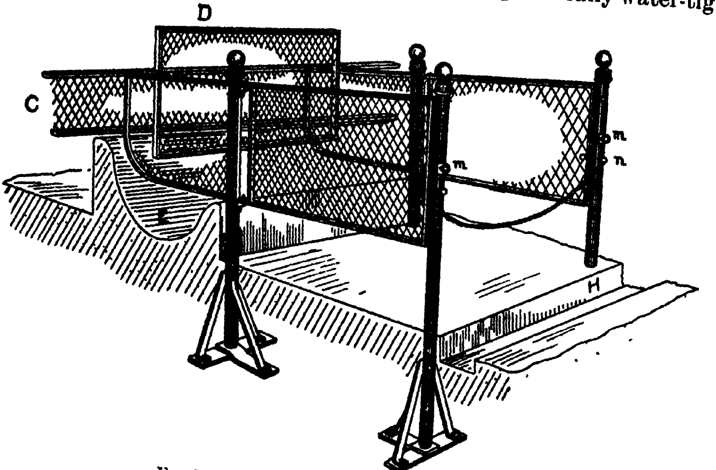

FIG. 5.—Perspective view of improved cow stall.

"The system of ventilation, originated by Prof. King for use in the stables, is shown in fig. 6 and is thus described by him: 'A single ventilating flue, D E, rises above the roof of the main barn, and is divided below the roof into 2 arms, A B D, which terminate at near the level of the stable floor at A A. These openings are provided with ordinary registers, with valves to be opened and closed when desired. Two other ventilators are placed at B B, to be used when the stable is too warm, but are provided with valves to be closed at other times. C is a direct 12-inch ventilator leading into the main shaft and opening from the ceiling, so as to admit a current of warm air at all times to the main shaft to help force the draft. This ventilating shaft is made of galvanized iron, the upper portion being 3 ft. in diameter. The covering on the outside is simply for architectural effect. The air enters the stable at various points as shown in the plan at F G, and in the vertical section by arrows at F. G.'"

State and national control of water, J. M. WILSON (*Irrig. Age, 14 (1899), No. 2, pp. 40–46*).—A paper by the State engineer of Nebraska presented at the eighth annual Irrigation Congress.

Reservoir irrigation on the plains (*Drainage Jour., 21 (1899), No. 8, p. 206*).

Water development, T. S. VAN DYKE (*Irrig. Age, 14 (1899), No. 2, pp. 47–53*).—Discusses especially the storage of water in California.

Douglas irrigation works on Vaal River, Griqualand West, W. CRAIG (*Cape Town: W. A. Richards & Co., 1899, pp. 13, pls. 15, figs. 4, map 1*).—This is a report to Parliament, and includes a "description of the schemes and information regarding the whole works as completed to December, 1898, with plan and photographs." About 887 acres are under irrigation.

Petroleum motors, J. GOBIET (*L'Ing. Agr. Gembloux, 9 (1899), No. 12, pp. 713-742*).

Disputed points in connection with the construction and maintenance of macadamized roads, H. IRWIN (*Trans. Canad. Soc. Civ. Eng., 12 (1898), pt. 2, pp. 148-176*).—The principal points discussed are grades, drainage, transverse section, the necessity for using the Telford foundation, and its construction, the construction of macadamized roads without the Telford foundation, quality of stone and size of the macadam, binding material and its usefulness, rolling by horse or steam roller, and repairs or maintenance.

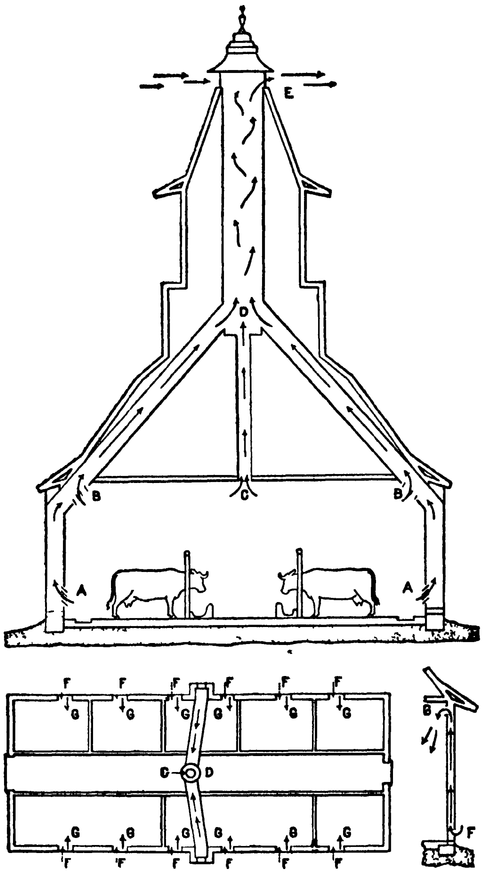

FIG 6.—System of ventilation

Natural and artificial methods of ventilation (*London: Robert Boyle & Son, Ltd., 1899, pp. XVI+66*).

Application of electricity in agriculture (*Deut. Landw. Presse, 26 (1899), No. 84, pp. 953, 954, figs. 15*).—Applications of electricity as motive power for feed cutters, mills, threshers, and dairy apparatus, and for heating ovens, kettles, irons, etc., are discussed.

STATISTICS—MISCELLANEOUS.

Eleventh Annual Report of Massachusetts Hatch Station, 1898 (*Massachusetts Hatch Sta. Rpt. 1898, pp. 172*).—This embraces a brief summary of the work of the year, including the organization list of the station and a list of available bulletins; a financial statement for the fiscal year ended June 30, 1898; and reports of the meteorologist, horticulturist, chemists, agriculturist, entomologist, and botanist, parts of which are noted elsewhere in this issue.

Eighth and Ninth Annual Reports of New Mexico Station, 1897 and 1898 (*New Mexico Sta. Rpts. 1897 and 1898, pp. 3-31*).—The staffs, publications, lines of work, and expenditures of the station for each year are given in the reports of the director, treasurer, and heads of departments.

Fifteenth Annual Report of Wisconsin Station, 1898 (*Wisconsin Sta. Rpt. 1898, pp. 312, figs. 70*).—This includes the organization list of the station; a report by the director on the staff, work, equipment, and publications of the station; numerous articles noted elsewhere; lists of exchanges and acknowledgments; a financial statement for the fiscal year ended June 30, 1898; and reprints, in an abridged form, of Bulletins 64, 68, and 69 of the station, embracing the following subjects: Sugar-beet culture in Wisconsin during 1897 (E. S. R., 10, p. 39); one year's work done by a 16-foot geared windmill (E. S. R., 10, p. 695); pasteurization experiments in butter making, score of butter as affected by size of package, and propagation of starter for ripening cream (E. S. R., 10, p. 889), and an improved curd test for the detection of tainted milk (E. S. R., 10, p. 386).

Experiment Station Work—XI (*U. S. Dept. Agr., Farmers' Bul. 108, pp. 32, figs. 5*).—This number contains popular articles on the following subjects: Excessive irrigation, cross-pollination of plums, root pruning of fruit trees, the oxeye daisy, poisoning by wild cherry leaves, preserving eggs, gestation in cows, the long clam, silage for horses and hogs, commercial butter cultures with pasteurized cream, and the stave silo.

Experiment Station Work—XII (*U. S. Dept. Agr., Farmers' Bul. 105, pp. 32, figs. 4*).—The following subjects are treated in this number: Seaweed, the tillering of grains, fertilizers for garden crops, sweet corn and pole beans under glass, girdling grapevines, cereal breakfast foods, food value of stone fruits, when to cut alfalfa, spontaneous combustion of hay, preservation of milk by pressure, and cream raising by dilution.

The mission of the agricultural colleges, W. H. JORDAN (*Massachusetts State Bd. Agr. Rpt. 1898, pp, 51-72*).

Agricultural education in foreign countries, W. E. DE RIEMER (*Pop. Sci. Mo., 56 (1899), No. 2, pp. 218-233*).

Agricultural education in Ireland, A. STEEDMAN (*Farmers' Gaz., 58 (1899), Nos. 35, pp. 745, 746; 37, pp. 772, 773, 791, 792; 38, p. 813; 39, p. 835; 40, pp. 857, 858; 41, pp. 877, 878; 42, pp. 907, 908; 43, pp. 929, 930; 44, pp. 949, 950; 45, p. 969; 46, p. 990*).—Series of articles on this subject.

Agricultural education in France (*Jour. Bd. Agr. [London], 6 (1899), No. 2, pp. 199-205*).—A general summary of the agricultural educational system of France.

The organization of a division of information in metereology and agriculture in the Department of Hérault, HOUDAILLE (*Organisation d'un service d'information météorologiques et agricoles dans le département de l'Hérault. Montpellier: Grollier, 1899, pp. 38*).

Practical lessons in agriculture, GAUDELETTE (*Leçons pratiques et lectures agricoles. Paris: Giard, 1899, pp. 196*).

NOTES.

ARKANSAS UNIVERSITY AND STATION.—J. T. Stinson, horticulturist, has resigned to accept the directorship of the new Missouri Fruit Experiment Station. Ernest Walker, of the South Carolina College and Station, has been appointed horticulturist and entomologist in the university and station.

COLORADO COLLEGE AND STATION.—The college intends to procure an illustrative herd of the best breeds of cattle. The farm committee of the State board of agriculture, consisting of Messrs. Harris, Chatfield, and Amiss, have been authorized to expend $4,000 for this purpose and to visit some of the best herds in the States east of Colorado to make the selection. A course in veterinary science has been arranged for, with George Glover, D. V. M., of Denver, in charge. Lectures and clinics will be given weekly. The State board of agriculture at its December meeting adopted rules and regulations for the experiment station, placing additional power and responsibility in the hands of the director. Provision was made for closing out the substations at Montevista and Monument, which have been suspended for several years past, and for reducing the area under cultivation at Rockyford and Cheyenne Wells, so as to enable the superintendents to act more as field agents and to be available in investigations which it is desirable to carry out in the localities. The name of the station at Cheyenne Wells is changed from Rainbelt to the Plains Substation.

CONNECTICUT STATE STATION.—At the recent annual meeting of the board of control Prof. S. W. Johnson resigned his position as director, desiring to be relieved of the executive duties which he has been charged with for nearly 23 years. In accepting his resignation the board adopted resolutions expressing its deep appreciation of the distinguished services of Professor Johnson and their regret that he felt moved to relinquish his more responsible duties. Professor Johnson has consented to retain connection with the station in the capacity of consulting or advisory chemist. E. H. Jenkins, who has been the vice-director for the past 17 years, succeeds him as director.

MISSISSIPPI STATION.—The station office building was burned December 24, 1899; the loss is nearly all covered by insurance.

NORTH CAROLINA STATION.—H. W. Primrose, instructor in chemistry and assistant chemist of the station, has resigned to accept the position as assistant chemist with a private firm at Ensley, Ala. He has been succeeded in his station work by J. A. Bizzell, formerly assistant chemist, and in his college work by W. A. Syme class of 1899. The former station farm has been assigned to the horticultural department. Large plantations of fruits have been made for the purpose of studying climatic difficulties with some, and the treatment of diseases and insects with all. The new lines of work in horticulture will be a special study of plant breeding and the improvement of varieties. The experiments in the culture of flowering bulbs for florists' use are being continued. These experiments are attracting wide interest among horticulturists. A study of edible and poisonous mushrooms is to be undertaken, and notes from mycologists in other stations will be welcome.

NORTH DAKOTA STATION.—W. C. Langdon, veterinarian, has resigned and Dr. J. W. Dunham has been elected in his stead. F. V. Warren, instructor in steam engineering and assistant in mathematics, resigned during the fall term to accept a position in Philadelphia, and P. S. Rose, formerly of Michigan Agricultural College, was elected to fill the vacancy.

EXPERIMENT STATION RECORD.

VOL. XI. NO. 7.

The cooperative experiment station exhibit which has been prepared for the Paris exposition is now practically completed and is on its way to Paris. The first steps toward representing the experiment stations at the Paris exposition were taken by the Association of American Agricultural Colleges and Experiment Stations at Minneapolis in 1897, by the adoption of a resolution favoring an exhibit and the appointment of a committee of five to take charge of the matter. This committee consisted of H. P. Armsby, chairman, W. H. Jordan, A. W. Harris, M. A. Scovell, and A. C. True. The stations were invited to contribute materials and charts illustrating special features of their work and results, original pieces of apparatus, models, designs, etc. By a division of labor early agreed upon, the Director of this Office, as a member of the committee, undertook to make a collection of photographs and of publications of the stations, to prepare a monograph on the experiment station enterprise of this country, and to look after the temporary installation of the exhibit in Washington and its final shipment.
